Iodoform gauze: Iodoform, 20 parts; paraffin oil, 10 parts; ether, 400 parts. The weight ratio is 460 parts to 500 parts. The gauze is allowed to soak for twelve hours, and is then dried and stored in an antiseptic air-tight jar.

Hernia.—Dr. Bannister (*Kansas Medical Journal*) concludes as follows: 1. The radical operation for the cure of hernia as now practised, especially by the Bassini and Halstead methods, is in the immense majority of cases eminently successful. 2. When performed by a competent operator under strict asepsis on a patient in good general health, the operation is devoid of danger to life. 3. By operating and securing a good result, the patient will not only be relieved of a great affliction, but will be spared the ever-threatening complication of strangulation, with all its dangers. 4. These propositions being true, it is the duty of the surgeon to advise operation in suitable cases, that is, in all cases in which the patient is not too old, or too fat, or in poor general health, whether the hernia can be retained by a truss or not. In the latter case, operation is urgently demanded.

Dr. De Garmo, of New York, says: (1) All reducible hernias should be operated upon, unless contraindicated by age or condition of the patient. (2) All omentum found outside the abdomen, or that will protrude under gentle traction, should be removed. (3) Multiple independent ligatures of good-sized silk, which surround the vessels alone or small pieces of fatty tissue, are believed to be safer. (4) The use of some film-forming substance, as aristol, on the stump, is believed to protect in a measure from subsequent adhesions.

Acute Pancreatitis.—Dr. Fowler (*Brooklyn Medical Journal*, April, 1896) gives the following diagnostic points: 1. The location of the primary seat of the disease in the epigastrium. 2. The suddenness of the attack, with severe gastric, epigastric, or abdominal pain, accompanied by great prostration and vomiting. 3. Tenderness in the epigastric region, with tympanites and a mass recognizable by deep palpation. 4. Absence of fever, or but moderate fever during the first two or three days of the attack.

Germ in the Vagina.—Many of the germs found in the vagina have no action upon the tissues. The fact "that micro-organisms are present in great variety" in the vagina does not endanger the parturient woman. The bacteria that possess pathological significance are mostly anaerobic. They do not enter the circulation or thrive in the blood, neither are they absorbed through the vaginal walls. They may be the source of fetid odors, which reflect upon the cleanliness of the patient. Doederlein has discovered a bacillus which intensifies the acid reaction of the vaginal secretion, and renders it unfavorable to the multiplication of the streptococcus.—WILLIAM T. LUSK (before the section on gynecology of the College of Physicians of Philadelphia, January 16, 1896).

Division and Immediate Suture of the Left Vagus Nerve.—Dr. Makins (*British Medical Journal*, May 16, 1896), in removing a secondary epithelioma of the neck, divided the left vagus nerve above the centre of its cervical portion and sutured it immediately. The muscles supplied by the recurrent laryngeal branch were paralyzed. The quality of the voice improved rapidly, and two months later it was nearly normal. Laryngoscopical examination showed the left vocal cord fixed near the middle line, and in phonation the right cord moved up to it. Apparently the adductor fibres partially recovered, but not the abductors. The operator admitted that the functional activity of the vagus might have been lowered by long-continued pressure by the tumors. He thinks it proves that one vagus can be divided without danger, and that at least a partial restoration of function is possible.

Wounds of the Peritoneal Cavity.—1. A penetrating wound of the peritoneal cavity is not accompanied by symptoms commensurate with the extent of the injury. 2. Many fatal lesions may be present, yet give rise to no marked symptoms. 3. Fatal lesions may exist, yet shock be wanting. 4. The wound of entrance should be enlarged, and, if the missile have entered the abdomen, a section is called for. 5. Operation is proper soon after the injury, before the peritoneal membrane has become infected or much blood has been lost. 6. Flushing the open peritoneal cavity with hot water or hot normal salt solution is an excellent stimulant to the heart. 7. The abdominal wound should be closed when practicable without drainage.—DR. TIFFANY, *American Journal of the Medical Sciences*, May, 1896.

Shock.—1. Inhalation of nitrite of amyl, not alone while the patient is on the operating-table, but repeated afterward at intervals. 2. The hypodermatic injection of nitroglycerin in large doses; that is to say, when this drug is indicated at all we must secure its full effect speedily, and in order to accomplish this the dose must be such as under ordinary conditions might be toxic. One-fifteenth to one-twentieth of a grain, repeated until the effect on the pulse is evident, should be the rule. 3. Repeated injections of hot saline solution, given by high enema so that the fluid will pass into the transverse colon, are most valuable adjuvants, not only tending to relieve vasomotor

spasm, but also supplying to the circulation the fluid lost by hemorrhage during the operation. 4. Finally, hypodermatic injections of strychnine, in the dose of one-fifteenth of a grain, assist markedly.—BOISE.

Brain Tumors.—1. A new growth may be present in the brain without causing any general cerebral symptoms whatsoever. In order to make an early diagnosis of a new growth it is well, therefore, to be guided by the symptoms present rather than by the absence of other customary symptoms. 2. A cystic tumor of the brain not of parasitic origin is not so innocent in character as many would believe. 3. The simple evacuation of such a cyst when found is not sufficient; if it is surgically possible, the wall and the surrounding brain tissue should be excised, in order to prevent a future growth of the malignant elements left in the wall of the cyst. 4. If the immediate excision is not possible, it would be advisable to open the wound a few months later and attempt to excise the collapsed cyst wall, which is compressed into a small space by the general cerebral pressure, in the same way in which an abscess cavity is quickly obliterated after evacuation.—DRS. STIEGLITZ, GERSTER, LILIENHAL, *American Journal of the Medical Sciences*, May, 1896.

How to Protect the Internal Organs in Gonorrhœa.—Dr. Auvard (*Arch. de Toccol. et de Gynéc.*, June, 1895) advises against the use of the curette in the course of acute gonorrhœa. Experience has shown that its use is attended with the danger of extending the disease to the tubes and ovaries. In spite of the greatest care, a minute piece of infected glandular tissue may be left behind. The entire surface of the uterine cavity may be disinfected by and after the scraping, yet then the mucosa, which acts as a rampart against microbic infection, has been destroyed. The probable entrance of specific pus from the vagina sets up a uterine gonorrhœa whose type is worse than the first attack. In order to prevent inflammation of the tubes and ovaries, complete rest must be enforced. In gonorrhœal salpingitis the great danger is sterility. The uterine cavity is best left alone. The vagina and cervix should be swabbed with a one-per-cent. solution of nitrate of silver once or twice a week, and a solution of bichloride of mercury (1 to 1,000) should be employed twice daily as an injection. In the early stages of inflammation of the appendages, Dr. Auvard uses ice topically. When pain is less intense, blisters will be of use. The patient should not get up till after all the pain has passed off. Then glycerin plugs should be applied about three times a week. By these methods of procedure, employed sufficiently early, sterility and the need of removal of tubes and ovaries may be averted.

Nitroglycerin.—It is an excellent stimulant in syncope, in threatening heart failure or collapse from various causes; in acute lobar pneumonia, used early enough and boldly enough, it may render venesections unnecessary, and its skilful use often aids recovery from apparently desperate conditions. It is useful in chronic interstitial nephritis, in conditions of arterial fibrosis and atheroma, in gout and rheumatoid arthritis, and sometimes in anæmia, chlorosis, and the anæmia of tuberculosis. In the management of cases of muscular and valvular disease of the heart it finds a wide field of usefulness; in dilatation it may be used with digitalis; in fatty heart it may be used without other drug; in cases of mitral lesion it may be conjoined with digitalis, strophanthus, sparteine, and the like; in cases of aortic lesion, atropine, strychnine, and caffeine may be used with it.—*Philadelphia Poly-clinic*.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 10, 1896:

	Cases.	Deaths.
Tuberculosis.....	112	90
Typhoid fever.....	24	5
Scarlet fever.....	50	4
Cerebro-spinal meningitis.....	1	3
Measles.....	33	6
Diphtheria.....	159	17
Smallpox.....	0	0

Antitoxin Collective Investigation (Second), American Pediatric Society.—To the Profession: The American Pediatric Society is encouraged to ask the co-operation of the profession in a further collective investigation. Laryngeal diphtheria is believed to furnish a crucial test for antitoxin; the present aim is to ascertain: (1) What percentage of cases of laryngeal diphtheria recover without operation, under antitoxin treatment. (2) What percentage of operated cases recover.

The society asks for records of cases of diphtheria involving the larynx, whether operated or not, occurring in private practice in the United States and Canada, treated with antitoxin. It is expected that cases occurring this year will probably be treated with reliable preparations of the serum, will be treated early, and will be given efficient doses.

In order to secure data which shall make the tables complete, circulars containing blanks for ten cases have been printed and are now ready for distribution. It is desired that physicians shall fill out the circular as cases occur, not trusting to memory, and shall urge their friends having similar cases to record them. Circulars can be had by applying to the committee, (address below). Several groups of cases in the first investigation arrived too late and were lost to the report. It is desired that circulars as soon as filled (ten cases) be returned to the committee. The collection of cases must close at the end of March, 1897.

The second report is designed to be a study of cases occurring between the closing of the first report, May 1, 1896, and the closing of the present collective investigation, April 1, 1897.

For extra circulars (blanks), for returning circulars (filled), and for further information please address the chairman of the committee, W. P. Northrup, M.D., 57 East Seventy-ninth Street, New York, N. Y.

The action of the society upon the first report. (1) **Dosage.** For a child over two years old, the dosage of antitoxin should be in all laryngeal cases with stenosis, and in all other severe cases, 1,500 to 2,000 units for the first injection, to be repeated in from eighteen to twenty-four hours if there is no improvement; a third dose after a similar interval if necessary. For severe cases in children under two years, and for mild cases over that age, the initial dose should be 1,000 units, to be repeated as above if necessary: a second dose is not usually required. The dosage should always be estimated in antitoxin units and not of the amount of serum.

(2) **Quality of antitoxin.** The most concentrate strength of an absolutely reliable preparation.

(3) **Time of administration.** Antitoxin should be administered as early as possible on a clinical diagnosis, not waiting for a bacteriological culture. However late the first observation is made, an injection should be given unless the progress of the case is favorable and satisfactory.

Syphilitic Reinfection.—According to the conclusions of a paper read at the late congress of dermatology in London by Dr. Cotterrell, one attack of syphilis, though generally conferring life-long long immunity, does not always do so, and reinfection, though rare, is surely possible. The negative evidence presented by several who spoke was preponderatingly outweighed by the statements of those who had seen instances.

A Doctor's Manifold Duties.—The following extract, says *La France Médicale*, is taken from the "Memoirs of Marshall Castellane:" The Marchioness of Talam is over fifty, but she believes it is absolutely necessary for the good of her health that she should have a man beside her at night. Whenever M. de Talam is absent she consequently makes her people sew up M. de Courtivron, one of his relatives, or else M. de Chavagnac, one of his friends, in a sack, and has him put into her bed. In the morning she is careful to summon her attendants, or, at all events, the chambermaid, in order that they may testify that the sack has not been unsewn. At present MM. de Chavagnac and de Courtivron both happen to be away at Madrid, attached to the embassy of M. de Talam, so it is M. Boirot, physician of the Nérís hydropathic establishment, who for the moment occupies the post of honor. I can assure you that this is in no wise a jest. My secretary is connected with the doctor, who, positively, is shut up in the sack every night.

The Surgical Corps in the Cuban Army consists of eighty physicians, distributed among its six different corps. The head of the service is Dr. Joaquin Castillo Duany, surgeon-general, a graduate of an American university, and formerly attached to the United States navy, in which capacity he formed part of the crew that started in the Rodgers relief expedition to the Jeannette. When the present revolution broke out he was medical inspector at the Juraque iron mines. He joined the ranks of the Cubans, together with Mr. Kilpatrick, one of the managers, and several of other employees, all Americans. Surgeons in the Cuban army have no limited time of service, receive no pay, acquire no fame or rank. These men, brought up under the refining influences of civilization, abandon their practices, their homes, their families, and start on a gloomy career of hardship and danger, with the possibility of being caught by the Spaniards and shot by the roadside. The surgeons are all provided with first-class French instruments and in their operations they always make a lavish and intelligent use of antiseptics, for in Cuba's burning climate tetanus and secondary suppuration set in with astonishing rapidity. Drugs are often hard to obtain, there being no regular base of supplies. In many cases in which mercury, bichloride, iodoform, and carbolic acid are unattainable, wounds are sprinkled over with finely powdered burnt coffee, which proves a powerful antiseptic. Fevers are often and successfully treated, in default of quinine, with a decoction of the "condeamor" leaves from creeping plants of valuable febrifuge properties. As alcohol can be had plentifully at any sugar plantation in a reasonably pure state, tinctures of many native plants are constantly prepared which have been found effective by previous trials. Chloroform and ether are things unheard of in those wildernesses, and nothing illustrates more graphically the Spartan heroism latent in the Cuban nature than the unflinching way in which they submit in full consciousness to the ominous knife. It is not strange there to see a man light his cigar and look on coolly while his arm or leg is being amputated, just as if it were a matter of no concern to him.—*Journal of the American Medical Association.*

The Total Abstainer's Tipple.—The following preparations were recently examined by the Massachusetts State board of health, with reference to the percentage of alcohol contained in them: Ayer's sarsaparilla, 26.2; Paine's celery compound, 21; Hood's Sarsaparilla, 18.8; Greene's nervura, 17.2.

The Drug Habit.—The American people have been called a medicine-taking nation. If the quantity of drugs prescribed by physicians, the masses of patent medicines, the barrels of so-called home remedies, such as teas, decoctions, infusions, and other monstrosities, swallowed by the American people were ascertained, collated, arranged, and published in a book, it would strike the reader dumb with astonishment.—ULRICH.

War Dogs.—In the German military manoeuvres of this year, dogs will be used in the ambulance department. At the command "seek," accompanied by a gesture indicating the direction in which search is to be made, the trained dog goes off to the field, finds the wounded man, returns with a cap, helmet, or piece of clothing, brings this to the ambulance men, and then returns with them to the spot at which the wounded man lies.—*The Physician and Surgeon*.

Every Medical Man should be a member of a medical society. He will never know how great a man he is till some one praises him in a discussion, nor how small a man till some pompous fellow-member takes him to task; but all these frictions serve but to round and smooth a busy life, and no one can do without it who desires to be a physician in the highest acceptation, and not a man who doctors.—*Atlantic Medical Weekly*.

Effect of Occlusion of the Nutrient Vessels of the Brain in Rabbits.—In some recent experiments (*Arch de Biol.*) C. Giltay found that temporary occlusion of the carotid and vertebral arteries in the rabbit caused, through vasomotor influence, dilatation of the collateral vessels arising from the subclavian arteries, recognizable by the augmented pressure in the cephalic portion of the carotid. The dilatation of the collateral vessels was sufficient to enable the animal to live after permanent occlusion of all four cerebral vessels if it were not brought about too suddenly (two or three minutes). The experiment was not successful unless the subclavians were left unoccluded.

False Alarm.—There is a physician in Cleveland who is pretty sure to stutter when under the stress of excitement. Some time ago he had occasion to officiate professionally on an interesting occasion, and his vocal infirmity was the cause of a funny misapprehension. The husband and prospective father, who, by the way, had set his heart on a son and heir, was nervously pacing the library when the doctor entered. "Well, doctor," cried the husband, forcing a smile, "is it twins?" "Tr—tr—tr," began the doctor. "Triplets! Great Cæsar!" "Qu—qu—qu—" stammered the doctor. "Quadruplets! Holy smoke!" "No, no," cried the doctor. "Qu—Qu—quite the contrary. Tr—tr—try and take it ph—philosophically. It's just a girl."—*Cleveland Plain Dealer*.

Longevity and Labor.—An English report mentions thirty-three persons upward of one hundred years of age alive in Great Britain in the year 1893. The oldest was a woman, one hundred and sixteen years old, if the claim was correct, though such cases are usually to be taken with some discount. One of the most striking facts regarding these centenarians is that their lives were those of simplicity and industry. It is not useful work, but anxiety which kills men. Overwork of the stomach, liver, or kidneys is vastly

more damaging to a man than overwork of the brain or muscles, since so long as the stomach is intact, overworked muscles may be easily repaired; and so long as the liver and kidneys retain their integrity, the effects of excessive brain work are easily removed by the elimination of the resulting poisons from the body. Many die from overwork, but it is overwork at the dinner table rather than in the field, workshop, or counting-room. Hard labor is healthful. The majority of men, and women also for that matter, are suffering, not from overwork, but from too light work. More work is required. It may be more mental activity or more muscular exercise. Evil results from work flow not from excessive work, but from a lack of the proper distribution of work so that every organ and every faculty receives its own share and not one organ an excess and another a deficiency.—*The Journal of Hygiene*.

The Survival of Typhus Fever.—Typhus fever has long been the reproach of Liverpool. Though greatly reduced in its proportions, it still lingers there in spite of all the efforts of the sanitary authorities. It looks, indeed, as if students of this disease would soon have no other field for its observation. It is disappearing in Ireland. Doubtless Glasgow could still supply a few cases. But in the hospitals of the Metropolitan Asylums Board of London last year there were only three cases, all in the Eastern Hospital; all the patients happily recovered. In any general hospital of London it is a veritable rarity, but in Liverpool the disease still has a habitation and a name. There were last year in the city, according to Dr. Hope's report, one hundred and sixty-two cases, of which twenty-four died. Even in Liverpool the increasing rarity of it makes diagnosis difficult, especially in the dirty and dark conditions under which the poor in Liverpool live. The first cases, it is said, usually occur among children. The symptoms are obscure and the eruption much covered and concealed. The ages at death of the cases were as follows: from two to five years, two; from five to ten years, one; ten to fifteen years, one; twenty to thirty years, one; thirty to forty years, eight; forty to fifty years, eight; fifty to sixty years, one; and sixty years and upward, two.—*The Lancet*.

Crimson Clover Hair Balls in Horses.—The division of botany of the United States department of agriculture has recently investigated the cause of death of horses that have been allowed to feed on overripe crimson clover (*Trifolium incarnatum*), a species of clover recently introduced from Europe. The calyx of this clover is densely beset with stiff hairs, which at maturity become thick-walled, and doubtless, though not so stated by the department, the cellulose, constituting the young cell of which the hair is composed, is transformed into lignin, or some other substance indigestible for the horse. The surface of the hair is marked by sharp-pointed tubercles bent toward the apex. Taken into the stomach of the horse, these hairs form themselves into masses of a spherical shape. They are arranged with their bases toward the centre of the ball, this position being facilitated by the tubercles pointing toward the apex of the hair. When the balls reach a certain size, apparently in from a few days to several weeks, they pass into the intestines, where they form obstructions, causing intense suffering and death in a few hours following the appearance of the first symptoms. No bad effects are observed when the clover is eaten before the seed matures. The fatal effects have mainly occurred when the plants were allowed to fully ripen and the straw and refuse, after threshing, had been fed to the horses.—*Pittsburg Medical Review*.

Teacher: Name the most important canal in America. Bright Youth: The alimentary canal.—*Kansas City Medical Record*.

The Hair of the Dog.—The natives of Bushmanland, in South Africa, swallow the poison from the glands of freshly killed snakes to obtain immunity from snake bite.—*North West Lancet*.

Roentgen-Ray Dermatoses.—Dr. Marcuse, of Berlin, has observed a peculiar brownish-red discoloration of the skin after exposure to the x-rays, followed by desquamation and falling of the hair, as in alopecia areata.—*Lancet*.

Management of Disease in Infancy.—No matter how strongly we may be convinced of the value of any drugs or combination of drugs, if they continue to disturb the stomach they are worse than useless. The use of all drugs is of very minor importance as compared with dietetic and hygienic treatment. In the management of any single (acute) case the important points are thorough evacuation of the stomach and bowels, and then rest to these organs again for from twelve to twenty-four hours. No patients do worse than those whose mothers cannot appreciate the value of starvation and insist upon giving milk in violation of the rules laid down.—DR. L. EMMET HOLT.

A Certain Doctor had occasion, when only a beginner in the medical profession, to attend a trial as a witness. Counsel, in cross-examining the young M.D., made several sarcastic remarks, doubting the ability of so young a man to understand his business. "Do you know the symptoms of concussion of the brain?" asked the learned counsel. "I do," replied the doctor. "Well," continued the attorney, "suppose my learned friend, Mr. Bagwig, and myself were to bang our heads together, should we get concussion of the brain?" "Your learned friend, Mr. Bagwig, might," said the doctor quietly.—*Argonaut*.

The Goat and Sheep Will Not Cross.—Ch. Cornevin stated before the French Academy of Science, August 3d, that certain biologists admitted that the sheep and goat were capable of cross-breeding, and that Gay in his writings had accepted this as the origin of the wool-producing animal of Chili called the chabin. Cornevin, however, found that while the male goat copulated freely with ewes, yet there was no offspring, and the same observation had been made during experiments instituted at the school of agriculture of Santiago. Further, it was shown at this school that the sheep and the chabin crossed freely, proving that the latter was only a race of sheep, as was further attested by its anatomy, which resembled that of the sheep and differed from that of the goat.

Graveyard Soil.—Dr. J. B. Young (*Journal of the Royal Microscopical Society*) writes that the soil of graveyards contains, as a rule, more bacteria than virgin soil, the difference being most marked in the deeper layers, although the number of bacteria is not so great as one might expect. The bacteria are not most numerous immediately surrounding the coffin, but at some distance above, while at a short distance below the coffin there is a marked diminution in the number. Liquefying bacteria are abundant in the soil in the immediate vicinity of the coffins. Burial has little if any effect in increasing the organic matter in the upper reaches of the soil, whereas it has a very marked effect on the layers containing the coffin, *i.e.*, at depths greater than four feet from the surface. The organic nitrogen and carbon in graveyard soil are by no means so great in amount as is commonly supposed.

Nostrum Selling in France.—According to the *Paris Journal de Médecine*, the tribunal of the Seine has decided a case against certain parties named Hirschfield, Bryant, Guillon, and Picard, who opened a store on the Boulevard Poissonnière, where they sold a "Le Tueur de Microbes Radam," or Radam's Microbe-Killer—a watery solution of sulphuric and sulphurous acids. The courts held that this was illegal practice of pharmacy and medicine. Each defendant was fined \$100 and expenses under the criminal code, and under the civil code were compelled to pay the Seine Society of Pharmacy \$200, with damages and interest. This finding must be published at their expense in two daily papers. The nostrum shop of Radam's wonderful American germ-slayer was ordered closed. Alas, that such a great discovery should be shut out! It is to be feared that American nostrum dealers will find fatal opposition in France.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

PROSTATIC ENLARGEMENT: REMARKS INTRODUCTORY TO A DISCUSSION ON ITS NATURE, DIAGNOSIS, AND TREATMENT.*

By J. W. S. GOULEY, M.D.,

SURGEON TO BELLEVUE HOSPITAL.

ALTHOUGH the subject proposed for discussion has long been under the scrutiny of the profession, and notwithstanding the progress made toward its elucidation, there is still need of much additional information respecting an ailment which is so distressing to humanity. The suffering caused by obstructed urination was graphically recorded by many observers in remote times, but the origin of any particular kind of obstruction was not discovered until the dissection of human bodies became frequent, and until Riolan, early in the seventeenth century, suggested that the neck of the bladder could be obstructed by a tumor of the prostate. Marked advances toward a more exact knowledge of the nature and treatment of prostatic enlargement and its effects began with this century, and honorably associated with these advances are the names of Everard Home, Jean Civiale, and Auguste Mercier. These eminent men were truly venerable pioneers in this field of investigation, and the present generation is reaping the benefits of their labors.

The results of recent researches into the nature, effects, and treatment of prostatic enlargement will, this day, be made known to the association, by several inquirers, in the hope that the debate they evoke may serve to help the general physician in the difficulties he sometimes encounters while endeavoring to form a diagnosis, and to enable him to give safe and speedy relief to the sufferers who have recourse to him in their distress.

The questions propounded for discussion are:

I. What is the nature of prostatic enlargement?

II. How is prostatic enlargement recognized?

III. What are the effects of prostatic enlargement, and how may they be counteracted?

IV. When is operative interference indicated, and what operations may be safely performed for prostatic enlargement?

Some consideration of the few subjoined points in the anatomy and physiology of the prostate is suggested as likely to be a helpful preliminary step in the direction of a right estimate of deviations from its normal state. This vesical prostatic body—said to have been discovered by Nicolas Massa about the middle of the sixteenth century—this mass of muscular and glandular substance, though ordinarily shaped somewhat like a chestnut, is subject to many variations, not only of form but of size and weight, as ascertained by the dissection of great numbers of specimens taken from men between the ages of twenty-five and fifty years, that apparently had had no serious urinary disorder. Among these specimens are very flat and short prostates, one inch in length, not over

half an inch in thickness, but occasionally very broad at the base, reaching two inches; there are also long and disproportionately slender prostates; and a few examples of the nearly globular which are one inch and a quarter in mean diameter. In a few cases they are undersized though of regular form; while others are in excess of size and weight of the normal typical organ, whose average length, from base to apex, is one inch and a half, whose average breadth, near the base, is one inch and three quarters, whose average thickness, near the base, is seven-eighths of an inch, and whose average weight is five drachms.

Springing from the antero-inferior part of the bladder, the prostate is directed downward and forward, its base embracing the vesico-urethral orifice and the anterior extremities of the seminal vesicles together with the ends of the spermatic canals, its apex being lost in the membranous portion of the urethra. Its antero-superior convex surface, distant from the pubic arch about three quarters of an inch, is covered by a closely adherent layer of muscle-tissue bands derived from the anterior wall of the bladder. Upon and among these superficial muscular bands are many veins which end in the plexus of Santorini, whose efferent veins pass along the sides of the prostate where the muscular layer is much thicker and gives attachment to the pelvic fascia and to the levator ani muscle. Its postero-inferior nearly flat surface, resting upon the lower end of the rectum, is invested with a prolongation of the thin layer of muscle tissue covering the seminal vesicles. This muscular layer is attached to the prostate by moderately dense connective tissue, and to the rectum by very loose connective tissue. Thus the prostate is securely encapsulated by layers of connective and muscular tissue. Its two lobes are united, from base to apex, by a superior isthmus and by an inferior isthmus, and this union forms the prostatic region of the urethral canal. The posterior third of the inferior isthmus, much thicker than the anterior two thirds, is called by Home the third lobe, and by Mercier the supramontanal region because it is above the *veru montanum*.

The prostatic body consists largely—from two-thirds to three-fourths of its bulk—of smooth muscle tissue which encloses the acini and tubes of great numbers of compound racemose mucous glands; the acini containing microscopic albuminoid sympexia, which first make their appearance during adolescence. The writer has found sympexia in the acini of prostatic mucous glands of boys of sixteen years. These acini, in adults, are about the one-three-hundredths of an inch in mean diameter; some of them are round and others are oval or oblong. In disease they are often distinctly visible to the naked eye. The tubes of different bunches of acini unite to form larger tubes, and these coalescing make up terminal excretory ducts, the greatest numbers of which open obliquely on the floor of the prostatic sinus at either side of the urethral crest. The orifices of some of the excretory ducts appear on the upper and lateral walls of the sinus, and a few open inside the utricle. The posterior third of the lower isthmus ("third lobe") seems to be the part which is richest in mucous glands.

* Read before the New York State Medical Association, October 13, 1896.

The prostate is well supplied with blood and lymph vessels, and derives its innervation mainly from the sympathetic system; the acini, the vessels, and the nerves being accompanied by fibres of connective tissue which form their delicate framework.

Physiologically considered, the prostate is both a genital and urinary organ. Genital, because its mucous secretion contributes largely to the dilution of the semen, and because, as a muscle, it helps much the ejaculation of the semen; urinary, because it aids in expelling the urine, being an integral part of the urethra. As a genital organ it is practically rudimentary until the period of adolescence, and does not attain its full size until about the age of twenty-five. It increases slightly in bulk after the age of fifty.

Question I. What is the Nature of Prostatic Enlargement?—Before endeavoring to answer this question, it is proper to say that the term enlargement is here used instead of "hypertrophy" with its strict meaning of overnourishment and its arbitrary signification of increase in size of existing individual component parts of organs as distinguished from hyperplasia—the multiplication of cellular elements—which occurs in the prostate as well as in other parts of the body. Although increase in size of the acini occurs in the prostate, hypertrophy cannot, with accuracy, be employed in respect of this organ, because the morbid states which give rise to increase of its volume are many and in none of them is the organ overnourished. The contrary seems to be the case, for the venous stasis which exists in diseased conditions of the prostate surely points to under rather than overnourishment. Physical exploration during life and dissection after death have long since demonstrated that prostatic enlargement is neither a single morbid entity nor a single morphic entity.

The chief morbid states that cause increase in bulk of the prostate are as follows:

1. *Acute inflammatory action* gives rise to prostatic enlargement which disappears when resolution is completed or which persists longer, as in the case of suppuration and abscess formation. In some cases acute prostatitis ends in the gradual shrivelling of the organ instead of its enlargement. A variety of acute inflammation with œdema of the prostatic mucous membrane extending to and closing the urethro-vesical orifice, and involving the prostatic ducts, causes not only retention of urine, but often general swelling of the prostate which, ordinarily, is transitory. Sometimes, however, this prostatic swelling persists several weeks or even several months after the subsidence of the acute inflammation. In subacute prostatitis the persistence of swelling is even more common than in this variety of the acute form.

2. *Chronic parenchymatous prostatitis* is a cause of transitory as well as of permanent enlargement of the organ. Transitory when, after a suitable course of treatment, the swelling vanishes, or, when rapidly increasing calcified sympexia are artificially removed, the prostate soon decreases or even shrivels. Permanent when dilatation of the acini occurs together with some increase of the muscle tissue, the calcified sympexia remaining almost microscopic in size. Such prostates generally become very large, are comparatively soft, and occur with greater frequency than the other kinds. In his work on "Diseases of the Urinary Apparatus," "Phlegmasiac Affections," 1892, the writer discusses the subject of chronic prostatitis and its effects at p. 170 *et seq.*

3. *Dilatation of the prostatic sinus* sometimes greatly increases the bulk of the organ. Of this kind, three cases have been observed by the writer. In one case the ectasia was due to the damming up of the urine by a narrow urethral stricture. The cavity thus formed had a capacity of sixty cubic centimetres. The

walls of the sac, consisting of the substance of the prostate, were of irregular thickness, from three to twelve millimetres. In consequence of cystitis and of frequent violent efforts to urinate, the bladder capacity was diminished, the walls of this viscus were thickened to more than a centimetre, and there was on the right side, close to the ureter, a diverticulum whose capacity was seventy cubic centimetres. There was also a well-marked urethro-vesical bar. The kidneys, which were not preserved after examination, showed signs of inflammation and fatty degeneration, and weighed two hundred and six grams. In another specimen the dilatation was quite as great and the prostatic sac contained a calculus which nearly filled it.

4. *Retention cysts*—due to extreme dilatation of acini from accumulation of the secretion owing to closure of excretory ducts—sometimes attain such dimensions as to increase very considerably the bulk of the prostate or interfere with urination. A prostate of normal size, dissected by the writer, contained a superficial retention cyst, one centimetre in diameter, at the right of and almost closing the urethro-vesical orifice. Large degeneration cysts are also sometimes found in this organ. Hydatid cysts very rarely occur in the substance of the prostate; they are generally found in its immediate vicinity and by mechanical pressure interfere seriously with urination.

5. *Tuberculosis*, though of rare occurrence in the prostate, increases markedly the volume of this organ, which it finally destroys. One specimen of this kind is in the writer's collection.

6. *True adenomata*—new-growths of adenoid substance with imperfectly elaborated and sterile structure—which do cause increase in size of the prostate, are very rare, and are transformable into carcinomata and sometimes into adeno-sarcomata. Careful examination of many hundreds of diseased prostates, during the past thirty years, has revealed to the writer only three cases of carcinoma of this organ.

7. *Fibrous tumors* are of extreme rarity and are transformable into sarcomata, but primary sarcoma does sometimes occur in the prostate to give rise to its enlargement.

8. *Diffuse increase of the prostatic fibrous framework* is also very rare and, like the isolated fibrous tumors, is liable to sarcomatous metamorphosis. Although diffuse increase of the fibrous tissue causes but little augmentation in bulk, it obstructs urination nearly as much as do very large prostates, owing to its hardness and to the urethro-vesical bar which it forms.

9. *Circumscribed multiple myomata* are known to cause increase in size of the prostate. Good illustrative specimens of this kind are preserved in the writer's collection.

10. *Diffuse increase of muscle tissue* makes up the greater part of the substance of some hard prostates, which do not always become very large, but cause obstruction to urination by forming a bar at the vesical neck.

Although the prostate is often uniformly enlarged without producing serious effects, it is clear that its enlargement cannot reasonably be regarded as a single morphic entity, as shown in the following statement of the main varieties of form:

1. The enlargement may be limited to one lobe of the prostate or may involve only the two lobes.
2. Enlargement of the lobes may be unequal, one being much larger than the other.
3. One or both lobes may project into the bladder.
4. One or both lobes may encroach upon and nearly close the prostatic region of the urethra, rendering its course irregular or even spiral.
5. The posterior third of the lower isthmus alone may be enlarged in the form of a roundish peduncu-

lated tumor, or of an irregular sessile mass, or of two separate sessile growths.

6. The whole of the lower isthmus alone may be enlarged.

7. Both lobes and the posterior third of the lower isthmus may be enlarged.

8. Both lobes and isthmi may be enlarged.

9. The enlargement of both lobes may be downward and backward toward the rectum, overlapping the anterior third of the seminal vesicles.

10. There may be only a bar at the neck of the bladder with little if any general enlargement of the prostate.

11. There may be intramural isolated tumors which are not perceptible before incision of the organ, or which, being sometimes superficial, are discoverable through rectal exploration.

12. Multiple tumors, from one or both lobes, may project into the urethra, with or without enlargement of the posterior third of the lower isthmus.

13. Multiple tumors, with or without general enlargement, sometimes spring into the bladder from the posterior third of the lower isthmus, and cause true incontinence of urine.

Here then are greatly differing morbid states which cause enlargement of the prostate with many varieties of form. Does it not seem plain, in consideration of such diversity of morbid states and freaks of form, that no exclusive method of treatment of these conditions can consistently be adopted, and that the proper management of any case must be premised by a diligent inquiry into the nature of the particular morbid state and the form and extent of the enlargement?

Chronic progressive enlargement, being the most frequent of the diseases of the prostate in elderly men, is entitled to the largest share of attention. Very often physicians are consulted by younger brethren in behalf of patients, under the age of forty, supposed to be suffering from chronic enlargement of the prostate, but in reality are harassed by dysuria due to transitory prostatic swelling or to spasmodic contraction of the vesical neck, either being a common sequel of urethritis or of persistent hyperlithuria. This misconception of the nature and era of chronic prostatic enlargement still exists in the minds of some physicians, notwithstanding the frequent reiteration, for many years past, that this affection does not generally occur until the sufferer has attained two score and ten years of age. The inexperienced are constantly mistaking transitory inflammatory swelling of the prostate for the chronic, slow, steady increase in bulk of this prostatic body, which very seldom begins before the age of fifty. It therefore seems justifiable to emphasize the often repeated statements that chronic progressive enlargement of the prostate is a disease of elderly men; that not more than forty per centum of men between the ages of fifty and seventy years are affected with chronic enlargement of the prostate; that the ailment does not ordinarily manifest itself before the age of fifty-five; that it rarely begins after the age of seventy; and that out of the forty per centum of cases not more than one in every six suffers seriously from disordered urination.

During the first half of this century, progressive enlargement of the prostate was regarded, by some physicians, as a result of chronic inflammatory action, but that opinion was not shared by many others, who, however, offered no better explanation, although they admitted the existence of passive congestion of the organ. A re-examination of the question, with the aid of modern methods of study, has led to the belief that phlegmasia action—often excited by persistent hyperlithuria, which is so common between the ages of fifty and sixty—is a potent factor in the causation of

this chronic enlargement. Post-mortem evidences point to a low grade of inflammation of the prostatic parenchyma, and microscopic inspection of the soft enlarged prostate of elderly men shows that its structure is not identical with what is known as a new growth, but that the increase of bulk is due to dilatation of the acini with augmentation of muscle-tissue bands. Such increase of muscle tissue seems to be an effect of violent and frequent contractions of the bladder and prostate in their efforts to expel retained urine. Therefore, this increase of muscle tissue is secondary to the diseased state of the acini involved in the passive phlegmasia, that yields an exudate sufficient to distend them and float the symplexia, which are soon encrusted with concentric layers of calcium phosphate, and thus become irritant bodies serving to aggravate the existing condition. Many of these calcified symplexia are discharged through dilated ducts and are found in the urine, but others remain in the acini or are impacted in ducts, and the consequence is accumulation of the secretion, further dilatation of the acini, and general or local increase of the prostate. Among the dissected prostates of men between the ages of fifty and fifty-five, many of the specimens showed marks of beginning enlargement of the lower isthmus and lobes and also in the form of small foci of dilated acini in the substance of the organ. In a few instances the foci projected to the surface of the posterior third of the lower isthmus. Some of these foci were not more than a millimetre in size, others were between two and three millimetres. The process of enlargement is so slow that the organ does not become inordinately bulky until the sufferer is much advanced in years. In some cases the muscle tissue is greatly in excess, while in the vast majority it is the dilatation of the acini which predominates. The gritty calcified symplexia are discernible when the prostate is incised with a sharp knife.

Analysis of the record of nearly every new case affords some evidence of the phlegmasia origin and slow development of chronic enlargement of the prostate. The following example is cited out of many carefully studied cases: A patient—now, May, 1896, fifty-five years of age—who had suffered from persistent hyperlithuria for more than five years before his first symptoms of chronic prostatitis, noticed, at the age of fifty-two, a slight muco-purulent urethral flow, particularly during defecation, together with uneasy sensations in the perinæum and rectum, but did not apply for treatment until a year thereafter, when he began to be annoyed by unduly frequent urination, for which he consulted the writer. At that time—when he was fifty-three years of age—there was no appreciable prostatic enlargement and he was able to empty his bladder. In the course of a year he was again examined through the rectum and the volume of the prostate seemed slightly increased, but there was no residual urine in the bladder. Six months after this he had an attack of cystitis, during which his urine was purulent and fetid, but became clear after six weeks' treatment, when his physician declared him well. Nevertheless, the frequency of urination by day increased and he was obliged to rise to urinate twice each night. He returned to New York, in May, 1896, complaining of pain in the hypogastric region and perinæum, and of frequent desire to urinate day and night. His act of urination, in presence of the writer, was characteristic of urethro-vesical obstruction. At the first attempt he could pass only an ounce of urine; after moving about for two or three minutes, he passed four ounces, and a few minutes later two ounces; in all seven ounces. A curved silk-web catheter was then easily introduced and four ounces of clear residual urine drawn. Digital rectal exploration revealed undue rotundity of the prostate and an

increase in volume estimated to be about one-third in excess of the normal average. By the aid of Mercier's short-beaked rectangular staff, a moderate increase of the posterior third of the inferior prostatic isthmus together with a corresponding depth of the lower vesical fundus was detected, and this accounted for the residual urine drawn. The hatching of the prostatic enlargement, in this case, seems to have lasted at least six years.

In the case of a man aged seventy-seven years, prostatic enlargement had existed ten years before complete retention of urine occurred and subsequent regular catheterism became necessary. In that time the prostate had not more than doubled in size. In another case fourteen years had elapsed from the beginning of enlargement before the catheter became indispensable. The patient was at that time eighty years of age, and during these fourteen years the prostate had more than quadrupled in size.

Mercier recognized the dilatation of the acini and the calcification of the symplexia, but was one of those that rejected the notion of the phlegmasiac origin of chronic enlargement of the prostate ("Recherches," etc., 1841); and yet he believed this enlargement to be due, in great part, to passive congestion. This admission is surely favorable to the phlegmasiac theory. Some modern writers regard chronic enlargement of the prostate as adenoma, but this view is certainly not in accord with the present definition of an adenoma, which is: a new growth of adenoid substance with imperfectly elaborated and sterile structure. It has already been stated that adenomata, as well as other new growths, are found in the prostate, but that their occurrence is very rare. In the great majority of cases of chronic enlargement, there is not the least appearance of new growth of glandular substance. The acini are not increased in number, but are greatly dilated—some of them from five to twenty times their normal dimensions—and ordinarily the muscle tissue is only slightly increased. Besides, there are, in and around these prostates, unmistakable signs of secondary phlegmasiac action. The periprostatic veins are gorged with blood, and in some cases are occluded by phleboliths. Although the surrounding tissues are indurated, the substance of the prostate is soft and spongy.

The diseased prostate sometimes attains very great dimensions. Among the last specimens dissected, one, taken from a patient who died at the age of sixty-seven, was, by external measurement, two inches and a half in thickness, two inches and a quarter from base to apex, and three inches and a half from side to side. In addition, the posterior third of the lower isthmus, one inch and a half broad, projected one inch and a quarter into the bladder, bulged toward the rectum, and pushed aside the spermatic canals and seminal vesicles, which were shrivelled and hardened. The length of the prostatic region of the urethra was two inches and three-fourths. The vesical wall at the lower fundus was much indurated and irregularly thickened from half an inch to three-fourths of an inch. The bladder, whose capacity did not exceed four ounces, contained a small phosphatic calculus. The calibre of the ureters was more than doubled, and there was on both sides pyelonephritis, the kidneys being more than twice their natural size. Notwithstanding the great increase of this prostate, the introduction of instruments was exceptionally facile; and the fact was accounted for after dissection, when the two lobes were found to be equally enlarged and the prostatic urethra very slightly curved, owing to inordinate thickness of the superior isthmus, the whole of the inferior isthmus being also very much enlarged. In a specimen prepared some years ago, the posterior third of the inferior prostatic isthmus

made up about one-third of the bulk of the diseased organ, in the form of a rounded mass, two inches in mean diameter, which nearly filled the lower vesical fundus. Many examples of extreme prostatic enlargement are on record, but only a few of them need now to be mentioned. In his work on "Diseases of the Prostate," fourth edition, Sir Henry Thompson figures and describes a prostate which was "nearly the size of a cocoanut, and weighed nine or ten ounces." The patient "expelled his urine very frequently and with difficulty, but emptied his bladder completely." This is a valuable illustration of the fact that general enlargement of the prostate, with great protrusion of the so-called third lobe, does not always abolish urination. Ford is cited by Mercier as having published, in 1802, the account of a diseased prostate that weighed nine ounces. Bartholinus is said to have seen a prostate equal in size to a man's head. This was regarded by Mercier as an exaggeration. Probably the largest prostate exhibited in modern times is the specimen figured by Dr. F. S. Watson, of Boston, in his essay on "The Operative Treatment of the Hypertrophied Prostate," 1888, plate xvii. The bladder having been dissected away, the diseased mass was photographed. The picture measured seven inches and one-eighth in extreme longitudinal diameter, five inches and three-fourths in largest transverse diameter, and four inches in smallest transverse diameter.

The other extreme in point of development is illustrated by a specimen taken from an elderly man whose death was due to the consequences of obstruction to urination by a very slight enlargement of the posterior third of the lower isthmus, which, however, had almost entirely closed the urethro-vesical orifice; the rest of the prostate being not more than two-thirds the average size.

Question II. How is Prostatic Enlargement Recognized?—To ascertain the existence of prostatic enlargement is often easy, but to identify any particular kind of enlargement requires a clear discernment of the several morbid states and varieties of form to which this organ is subject. Hurried, superficial examination is almost certain to lead to erroneous diagnosis, and this to improper treatment. A case in point is that of an elderly man, affected with prostatic enlargement, whose physician seemed to take into account only the fact of the enlargement, and therefore suggested what he conceived to be a radical operation. The patient then consulted another physician, who, after a very careful examination of the case, advised against any operative interference, for the time being, other than evacuative catheterism and daily vesical irrigation, because his diagnosis was sarcoma of the prostate, with a secondary nodule in the hypogastric region of the abdominal wall. The prostate then increased so rapidly that suprapubic cystotomy for drainage became necessary, and afforded great relief to the doomed sufferer.

In its inception, enlargement of the prostate is seldom recognized. Patients very rarely seek medical advice until the disease has advanced sufficiently to impede urination. In the case of those who do not suffer in consequence of the enlargement of their prostates, this condition is often only incidentally discovered. Large prostates, that had not caused the least inconvenience and the existence of which was never suspected, have been found in the bodies of old men dead of acute disease. In like cases, the enlargement is generally uniform. It should, however, be borne in mind that these prostates are liable to such swelling—due to exposure or to debauch on the part of the patients—as to cause retention of urine and cystitis, necessitating frequent catheterism; and that this swelling often lasts many weeks or even months, finally

subsiding so that the patients are able to urinate in a good stream and empty their bladders.

When urination is much disturbed, day and night, in an elderly man free from urethral stricture or vesical stone or tumor, the existence of multiform enlargement of the prostate may be predicated. It has already been said that the hatching of chronic prostatic enlargement is a very slow process, several years generally elapsing before any symptoms of impediment to the exit of urine are perceived. The patient then first becomes conscious of something being wrong with his urinary apparatus, on account of frequent desire to urinate, and, later, of difficult and sometimes painful urination; but these symptoms, being common to several other urinary affections, are likely to lead him astray as to the nature and, consequently, as to the management of his complaint. Frequent and difficult urination by day and by night, a sense of fulness and weight in the perinaeum and rectum, lumbago, and sciatica, are valuable symptoms when rightly interpreted. Frequent urination points to stagnation of urine and consequent cystitis. Difficult urination is evidence of obstruction, but the obstruction may be of the nature of a urethral stricture or of the impaction of a calculus in the urethra. However, in the case of an elderly man, free from urethral or calculous disease, difficult and frequent nightly urination forebodes prostatic obstruction. Chemical and microscopical examinations of the urine, so helpful in diagnosis, prognosis, and therapeutics, need to be made from time to time during the conduct of each case.

The mode of urination as indicative of prostatic obstruction is worthy of special notice. The patient stands leaning forward with his legs spread. After some delay the urine issues in a small, feeble, vertical stream, which soon stops, to be followed by the dribbling of twenty or thirty drops, that are succeeded by the small stream; and this continues until, in the course of two or three minutes, one or two ounces may thus be expelled. This process is repeated two or three times, with varied success, when the introduction of a catheter reveals the presence of six or eight ounces of residual urine. This kind of urination only specializes obstruction from prostatic enlargement; it does not characterize any of the varieties of form.

Digital rectal examination reveals, with sufficient precision, the extent of enlargement of one or both prostatic lobes, abnormal rotundity of these lobes, or multiple nodules indicating the presence of large calcified symplexia, isolated myomata, or cancerous growths. Hardness does not necessarily signify induration of the whole prostatic mass, for the peripheral parts only may be indurated, while the central portion may be soft and spongy. Exploration through the urethra with Mercier's rectangular short-beaked metallic staff reveals the existence of a urethro-vesical bar, or of a more or less extensive growth of the posterior third of the lower isthmus. Digital rectal exploration is negative when there is no enlargement of the prostatic lobes. In that case the physical diagnosis is made entirely by the urethral route, either with the rectangular staff or with the cysto-pylometer, by the aid of which the thickness of a urethro-vesical bar may be determined.

The exact statement of the diagnosis of prostatic enlargement is of importance not only to the practising physician but to the vital statistician. Too frequently only a condition common to prostatic enlargement, urethral stricture, and stone in the bladder appears in tables of diseases without explanation, as "retention of urine, chronic cystitis," etc. The writer, in endeavoring to obtain information respecting the relative frequency of the urinary diseases of males, examined the annual reports of many institutions for the care of disabled elderly men, and found it very

difficult and sometimes impossible to determine the character of the diseases catalogued in these reports, whose great value would undoubtedly be much enhanced if the compilers were permitted to place in brackets and in italics the name of the primary disease—as, for instance: Retention of urine [*from urethral stricture, from prostatic enlargement, or from vesical stone*], as the case may be; chronic cystitis [*from prostatic enlargement, from urethral stricture, or from vesical stone*], etc. Such additions would lighten the labors of, and be gratefully appreciated by, medical investigators and statisticians.

Question III. What are the Effects of Prostatic Enlargement, and How may They be Counteracted?—Uniform general enlargement of the prostate, without encroachment upon the urethra or bladder, except in the case of malignant disease or of tuberculosis, gives no inconvenience to the affected individual, who, however, if he be exposed to cold and moisture after excess in drink, is likely to suffer from retention of urine, due to transitory swelling of the already enlarged prostate, which generally yields to rest, systematic catheterism, and vesical irrigation.

The effects of those forms of prostatic enlargement by which the capacity of the urethra or of the vesico-urethral orifice is lessened are soon felt by the bladder, that vainly struggles, for weeks or months, against the obstacle, to rid itself of irritating urine. Hence the dysuria, the strangury, and the increase of muscle tissue of the bladder and of the prostate itself. The stagnant, alkaline, slimy urine affords sustenance to myriads of saprophytic and other organisms, and the resultant cystitis adds to the distress of the patient. Later, the phlegmasia process, if not checked, creeps up the ureters, reaches the kidneys, and the sufferer succumbs to ascending microbic pyelonephritis. Such is the end of neglected cases of prostatic obstruction to micturition. These ill-effects are often counteracted by regular evacuative catheterism—from two to five times in the twenty-four hours—and thorough cleansing of the bladder with a solution of corrosive chloride of mercury, 1 to 10,000, adding thereto one per centum of phenol, or 1 to 1,000 of formalin. In the course of a few days, a solution of nitrate of silver, 1 to 5,000, may be used once daily for vesical irrigation. This weak solution of silver nitrate seems to act beneficially upon the vesical epithelium, while it is as destructive of the bacteria as are the other antiseptics. When the bladder is very foul, the sublimate and phenol solution may be used in the morning, and the silver-nitrate solution in the evening, after having rinsed the bladder with warm sterilized water. Not more than four ounces of fluid should be injected into the bladder at a time, but three or four such injections may be made at each sitting. This palliative treatment is of great value, and often is the only kind indicated or practicable. In the case of small recurring phosphatic concretions, irrigations with acidulated water—one part of hydrochloric acid to two hundred parts of warm water—destroy the calculi without injuring the vesical mucous membrane. The same result is obtained by the use of acetate of lead, first suggested by Dr. Hoskins, of Guernsey—one part of acetate of lead and one part of acetic acid to four hundred parts of warm water.

The treatment designed to counteract many of the ill-effects of prostatic enlargement may be summed up as follows, and consists in taking suitable means:

- I. To combat hyperlithuria.
- II. To secure moderate acidity of the urine.
- III. To empty the bladder artificially—slowly and gradually when it is much overdistended.
- IV. To effect gradual hydraulic dilatation of the bladder when its capacity is lessening.
- V. To combat existing cystitis by daily vesical irrigation.

VI. To disinfect the urinary tract, as well as the prepuce and glans penis.

VII. To prevent calculous formation.

VIII. To preserve or improve the physical condition of the patient by such hygienic or medicinal treatment as may be required.

It is often asked: "What kind of catheter is best and safest for general use in cases of retention of urine due to prostatic enlargement?" If this enlargement were invariably the same in form and size, one single kind of catheter would undoubtedly always answer the purpose of relieving the bladder. But, since the enlargement is so frequently multiform and progressive, the physician must be provided with several species and varieties of catheters, out of which he may select one of a form suitable to the particular variety of prostatic enlargement affecting his client. The pliable catheters, with lateral or terminal eye, made of silk webbing coated with varnish, or of India rubber, are the safest that can be used. There are ordinarily eight different forms: (1) The straight, which may be used with a stylet, in the case of false routes, according to the method of Hey; (2) the curved; (3) the elbowed; (4) the crutched; (5) the double elbowed; (6) the straight olive tipped; (7) the curved olive tipped; (8) the "velvet-eyed" India-rubber catheter. No instrument which cannot be rendered aseptic should be used, neither should any fatty substance be employed to anoint the catheters. Soap, deprived of glycerin and free alkali, is an efficient and unirritating lubricant when mixed with a decoction of quillaja and duly sterilized. The following is a modification of the formula for a saponic lubricant, published in the *New York Medical Journal*, July 22, 1893:

R White castile soap, powdered.....	fl. i.
Water.....	fl. iiij.
Mucilage of chondrus crispus.....	fl. iiij.
Formalin (40 per cent.).....	℥ x.
Thymol.....	gr. v.
Oil of thyme.....	℥ v.
Alcohol.....	℥ xv.

Mode of preparation: Heat the soap and water, and stir until a homogeneous slime is formed; then add the three ounces of mucilage (made of the strength of one ounce of chondrus crispus to the pint of water). When cool, pour in the formalin, then the thymol and oil of thyme mixed with the alcohol; stir, strain, and keep in a covered vessel until all air bubbles have vanished. The result is an opalescent, slimy substance, of the consistency of honey, which should be put up at once in two-ounce collapsible tubes and sterilized. The chondrus crispus is substituted for the quillaja of the original formula, because of the objectionable quantity of alcohol in the tincture, and because quillaja decoction imparts to the mixture a dirty pinkish tint, whereas the chondrus crispus mucilage is colorless. The *Cetraria Islandica* was tested repeatedly and found unsuitable. The lubricant, in its present form, is sufficiently viscid, adheres well to the surface of all instruments, does not lump, and is unirritating to mucous membranes. The same quantity of chloral hydrate, or half the quantity of chloroform, or thirty grains of boric acid, may be used instead of the formalin if desired, since it is intended solely as a preservative of the mucilage.

All web catheters should be kept at full length and never coiled; otherwise the varnish will surely crack.

Web catheters should be loosely wrapped in dry antiseptic gauze, and preserved in tightly-closed metal cases until wanted for use.

Before using a web catheter it should be slightly warmed by friction in clean hands, and by a momentary immersion in a warm one-per-centum carbolic-acid solution to prevent cracking of the varnish, particularly during cold weather.

After using a web catheter it should be well washed by forcing a stream of water through the instrument, which should then be dipped for a moment into a one-per-centum carbolic-acid solution. It should then be thoroughly dried, wrapped in antiseptic gauze, and enclosed in a metal case. Catheters may be carried in hollow walking-sticks, but never in the pockets of patients.

All web catheters are liable to harden, lose their suppleness, and be unfit for use in the course of a few years, especially when they have not been in use. On the first appearance of the hardening process, the instruments should be cast aside.

Soft India-rubber catheters should be kept at full length, never coiled, and should be wrapped in moist antiseptic gauze, and preserved in tightly corked glass tubes, because exposure to the air leads to rapid oxidation, which causes the instruments to become hard and brittle.

Before using a rubber catheter, it should be well washed and momentarily dipped into a one-per-centum solution of carbolic acid.

Rubber catheters become brittle in about two years, and sooner if unused and exposed to the air. But when daily lubricated with fats they seldom last more than three or four weeks; then swell, lengthen, and become so soft as to be liable to be torn across during withdrawal. Several inches of such deteriorated rubber thus often remain in the bladder.

When it is possible to teach a patient the use of the catheter, perhaps the safest instrument that may be placed in his hands is the "velvet-eyed" India-rubber catheter, which he must cleanse thoroughly before and after its employment.

Metallic catheters, with very few exceptions, should not be employed in attempts to relieve the distended bladder, because of their likelihood to damage the urethral canal and plough their way into the substance of the prostate, sometimes even when introduced with ordinary care. Being absolutely rigid, they cannot readily follow the abnormal incurvations of the urethra common to multiform enlargement of the prostate. The so-called prostatic catheter is particularly dangerous, for it seldom reaches the bladder without detriment to the urethra, and too often finds lodgement in the recess of some false route, which, perhaps, it has made. When a false route renders impossible the passage of ordinary instruments, the contrivances known as Hey's and Mercier's modes of catheterism are generally successful. Hey's method consists in passing, as far as, but not into, the mouth of the false route, a silk-web catheter, No. 9 or No. 10 (English), armed with a curved stylet, which is withdrawn with one hand at the same moment that the catheter is pushed toward the bladder with the other hand, when the instrument overrides the false route and enters the bladder. Mercier's method consists in the use of two catheters, which together he has named the invaginated catheter. This instrument is composed of a female and a male part. The female part is a No. 10 (English), slightly curved, thin-walled, metallic catheter, eleven inches in length, having in its concavity, half an inch from the point, an oval eye five-eighths of an inch long and three-sixteenths of an inch broad. From the vesical extremity of this eye is an inclined plane, lost in the opposite wall of the catheter at about one-fourth of an inch from the vesical edge of the eye, serving to tilt up the point of the male part, which is a No. 6 (English), silk-web, one-eyed catheter eighteen inches long, and fitting loosely in the lumen of the female part. In using the invaginated catheter the male part should first be slid into the female part down to the eye thereof. The instrument thus armed is passed into the urethra as far as the obstacle, engaging its point in and with it blocking up the false route. The male

part, which is then projected, soon reaches the bladder. It sometimes happens that no urine flows after the successful introduction of the male part. This is owing to closure of the eye by a clot of blood, which can be washed away with a little water injected into the catheter. The female part may then be withdrawn, and the male part left in as long as desirable. This is the reason for the great length of the male part.

Some of the other effects of neglected prostatic obstruction to urination, besides the damming up of a few ounces of urine and myxo-cystitis, are chronic retention of urine, the management of which has already been detailed (Transactions of the Association, 1890); increase of the vesical and prostatic muscle tissue, contracture with diminished vesical capacity (Transactions, 1885), interstitial cystitis, abscess in the thickened vesical walls, calculus formation, saccululation of the bladder (Transactions, 1886), ureteritis with dilatation, pyelitis, pyonephrosis, pericystitis, paracystitis involving the seminal vesicles and spermatic canals, and consequent abolition of the genetic function. Unclean and roughened catheters, used several times daily by careless patients, have often been the exciting cause of several of these disastrous consequences.

The frequent evacuative catheterism necessitated by prostatic obstruction causes a subacute urethritis, which demands daily irrigation of the urethra, whose mucous membrane sometimes becomes so œdematous as to render catheterism difficult and even dangerous. In such cases the careful introduction of flexible web bougies or of steel sounds, of increasing size to No. 15 (English), every second or third day for two or three weeks, relieves the sodden mucous membrane, restores the suppleness of the canal, and facilitates the evacuative catheterism. Another ill-effect of this indispensably frequent catheterism is acute orchitis, due generally to the use of unclean and fissured instruments. This occurs, in some patients, as often as every three or four months, first on one side, then on the other, seldom on both sides at the same time. After several attacks the orchitis becomes chronic, and sometimes small purulent foci are formed in the substance of the testes. These abscesses generally open spontaneously and are rarely incised, the patients objecting until they are taught by experience that early incision is wise and proper. Finally, the spermatic canals are occluded, and the genetic function is at an end.

Chronic inflammation of the seminal vesicles and spermatic canals appears to be frequently associated with chronic inflammation and progressive enlargement of the prostate. In seventy-five per centum of the chronically enlarged prostates of elderly men dissected by the writer, there were marks of phlegmasiac action between the base of the bladder and the rectum, such as induration of the ambient connective tissue, particularly that which bounds the seminal vesicles; and these vesicles were, in general, hardened and shrivelled, and in some cases their fluid was purulent. The absence of spermatozooids and the presence of many enlarged symplexia were conspicuous in the mucus of the vesicles. The spermatic canals were abnormally hard and sometimes occluded. In a few cases there were cystlike dilatations in the vesicles, due to the occlusion of their excretory ducts.

Question IV. When is Operative Interference Indicated, and What Operations may be Safely Performed for Prostatic Enlargement?—The determination of the indication of operative interference for the relief of obstruction to urination due to prostatic enlargement requires serious consideration, a judgment founded on extended clinical study of the phases and complications of the diseases of this organ, and correct notions of its patho-histology.

Operative interference is indicated when the blad-

der is permanently contracted and its capacity inordinately and irremediably lessened, when catheterism is extremely difficult or is followed by rigors and fever, when there are prostatic false routes, or in some cases when autocatheterism is not possible. Early operative interference is justifiable, as prophylactic of the lesions consequent upon stagnation of urine.

Operative interference is contraindicated when the upper urinary organs are damaged beyond remedy.

Operative interference may be palliative or radical.

Palliative Operative Interference is resorted to in the case of malignant or of tubercular disease of the prostate, in the case of permanent contracture with diminished vesical capacity, in the case of beginning involvement of the upper urinary organs, and sometimes in the case of prostatic false routes. The palliative operations are: (1) Suprapubic cystotomy; (2) the establishment of a suprapubic fistula; (3) divulsion of a false route; (4) puncture of the bladder.

1. *Supra-pubic cystotomy*, with maintenance of a free opening for drainage and daily irrigation, may be regarded as a palliative measure of great value in the case of malignant or of tubercular disease of the prostate, of permanent contracture with diminished vesical capacity, and in the case of beginning involvement of the upper urinary organs, particularly when catheterism has become insupportable. In these circumstances, the last few months of the sufferer's existence are rendered tolerable by the easy exit of the urine through the ample artificial orifice.

2. *The establishment of a permanent supra-pubic fistula*, as a palliative measure, in cases of great protrusion of the lower isthmus, in which catheterism has been extremely difficult, has proved useful in many instances, and has been successfully effected by Van Buren, Thompson, McGuire, and many other surgeons.

3. *Divulsion of a false route*, impeding catheterism attempted for the relief of a bladder distended with urine, has given results that warrant its adoption as a safe palliative agent. This mode of palliation, employed frequently by the writer, is as follows: When the point of the female part of the invaginated catheter is once lodged in a prostatic false route and the male part has entered the bladder, the two parts together are pushed onward until there is no longer any resistance; the urine flowing through the female part on withdrawal of the male part indicates that the divulsion is complete. This operation should be done with the greatest care or else abandoned, particularly if much force be required, for then no divulsion would be effected, and the male part would be likely to be severed by the distal edge of the eye of the female part, and perhaps remain in the bladder. As a general rule, divulsion occurs on very moderate pressure. The deep rent extends beyond the obstacle, and is similar in effect to incision of the vesical neck. Although spontaneous urination continued on an average of only two years after this procedure, and the patients were then obliged to return to autocatheterism, the false routes were cured by the operation, catheterism was thereby rendered easy, and the temporary relief was comforting.

4. *Capillary puncture of the bladder*, in the hypogastric region, with pneumatic aspiration of retained urine, is rarely necessary. In cases of emergency it may be done once for the mitigation of suffering, and should not be repeated unless better means are not soon obtainable. Many observations of the ill-effects of repeated punctures have led the writer to abandon the practice of puncturing the bladder in any way and for any purpose, and to regard suprapubic cystotomy as a safer measure in cases of retention of urine from prostatic obstruction when other modes of operation are not clearly indicated.

Radical Operative Interference is resorted to in the

case of urethro-vesical bars, of outgrowths of the posterior third of the lower prostatic isthmus, and of increase of the lobes. The radical operations are: (1) Incision of urethro-vesical bars; (2) excision of urethro-vesical bars, or of the central part of the posterior third of the lower isthmus; (3) excision of pedunculated urethro-vesical growths; (4) avulsion, excision, or enucleation of the posterior third of the lower isthmus and of portions of the lobes; (5) enucleation of the whole prostate.

1. *Incision of urethro-vesical bars*, originally suggested by Guthrie, was performed by Mercier, then by Civiale, Leroy, Costello, and other physicians. The operation is now known as internal prostatotomy. Mercier devised ingenious instruments to be introduced by way of the urethra, and to divide the bar or valvule, as he called it. One of these instruments is designed to clamp tightly and to divide the compressed bar when the operator slides to and fro a long metallic stem with a cutting blade concealed in the jaws of the instrument. This last improvement in the operation is intended as a bloodless method. Mercier has sometimes found it necessary to repeat the incision several times in the course of a year or two years. The after-treatment consists in daily vesical irrigation and in dilatation and depression of the urethro-vesical orifice every third day for two weeks, then every week for two or three weeks, or until cicatrization is perfect. Complete division of the bar has given good results in great numbers of cases.

2. *Excision of urethro-vesical bars or of the central part of the posterior third of the lower isthmus* was first performed by Mercier, with an instrument introduced through the urethra by which a segment of the bar or of the lower isthmus was punched out. The operation is now designated internal prostatectomy. Several modifications of this prostatectome have been made, but they all retain the original principle of action. The writer has combined internal and external prostatectomy with advantage, and recommends performing the internal operation first, then immediately following it by opening the urethra *in perineo* for drainage. Excision should be reserved for certain cases of thick urethro-vesical bars, and of comparatively slight increase of the posterior third of the lower isthmus, with little if any increase of the lobes. Hemorrhage has seldom been excessive in this operation. The after-treatment is the same as in prostatotomy. (See the writer's article on "Some Points in the Surgery of the Hypertrophied Prostate," in the Transactions of the American Surgical Association, vol. iii., 1885.)

3. *Excision of a pedunculated urethro-vesical growth* was performed by Amussat during suprapubic lithotomy, and this operation has since, from time to time, been resorted to by others. Some of the (perineal) lithotomists of the past two centuries, among whom may be named Covillard and Desault, have occasionally, by accident, seized with the forceps and torn away urethro-vesical pedunculated growths mistaken for calculi, or extracted them together with calculi. The same accidents have repeatedly occurred in the hands of modern lithotomists, who have, in other cases, incised and enucleated the growth after extracting the stone. The results were generally good, and the patients were able to empty the bladder spontaneously (Fergusson, Cadge, Williams, Bickersteth, and others).

4. *Avulsion, excision, and enucleation of the intravesical protrusion of the enlarged lower isthmus, and occasionally of portions of the lobes*, have been effected through suprapubic cystotomy, sometimes supplemented by perineal incision of the urethra. On November 11, 1887, Mr. A. F. McGill read, before the Clinical Society of London, a paper bearing the title of "Suprapubic Prostatectomy," in which he gave a full account of three successful cases. The operation

consisted partly in avulsion and partly in excision of the intravesical growth. The subsequent drainage was entirely suprapubic, as the perinaeum was untouched. Some of the advocates of the suprapubic method have since added the urethral incision *in perineo*, the better to control hemorrhage and also for drainage. While the details of the operation are often varied, the fundamental idea of removing parts of the prostate from above is uniformly carried out by the several operators, who in certain cases substitute enucleation for avulsion and excision. Drs. Atkinson, Belfield, Briddon, Browne, Bryson, Cabot, Dittel, Fuller, Keyes, McKinnon, Moullin, Raffa, Robson, Rohmer, Watson, Wyeth, and others have reported cases of suprapubic prostatectomy with divers modifications and very satisfactory results that have led to the undertaking of the seemingly bolder, though in reality safer, bimanual enucleation of the whole prostate, as performed by Dr. James H. Nicoll, of Glasgow, and Dr. Samuel Alexander, of New York. Exactly how far back may date the idea of removing the entire prostate, the writer does not know. The only records he has found thus far relating to this operation are the following: It appears that total extirpation of the prostate was proposed by Kuechler (*Deutsche Klinik*, No. 50, 1866), and later was performed by Billroth, and still later by Demarquay, who, in 1873, reported, in the *Gazette Médicale de Paris*, two cases in which the prostate and part of the rectum were removed. In the *Arch. für klin. Chir.*, Berlin, vol. xxviii., 1882-83, p. 578, is a paper entitled "Tumor Prostatae; Totale Extirpation der Prostata," by H. Leisrunk. The patient, sixty-four years of age, was suffering from the effects of a large prostate. The diagnosis was malignant disease, and it was decided to extirpate the prostate in totality. The operation was performed on December 24, 1881, and the patient died of exhaustion on the thirteenth day thereafter. Extirpation of the prostate or of any part thereof for malignant disease is surely unjustifiable, and the only proper operative procedure in such circumstances is a palliative epieystotomy solely for drainage.

5. *Enucleation of the whole prostate* through the perinaeum is apparently the latest legitimate endeavor of modern surgery to eradicate the evil of obstructed urination. It seems to be the outcome of a more precise knowledge of the organ in health and disease, and of the analysis and comparison of the several operative methods already named. Experiments on the dead subject have shown that the normal prostate is with great difficulty if at all enucleable, that the diseased *hard* prostate is not at all enucleable, and that the diseased *soft* prostate is enucleated with comparative facility. Moreover, the dissection of enlarged prostates of elderly men has demonstrated that while they are often dense and hard peripherally—owing to secondary phlegmasia action—they are soft and spongy interiorly—from great ectasia of the acini—and enucleable with the finger. Therefore, enucleation is applicable only to the *soft* prostate, which happens to be the most frequent of the morbid states of this organ in elderly men. The cases of perineal enucleation of the prostate so far reported are too few for generalization, but the indications for its performance are clear. This operation, founded on a sound anatomico-surgical basis, is a valuable addition to the resources of the surgeon, and is worthy of extended trial, particularly in the early period of senile enlargement of the organ, before any serious implication of the bladder. It is hoped that it will not be performed indiscriminately, for, in the case of involvement of the upper urinary organs, the mortality will surely be discouraging.

The chief advantages claimed for this, over other methods of operating, are:

I. The combination of suprapubic and intrapubic section for exploration, as well as for bimanual enucleation.

II. The rapidity with which the operation is performed, the patient being under anaesthesia not more than half an hour.

III. The slight and controllable hæmorrhage during and after enucleation.

IV. The little injury done to the urethra and bladder.

V. The suprapubic irrigation and thorough perineal drainage.

Dr. Nicoll's method of operating is substantially as follows: The bladder is opened above the pubes, and its edges are stitched to the cutaneous wound. A median perineal incision is made to and through the prostatic capsule, without opening the urethra or neck of the bladder. The prostate is then pressed down and steadied from above, so as to be within reach of the right forefinger, with which it is shelled out through the perinæum, all drainage being effected through the suprapubic opening. Dr. Nicoll has published four cases successfully treated in this manner (*Lancet*, April 14, 1894).

Dr. Alexander's mode of operating is as follows: After due preparation, disinfection, and anaesthesia, the patient being supine on the operating table, the bladder is opened longitudinally above the pubes, to a sufficient extent to admit two fingers for exploration and the determination of the size of intravesical prostatic growths. This done, "the suprapubic opening is covered with gauze, the patient placed in the lithotomy posture, and a staff is passed through the urethra and held by an assistant. The membranous urethra is then opened by a median [longitudinal] perineal section, the floor of the urethra being thoroughly cut from just behind the bulb back to the apex of the prostate. The staff is then withdrawn and the gauze removed from the suprapubic wound. Two fingers of the left hand are then passed through the suprapubic wound, and by these the prostate is pressed downward into the perinæum. With the forefinger of the right hand, the surgeon begins the enucleation, which is performed entirely through the perineal opening. The outer sheath of the prostate is broken into by the finger just beneath the mucous membrane of the prostatic urethra, and the entire prostate is shelled out from within its sheath by digital dissection. The mucous membrane of the bladder and prostatic urethra, with the underlying muscular tunic, is stripped up, but is not opened. The right and left lobes are first removed, after which, if there be a middle projecting tumor, this can be pressed downward into the perineal wound and enucleated in the same manner. During the enucleation the prostate is to be drawn down into the perineum by forceps. After the removal of all the prostatic growths, the wound is flushed with 1 to 5,000 bichloride solution, a perineal tube is inserted into the bladder, and a rubber drainage tube of moderate size is placed in the bladder above the pubes. The after-treatment consists in daily washings of the bladder, fluid being injected into the suprapubic tube. All urine flows out of the perineal tube. The upper tube is removed on the sixth day, and the lower tube three days later, after which the bladder is washed by catheter through the perinæum for a few days. A full-sized sound is passed at the end of the second week, and then every five days until the perineal wound closes. The wounds have usually healed in the course of five weeks" (*New York Medical Journal*, February 8, 1896).

Of eight enucleations performed by Dr. Alexander, two patients died from suppression of urine due to pyelonephritis, and six recovered and were able to urinate spontaneously. One of these six patients, examined by the writer six months after the operation, had

only three drachms of clear residual urine in the bladder. In this case but one lobe and the lower isthmus had been removed. In all of the cases hæmorrhage during the operation was inconsiderable, and the perineal drainage was complete. In one case there was incontinence of urine for several weeks after union of the wounds, but this finally ceased, and at last accounts the patient was able to retain his urine and to empty his bladder at normal intervals without artificial means.

When, in 1878, the writer introduced to the American medical profession Dr. Mercier's operations for the relief of prostatic obstruction, very few surgeons were willing to perform them or afterward to test the modifications proposed and successfully practised. At that time and long thereafter, these operations were condemned by leading continental and English surgeons, except by the late Mr. W. F. Teevan. Now, eighteen years after the date of the writer's first operation, prostatotomy and prostatectomy are performed with such excessive frequency, not to say recklessness, that they are in danger of falling into utter discredit, if not of being altogether abandoned. It is, therefore, hoped that persistent efforts will be made to preserve them from these besetting dangers by those who know so well the real value and special indication of each of these procedures, and employ it with due discernment.

Time and space forbid even the enumeration of the medicinal and chirurgical contrivances that, during the past three decades, have been proposed, tried, and found wanting in efficacy, or positively mischievous, for the "cure" of prostatic enlargement. Each failure has been quickly succeeded by a "new cure," which, however, has proved as pernicious or as preposterous as its predecessor, but, fortunately, quite as ephemeral. The fact that enlargement of the prostate is not a single morbid or morhic entity, is more than suggestive of there being no easy or exclusive way to the proper management of this ailment. Therefore, no treatment can be rational or successful which is not based upon accurate diagnosis, and which is not adapted to the particular condition of the diseased organ and to its effects upon the organism. In stating his appraisal of the several modern therapeutic procedures pertaining to prostatic enlargement, the writer has not deemed it necessary to specify those that he regards as useless or harmful.

Infantile Diarrhœa.—Stomach washing should be employed in cases in which vomiting is obstinate, and irrigation of the lower bowel will often be found very useful in acute cases. In the acutest form of diarrhœa and vomiting, known as "cholera infantum" and characterized by great general irritability, by innumerable and copious watery motions soon becoming neutral or alkaline, and by rapidly ensuing collapse and wasting, with sunken fontanelle, stupor, coma, or convulsions, we must at first give nothing but frequent small doses of brandy and plenty of cold water or barley water to assuage thirst, and should endeavor at once to arrest the vomiting and diarrhœa by repeated subcutaneous injections of morphine, beginning, in the case of children under a year old, with not more than one-one-hundredth grain. If vomiting still continue, brandy or ether must be injected subcutaneously. Hot mustard baths are to be ordered in the stages of collapse. When in the early irritable stages the temperature runs high, a warm bath gradually cooled down to about 85° F. should be given and repeated with subsequent accesses of fever.—DR. H. BRYAN DONKIN, *The Diseases of Childhood*, p. 54.

NOTES ON THE TREATMENT OF FÆCAL FISTULÆ.¹

BY FREDERICK HOLME WIGGIN, M.D.,

VISITING GYNECOLOGIST TO THE NEW YORK CITY HOSPITAL AND VISITING SURGEON TO ST. ELIZABETH'S HOSPITAL.

THE three cases to which it is the chief purpose of this paper to call attention seem to be of sufficient general interest to warrant their presentation for consideration and discussion. All of them were successfully treated by surgical procedures—one by enterectomy and anastomosis, by the method of Maunsell; and the others by enterorrhaphy. There are few conditions to which patients are liable that cause them greater mental and, at times, bodily distress, than do the occurrence and persistence of a fæcal fistula. While it produces directly serious disturbance to bodily nutrition only when it is situated at some distance above the ileo-cæcal valve, it indirectly causes bodily deterioration, as wherever located it causes much cutaneous irritation and entire loss of control by the patient of the intestinal contents, rendering those so afflicted most offensive, in spite of all that can be done for them by means of pads and trusses, and limiting their usefulness during the duration of the defect.

The most frequent cause of the occurrence of fæcal fistula may be stated to be the delay in resorting to operative measures for their relief to which patients suffering from typhlenteritis and strangulated hernia, whether it be of the internal or external variety, are too often subjected while their ailment is carefully diagnosed. Among the other more common causes are the employment of drainage following abdominal operations, especially by means of tubes; imperfect technique in operations upon or about the intestines; as a result of an ulcerative process within the gut; or from gunshot or stab wounds. A recent writer on the subject under consideration stated that, in his opinion, "the best treatment for this condition consists in its prevention, when possible, by a resort to early operation in those cases in which the occurrence of a fæcal fistula is a possible result." In this view the writer of this paper heartily concurs.

But in a case in which this dread condition has followed in the train of some intestinal disorder, whatever the cause, what course should the physician advise his patient to follow, to the end that he may be relieved from his distressing disability with as little risk to life and the least possible inconvenience? As is well known, many of these fistulæ gradually contract and close spontaneously; and, therefore, it is well, if the fistula is of small size, with only a slight fæcal discharge, and can be located near or below the ileo-cæcal valve, to postpone operative measures for a reasonable time, in the hope that it will gradually contract and eventually close spontaneously. In those more serious cases in which the opening, on account of its size, location, and the fact that it is accompanied by an intestinal flexure or a growth causing obstruction to the passage of the bowel contents, fails to diminish in size after a few weeks, operative measures should unhesitatingly be advised.

On May 16, 1896, the writer received an invitation, extended to him by reason of a vote of the medical board of the Hartford (Connecticut) Hospital, as well as a personal request from the visiting surgeon, Dr. H. G. Howe, then doing duty, to visit that institution for the purpose of operating upon two patients, each of whom was suffering from a fæcal fistula, with a view to demonstrating the method of intestinal anastomosis by invagination and suture devised by Maunsell, which the writer has advocated for several years past as preferable to and more surgical than that orig-

inated by Murphy, of Chicago, in the event of simple suture of the bowel opening not sufficing to remedy the defect. Accordingly, on May 17th, the writer visited the hospital, and, with the kind and valuable assistance of Dr. Howe and Dr. Ingalls, the operations were performed. For the histories of the two cases the writer is indebted to the house surgeon, Dr. Naylor.

CASE I.—L. M.—, male, aged twenty-two years, a farmer, was admitted to the Hartford Hospital, on August 3, 1894. He said that about six weeks previous to admission he had had an attack of what was diagnosed as bilious colic, and for nine days nothing had escaped from the bowels. Under medical treatment the bowels finally moved, greatly to the patient's relief. Four weeks after the seizure, an abscess opened spontaneously in the patient's groin, near the lower end of Poupert's ligament. Four days later, another opening occurred in the right iliac region. Both openings remained patent, and discharged pus and fæcal matter freely.

On August 7th the patient was operated upon. The whole layer of the abdomen above the muscle was covered with pus and fæcal matter. On opening the abdomen an abscess cavity was discovered, in which the appendix was found in a gangrenous condition. This was removed, and the abscess cavity drained. Fæces, however, continued to be discharged through the wound.

On August 25th, another attempt was made to close the opening which was found in the gut. The peritoneal surfaces were approximated by means of Lembert's sutures, over which the omentum was grafted.

On September 1st it was noted that the stitches had not held, and that in consequence the fistula had reopened and was discharging fæcal matter.

On November 25th the patient left the hospital, with the bowel opening still patent.

He was readmitted on May 3, 1896, with the local condition unchanged. He was given light diet, and on May 17th, after the usual preparation, he was anesthetized, and examination revealed the fact that a fæcal fistula of large size existed, the external opening being located at a point in the old cicatrix opposite the anterior superior spine of the ileum, about two and one-half inches to its inner side. The peritoneal coat of the intestine surrounding the opening in the gut had united to the parietal peritoneum, and the mucous coat of the intestine had united to the cutaneous tissue and was everted, forming an artificial anus. The parts, including the interior of the bowel adjoining the fistulous opening, were washed with hydrozone. The foam resulting from the decomposition of the liquid and the liberation of the contained oxygen was allowed to remain for some minutes before it was removed; after which an incision, about four inches in length, was made, having the opening in the gut for its centre. The old scar tissue was excised as far as possible, and the remaining fistulous tract vigorously scraped with a sharp spoon. When the peritoneum was reached, the gut was freed from it by dissection. The edges of the opening in the gut were then caught and held by clamps, while the adhesions which bound down the flexed knuckle were dissected away and broken up. The loop of gut containing the opening was then brought outside of the abdominal cavity, which was shut off by means of gauze and sponges. It was found to be located in the lower portion of the ileum. It was laterally situated, involving a large portion of the intestinal calibre, and was so irregular in shape that it was thought wise to excise the damaged and thickened portion of the bowel, which was about four inches in length.

This was accomplished after the application of McLaren's clamps to the gut at some distance from the points of incision, and the anastomosis of the divided

¹ Read at the thirteenth annual meeting of the New York State Medical Association, October 13, 1896.

ends was effected by means of the technique already alluded to, devised by the late Professor Maunsell, and described by the writer in an article entitled "The Technics of Maunsell's Method of Intestinal Anastomosis," which appeared in the *New York Medical Journal* of December 14, 1895. Before the anastomosed bowel was returned into the peritoneal cavity, the points of suture were well washed with a fifty-per-cent. solution of hydrozone in sterilized water. Some of the full-strength hydrozone was again poured over the tissues in the former site of the fistulous tract, for the double purpose of arresting the oozing, which was free, from the remaining cicatricial tissue, as well as to render the parts aseptic. After the return of the bowel into the peritoneal cavity and the placing of a single row of silkworm-gut sutures, which included all the layers in the abdominal wall, the cavity was flushed with saline solution, some of which was allowed to remain. The sutures were then tied, thus closing the wound without drainage. The cutaneous surface about the wound was washed with hydrozone and then freely dusted over with acetanilid powder, and the usual dressings were applied.

The convalescence was uneventful. The patient's bowels moved four times on the fourth day, and daily thereafter. On the same day his pulse rate and bodily temperature became normal, and have remained so. The wound in the abdominal wall united primarily, except for about one inch of the skin, in the middle. On the twelfth day following the operation the patient was allowed to leave his bed, and was given ordinary diet. At this time it was noted that the patient slept well, that his pulse was strong, that he was free from pain, and that his general condition was good.

CASE II.—W. R.—, male, aged five years, was admitted into the Hartford Hospital during May, 1895, suffering from typhlenteritis. The abdominal cavity was opened and a large abscess was found, the cavity of which was washed out and drained without any attempt being made to find the appendix. Soon after the performance of the operation, faecal matter appeared in the discharge. During the year several unsuccessful efforts were made at intervals to close the fistula by suture, prior to May 17, 1896, when the following procedure was undertaken for the patient's relief:

The fistulous opening was located about one inch and a half from the anterior superior iliac spine, on a line drawn therefrom to the umbilicus. After the usual preparations the surrounding skin was washed with hydrozone, and this was also injected into the sinus. An incision was then made on either side of the old cicatrix, and it was removed. The peritoneum was separated from the opening in the gut, the edges of which were held together by clamps. The intestinal opening, which was one inch and a half in diameter, proved to be situated in the cæcum near the ileo-cæcal valve. The head of the colon and adjoining gut were freed by dissection till that portion containing the opening could be brought outside of the abdomen. The general cavity of the peritoneum having been shut off by gauze, the gut was again washed with a fifty-per-cent. solution of hydrozone. The edges of the fistulous opening were approximated by a purse-string suture of silk. The peritoneal coat of the gut was then approximated by means of Lembert's sutures, and, finally, after using more of the fifty-per-cent. solution of hydrozone, a portion of omentum was placed over the gut at this point and caught down on either side by sutures, and the bowel was returned into the peritoneal cavity. The old opening in the abdominal wall was scraped and washed with hydrozone, and the edges of the abdominal wound were united by silkworm-gut sutures, which included all the layers. As there had been such long-continued discharge of faecal matter and pus, it was thought best to leave one of the

stitches untied, and for drainage a narrow strip of gauze was passed down to the bottom of the cavity.

The convalescence was uneventful, except for the formation of a small abscess at the point where the gauze drain was inserted. This was cleaned out with hydrozone and healed kindly, and on May 30th, the thirteenth day after operation, it was noted that the patient was free from pain, that he had a good pulse and appetite, and that his general condition was all that could be desired.

CASE III.—On May 17, 1896, the writer was invited by Dr. Nathan Mayer and Dr. P. H. Ingalls, of Hartford, to see in consultation C. H.—, male, aged fifty-two years, whose history was as follows:

On March 17, 1896, he had been seized with an attack of what proved to be typhlenteritis, and on March 25th a large abscess was opened and its contents were evacuated. After the cavity had been irrigated, it was packed with gauze. No attempt was made to find the appendix. About five weeks after the operation faecal matter began to escape from the remaining wound and a faecal fistula developed, through which more or less of the contents of the intestinal canal passed. On examination, an artificial anus was found, situated about one inch and a half from the anterior superior iliac spine, on a line from this point to the umbilicus, and about one inch in diameter. The mucous lining of the bowel was adherent to the cutaneous tissue, and was everted and protruded. As it was possible by the use of pads largely to control the passage of faecal matter through the opening, and the patient's condition was not considered favorable, immediate operation was not advised; but the opinion was expressed that on account of the size of the opening and the attachment of the mucous membrane to the cutaneous tissue and its eversion, it was improbable that the opening would close spontaneously. A few weeks later, the patient's general condition having improved, on account of the annoyance caused him by the lack of control over the bowel contents and the irritation of the skin by the passage over it of faecal matter, it was deemed best to attempt the closure of the opening.

On June 17th, assisted by Dr. Ingalls, Dr. Mayer, Dr. Shepard, and Dr. Stearn, of Hartford, and Dr. Parker Syms, of this city, at the patient's home, the following operation was performed: After the preparation of the patient in the usual manner and the administration of the anæsthetic, the skin surrounding the opening was washed with hydrozone, some being also injected into the interior of the bowel. Then a small sponge attached to a piece of silk was passed into the bowel, plugging the opening. An incision was made on either side of the old cicatrix, having the bowel opening for its centre. Thus the old scar tissue was excised. The parietal peritoneum was next freed from its attachment to the gut, and existing adhesions were broken up and the gut was withdrawn from the peritoneal cavity, which was shut off by gauze. The opening proved to be situated in the side of the cæcum, above and about one inch and a half from the point of attachment of the appendix, of which two and one-half inches remained. This was removed after the opening in the gut had been closed, first by a purse-string suture, and then by several rows of Lembert's sutures. After this, the bowel surface was washed with a fifty-per-cent. solution of hydrozone, and as an additional precaution the omentum was drawn over and sutured to the bowel. The abdominal walls were approximated by silkworm-gut sutures, which passed through all the abdominal layers; but, as there had been some loss of tissue during the continued suppuration, the fascia was approximated by interrupted sutures of catgut. Drainage was not employed.

Convalescence was uneventful, aside from the formation of a stitch abscess, and the patient has remained in good health up to the present time.

The cause of the fistulous openings in Cases I. and II. was undoubtedly the failure in the first, and delay in the second, to resort to surgical measures for their relief. In both of these cases the trouble apparently originated in an attack of typhlenteritis, to which was added, in the first case, probable strangulation of the lower portion of the ileum by a band, and which perforated after it had become shut off from the general cavity by adhesive peritonitis. In the second case, the abscess apparently ruptured into the cæcum before the external opening was made. In the third case, the cause of the opening was either the pressure on the gut of the material used to drain the abscess cavity, or it was the result of an inflammatory process within the cæcum, as the perforation did not manifest itself until five weeks after the opening of the abscess. Another point of interest in Cases I. and II. is the fact that several previous unsuccessful efforts to close the openings in the bowel had been made. The reason why these efforts had proved ineffectual, in the writer's opinion, is that the operative measures undertaken for their relief were not sufficiently radical in character, the efforts being directed to closing the bowel opening only, and no attempt being made to restore the faecal passage by breaking up the existing adhesions which had caused more or less intestinal angulation, and consequently too much pressure was brought to bear on the sutures, and they quickly cut out, allowing the fistulæ to reopen.

The method of closing faecal fistulæ without opening the peritoneal cavity and relieving the obstruction from adhesions seems to be approved by J. Gregg Smith, in a paper which appeared in the *Bristol Medico-Chirurgical Review*, March, 1895. Undoubtedly, it is well when possible to close the opening in the bowel before breaking up the peritoneal adhesions, but as soon as this has been accomplished an effort should, in all cases in which operation is deemed a necessity, be made to remove the existing obstruction to the faecal current by destroying the adhesions which hold the bowel in a malposition. In fact, few cases which would not heal spontaneously will be benefited by simple closure of the bowel opening, if the obstruction is allowed to continue.

Ever since September, 1893, when the writer proved the value of hydrogen dioxide as an effective antiseptic which in proper solution did not unduly irritate the peritoneum, when followed up by a six-tenth-percent. saline solution, he has had little reason to fear the danger of causing septic peritonitis from the accidental escape of pus or faecal matter while operating. He employs all possible measures to prevent the occurrence of this complication, but when it occurs it is invariably successfully met by the use of hydrogen dioxide, as heretofore described. In those cases in which the gut around and about the opening is much thickened and friable, by reason of the long-standing inflammatory process, it is the writer's belief that it is best to resect the diseased portion of the bowel, and join the ends of the bowel by the suture method of Maunsell. With a proper understanding on the surgeon's part of the technique and the objects to be attained by operation—*i.e.*, the restoration of the integrity of the intestinal canal, as well as the closure of the bowel opening—the operation undertaken for the relief of patients suffering from faecal fistula should be devoid of unusual danger, and failure to succeed in rescuing these patients from their unfortunate and distressing plight should prove the exception rather than, as at present, the rule.

THE ADMINISTRATION OF THYROID IN EPILEPSY, WITH REPORT OF FOUR TRIAL CASES.

By L. PIERCE CLARK, M.D.,

ASSISTANT PHYSICIAN, CRAIG COLONY, SONYEA, N. Y.

SINCE the administration of thyroid in various nerve lesions, aside from myxœdema, has been attended with favorable results, a trial of its efficacy in epilepsy was made. To be sure, its administration was not rational, but it was given, as it has been in many other nerve lesions, purely from empiricism. The cases selected were those in which many congenital defects were noticeable, and in which epilepsy had been a prominent feature of the patient's life since early infancy. An effort was also made to select those cases in which defective development mentally as well as physically was manifest.

CASE I.—C. D.—, male, aged twenty-one, no occupation. His epilepsy began at the age of six. No prenatal causes were found, and all bad heredity was denied. The cause of his epilepsy was not given. His attacks were of the grand-mal type, preceded by no aura and followed by considerable stupor and mental depression. The attacks occurred generally at night. On his admission the physical examination showed marked cardiac hypertrophy. The pulse registered 80, of fair quality and quantity. There were retraction and consolidation at the apex of the right lung. The right shoulder had suffered displacement downward, and joint atrophy had taken place as a result. Yet it is a question as to whether this condition of joint atrophy was caused by trauma or whether it was a result of congenital defect, such as is described by various authors as often attending epilepsy in idiocy and imbecility. All active muscular movements of the patient were very slow, awkward, and uncertain. Intellection was very difficult and imperfect. At the time of the patient's admission to the colony it was necessary to assist him to dress and undress. For some years previous to his admission to the colony, the patient had been addicted to inhaling the smoke of large numbers of cigarettes daily, and consequently suffered from a condition of atrophic rhinitis. This case was placed upon thyroids, the same as the following cases—five grains of the desiccated thyroid, t.i.d. After the first three days of the administration of the thyroid, the patient showed the toxic effects of the drug, which were manifested by a profuse perspiration, increase in rapidity and irregularity of pulse beat, and a diffuse congestion of the skin of the face and hands, giving a typical "boiled-lobster" appearance. The patient was a little more active in his physical movements, and his mental processes were a little brighter, but not more so than might arise from the stimulating effect of the thyroid. Fifteen grains per day were administered for twenty-one days, at which time treatment was discontinued. Some permanent improvement in the physical and mental condition has been noticed in this case. Whereas before commencing the treatment he was not able to care for himself, he is now able to do so, and, in addition, engages in field labor with the farmers for two or three hours each day. Notwithstanding the treatment did not materially lessen his attacks, yet it was followed by physical and mental changes warranting its use in such a case. Besides, the writer is not prepared to admit that a diminution in the frequency of attacks is the only favorable indication of improvement in an epileptic, especially in such a one as is described here.

CASE II.—O. H.—, male, aged sixteen, no occupation. His epilepsy began at the age of five months. A cousin had been afflicted with epilepsy and a sister suffered from exophthalmic goitre. Phthisis had been quite prevalent in the family. The cause of the pa-

tient's attacks was not stated, but they were evidently due to congenital defect plus a bad heredity. His seizures were of the grand-mal type, preceded by no aura and followed by a prolonged sleep stage. The attacks occurred both by night and by day. Considerable hypertrophy of the heart was found, but circulation was normal. On his admission the pulse registered 84, and was normal in force and rhythm. The speech was monotonous and expressionless. The patient presented left thyroid enlargement, but no noticeable exophthalmos. He had a narrow, high-arched palate; thick, rough lips; and massive, underhanging jaw. The patient's active muscular movements were sluggish, awkward, and uncertain; and his mental processes were slow, indefinite, and purposeless. He required some assistance to dress and undress. This patient did not manifest so many toxic effects of the thyroid treatment as did the patient in Case I. After the first day of the administration of the thyroid, the patient began to dress himself and engaged in daily out-door work, which he has continued to perform up to the time this report is made. Although the physical health of the patient has improved during the thyroid treatment, but little mental change is manifest. His epilepsy remains unchanged.

CASE III.—M. J.—, female, aged seventeen. She was able to perform some light housework. Her epilepsy made its appearance in very early infancy. The cause was probably a congenital defect plus any slight excitant. Heredity unknown; prenatal influences unknown. Her attacks were of the grand-mal type, and occurred monthly, both by day and by night, preceded by no aura and followed by prolonged mental stupor. The patient was a low-grade imbecile, very talkative, industrious, and cheerful. The heart action was irregular in force and rhythm, and the pulse rate was 90 per minute. Patient presented a great number of the stigmata of degeneration—somatic and physical. The administration of thyroid in this case was attended by nearly the same toxic effects as were noticed in Case I. During the latter part of her treatment her seizures became very much less frequent, and she was able to perform mental and physical acts with greater celerity.

CASE IV.—E. McC.—, female, aged seventeen. On admission she was able to perform light household duties. Her attacks began in early infancy; cause, probably a congenital one. Her attacks were reported to be grand mal in character and to occur every two months. They were preceded by no aura and followed by but little mental depression. Patient was a high-grade imbecile. Physical examination showed that the heart was normal and pulse rate was 96. A convulsive tic of the orbicularis palpebrarum of the right side was discovered. The treatment in this case was followed by an increased motor restlessness and mental activity. The latter named condition was in marked contrast to her former apathy and indisposition. She became very mischievous and unmanageable. On July 26, 1896, three weeks after treatment was established, the patient had her first seizure since her admission to the colony (February 14, 1896). The convulsive seizure began with the typical epileptic cry, followed by tonic and later by clonic muscular spasm. The attack lasted for five minutes, and in three hours was followed by another, and in four hours by a third. The last two were, to all appearances, of the same general character as the first. It would seem as though these seizures were caused, in a measure at least, by the administration of the thyroid; or the administration of the thyroid and the occurrence of the seizures just at this time was a remarkable coincidence.

CASE V.—C. W.—. In this case the thyroid was administered principally for the purpose of reducing obesity, and it resulted in the patient losing nineteen pounds in one month. It is true that this subject was

also placed upon restricted diet and made to perform considerable physical labor, which undoubtedly increased the reducing power of the treatment. An important fact which seems to the writer to show quite conclusively that the reducing power of thyroid is mainly due to its toxic properties, is that the four selected subjects quickly regained their lost weight, although under the same diet and performing the same amount and kind of physical labor. In Case V, the patient gained twelve pounds in weight in two weeks after the discontinuance of thyroid, diet and exercise remaining the same as during the administration.

It would appear that the administration of thyroid in these cases was not attended with very good results. While all seemed to be benefited for the time being in some ways, I doubt whether there will be any permanent improvement. Although remarkable reducing power in obesity seems to be due to the toxic effects of thyroid, yet in some cases in which it is given for the sole purpose of reducing weight it is not attended by such marked physical disturbances as in those cases in which but little weight is lost. All of the trial subjects lost from three to ten pounds in weight during the treatment. This the writer attributes mainly to the drug's toxic properties and the excess of tissue changes produced by such upon the organism. On the whole, its small effect upon epileptic seizures in these trial cases would not seem to justify its continued use in epilepsy, and its further administration has not been attempted.

Progress of Medical Science.

Chloride of Calcium, in dose of eighteen grains dissolved in half a glass of water, to which a teaspoonful of tincture of bitter orange peel and two dessert-spoonfuls of chloroform water are added, taken always after meals, is advised by Dr. Wright in the treatment of pruritus and urticaria. The dose in obstinate cases can be increased gradually to twice the quantity mentioned.—*Rev. Internat. de Méd. et de Chir.*, September 25, 1896.

Is Inherited Syphilis Contagious?—Dr. Robert W. Parker, after twenty years' experience at the East London Children's Hospital, has arrived at the following conclusions: 1. The children of syphilitic parents very frequently show manifestations of a disease which is almost universally called "inherited syphilis." 2. In a large proportion of cases this inherited disease is not syphilis at all, in that the disease is non-contagious, and would be better named "inherited from syphilis." 3. This inherited disease is true syphilis only if it conform to the ordinary tests which pertain to contact syphilis and prove to be infectious and contagious. 4. The children of syphilitic parents occasionally inherit syphilis. 5. The mother suckling a child with such a disease may be infected by it. 6. A healthy wetnurse and other persons brought into contact with such a child are even more liable to be infected by it than the mother. 7. Lymph taken from such a child, even although apparently well at the time, will probably, or possibly, invaccinate syphilis. 8. In reply to the question, Can a healthy woman give birth to a syphilitic child? the answer must be No. 9. Many women give birth to children who suffer from what is called "inherited syphilis" without themselves appearing to be infected. The explanation is obvious: this "inherited syphilis" is not syphilis in the true sense, and the mother's so-called escape depends on this fact. 10. There is no recent clinical evidence which fully realizes Colles' teaching, viz., a mother suckling her own syphilitic

infant and escaping an infection to which a healthy wetnurse suckling the same infant and other members of her family, who have merely handled this infant, have succumbed, the latter facts being essential, if only to establish the contagiousness of the infant's disease in any and every given case asserted to be "inherited syphilis."—*Edinburgh Medical Journal*.

The Treatment of Pain in Renal Colic.—In this condition, in which the pain is often atrocious and perhaps associated with persistent anuria, with danger of uræmia, the following treatment is recommended. In the first place a poultice containing a large amount of laudanum is placed upon the lumbar region or upon the anterior abdominal walls. The heat not only acts as an antispasmodic and thereby modifies the spasmodic contractions of the ureters, but also in this way favors the escape of the stone. Full doses of the extract of opium or morphine should be given, and should the stomach be too irritable to retain it the extract of opium or laudanum may be given by rectal injection. The great difficulty in using hypodermic injections of morphine in these cases is that the patient gets into the habit of handling the syringe himself. As a rule it is wise not to use any more morphine than is absolutely necessary to make the pain bearable. In some instances the following suppository is useful:

℞ Extract of belladonna gr. $\frac{1}{2}$.
 Extract of opium gr. $\frac{1}{3}$.
 Cacao butter gr. xlv.

In other instances it has been found that the administration of antipyrin by the mouth or by hypodermic injections is useful, although hypodermic injections of this drug are exceedingly painful for the first few minutes. It is thought by some that the antipyrin also aids in the elimination of uric acid. If hypodermic injections are used, the following formula may be employed:

℞ Antipyrin gr. xl.
 Water ℥ iij.

A hypodermic syringe of this solution to be given at a dose.

In other instances chloral by rectal injection tends not only to produce nervous quiet, but also to permit sleep. The following formula may be used:

℞ Chloral gr. xxx.
 Wine of opium gtt. x.
 Decoction of marshmallow ℥ iv.

This injection should be warm. The advantage in adding the opiate is a double one, in that it relieves pain and tends to cause the retention of the injection until the chloral can be absorbed.

If the pain is very severe, chloroform or ether may be used until the development of an anæsthesia equivalent to that produced ordinarily during parturition, or, in other words, until enough is given to relieve the acme of the paroxysm. Sometimes a general hot bath is of value in relaxing the local spasm and producing general relaxation.—*Therapeutic Gazette*.

Subcutaneous Wiring of the Patella.—Dr. Barker (*British Medical Journal*, April 18, 1896) describes his method of operating for fracture of the patella. The ligature used is silver wire instead of silk. The operation is to be done at once on the entrance of the patient to the hospital, usually within twelve hours of the fracture. The method is not adapted to old cases, but only to recent ones. No splint is used, simply the dressings, and massage and slight passive motion are made immediately following the operation. He operates as follows: The field of operation is made aseptic and the lower fragment

steadied between the operator's left finger and thumb while a narrow-bladed knife is thrust exactly through the middle of the upper attachment of the patellar ligament, with its upward edge cutting on the bone. When the blade has entered the joint it is withdrawn, still cutting on the lower edge of the lower fragment, and enlarging the skin wound upward to the extent of two-thirds of an inch. Through this opening a long stout needle is thrust into the joint behind both fragments and made to pierce the tendon of the quadriceps close to the upper edge of the upper fragment, exactly in the middle line. A knife is then entered alongside of the needle and a cut made down to the bone. A stout silver wire, the size of a No. 1 English catheter, is then threaded in the needle and withdrawn. The needle is unthreaded and passed from the lower to the upper opening between the skin and upper surface of the fragments. It is then threaded with the wire and withdrawn. The two ends of the wire emerging from the lower opening are then wrapped around a couple of rods to secure a firm hold, and crossed, drawn tight, and twisted three times. Before twisting, the blood should be squeezed out of the joint. The whole operation should not take more than five minutes. By this method a firm limb is said to be obtained with good flexion and extension and apparently bony union. In cutting off the wires, ends half an inch long should be left, which are to be passed back into the opening and spread out in the soft parts. The broken ends of the bone should be well rubbed together before operating, so as to clear the separated parts of all clots and fibrous tissue.—*The University Medical Magazine*.

Penetrating Wounds of the Spinal Cord.—Dr. Enderlen has announced the following conclusions, based on experiments on animals: 1. The degeneration of the spinal cord after a wound is not localized to the point of the lesion, but extends to adjacent parts. 2. The extension of the degeneration is not always uniform; that is, there does not appear to be any rule governing the process; however, the more extensive the lesion, the greater the extent of degeneration. 3. In the course of time the number of swollen axis cylinders decreases, but they may be found for a comparatively long time (thirty-fifth day). 4. In consequence of the lesion there is an increase in the neuroglia. 5. The gray substance assumes its normal condition in a short time; above and below the wound there is seen an increase of the ganglion-cells; in the region of the wound these cells degenerate. 6. Independently of the point of lesion there are points of degeneration in the spinal cord, partly on the side of the puncture, and partly in the other half. 7. As regards the arrest of degeneration in the several fibres, it will be found that in many cases the posterior fibres are already free, while in other tracts there are still swollen axis cylinders and wide glia meshes. In a few cases the opposite may exist. As regards the swelling, the author noted its presence two hours after the wound. He could find no instance of regeneration after injury. The author also injected fresh blood above and below the dura, and also introduced small particles of kidney beneath the dura, and found degeneration as a result. This he did not think due to pressure, but to disturbance of the circulation, either active or passive.—*Deutsche Zeitschrift für Chirurgie*.

The Pathogeny of Diabetes.—Dr. Kaufmann says in the *Medical Week* that the functional activity of the organism determines not only the consumption of sugar, but its formation by the liver. The consumption of sugar is an inherent property of the vitality of the cells, like the consumption of oxygen, and any variations in the amount of sugar in the blood depend not upon this, but upon the supply, which is, however,

governed by the demand. In hibernating animals the sugar in the blood diminishes during the period of stupor, but rapidly increases after the awakening, which is quite contrary to what we should expect if the amount of sugar in the blood were dependent upon its consumption in the tissues. In the horse glycæmia increases under the influence of muscular exertion. The liver forms sugar and stores it, but if its storage limits are exceeded an excess may pass into the blood, and this occurs during the digestion of saccharine substances. The storage capacity of the liver is diminished by pathological changes which interfere with the vitality of the hepatic cells, *e.g.*, in cirrhosis. The internal pancreatic secretion moderates the glucose-formative power of the liver and at the same time expands its storage limits. Toxic and asphyxial glycosuria are due to over-stimulation of the glucose-formative function of the liver. In true pancreatic diabetes there is no valid reason for supposing that the mechanism is otherwise. The most recent researches (Voit, Leo) have reversed the older conclusion that diabetics absorbed less oxygen and exhaled less CO₂ than healthy persons. The observation of Lépine and his collaborators that diabetic blood has a diminished power of destroying sugar is at least exceptional, as the author found the consumption of sugar in healthy and diabetic animals to be the same, not in one experiment but in a series of comparative experiments. He does not deny that in some cases of diabetes at certain stages there may be a decrease in the consumption of sugar, but this is not constant and appears only under special circumstances. Diabetes mellitus, however caused, is invariably produced by an excessive production of glucose and not by arrested or defective destruction of sugar in the capillaries.

Camphorated Naphthol by injection in the treatment of lupus is particularly indicated in nodules of medium size without ulceration. Two parts of camphor to one of naphthol are employed. The skin is rendered aseptic with a sublimate wash (four per cent.). Half a drop of the injection fluid is deposited in the centre of three or four nodules at each sitting. An interval of from four to eight days is advised between the sittings. In mild cases a cure is effected in from two to four months, during which time the patient goes about his usual occupation. Cod-liver oil with creosote is administered at the same time.—*La Méd. Moderne*, September 23, 1896.

Potassium Nitrate in the Treatment of Burns.—Dr. Poggi, in a recent thesis on this subject, gives an account of a treatment that has given excellent results in all kinds of burns of whatever degree. It consists in the employment of potassium nitrate, which is administered in baths or in applications of compresses that have been wetted with a saturated solution of this salt, or in lotions that contain the nitrate. According to M. Poggi the nitrate acts especially as a refrigerant. As it becomes dissolved in the water it produces a notable lowering of the temperature of the liquid of from 5° to 9° F. If a burned hand or foot is plunged into a basin of water to which a few spoonfuls of the nitrate have been added, the pain ceases rapidly; if the water becomes slightly heated, the pain returns, but it is allayed as soon as a fresh quantity of the salt is added. This bath, which is prolonged from two to three hours, may bring about the definitive disappearance of the pain and even prevent the production of blisters. The application of the compresses also exercises the same influence. By this means the pain is allayed and cicatrization takes place without delay. Another remedy in the treatment of burns is calcined magnesia, which, says the writer, has been employed by M. Vergely, who obtained favorable results with it in burns of the first

and second degree. The affected parts are covered with a thick layer of a paste, which is prepared by mixing the calcined magnesia with a certain quantity of water. This paste is allowed to dry on the skin, and when it becomes detached and falls off it is replaced by a fresh application. Very soon after the paste is applied the pain ceases, and under the protective covering formed by the magnesia the wounds recover without leaving the cutaneous pigmentation which is so often observed to follow burns that have been allowed to remain exposed to the air.—*New York Medical Journal*.

Pyosepticæmic Puerperal Exanthem Simulating Hemorrhagic Variola.—Dr. Heitzmann has recently published, in the *Wiener medicin. Wochenschrift*, a case in which the eruption appeared a few days after confinement, first as a diffuse redness covering the whole body like a scarlatina, accompanied by abundant sweating and œdema of the lower extremities. Two days later there were rheumatoid pains in the shoulders and knees. There was high temperature and rapid pulse. On the eighth day appeared small, disseminated pustules, covering the trunk, some of which resembled those of small-pox. Between the pustules were hemorrhagic points and petechiæ, as well as sudamina and ecchymoses. Small dermic abscesses subsequently appeared, some of which had to be opened. The general appearance, especially of the trunk, was that of variola.

The Ultimate Results in Eighty-Six Cases of Fibromata of the Uterus Treated by the Apostoli Method.—Dr. G. Betton Massey reported to the American Electro-Therapeutic Association at its annual meeting in Boston, September 28, 1896, eighty-six consecutive cases of uterine fibroids treated by the Apostoli method. After considerable correspondence and inquiry, the ultimate results (or those existing from two to eight years after cessation of treatment) were ascertained in seventy-five cases, and were found to be as follows:

Anatomic and symptomatic cure:

(a) Destroyed piecemeal by electrolysis through cervix....	1
(b) Extruded through cervix in whole or part.....	4
(c) Disappeared under absorption.....	12

Symptomatic cure:

(a) With great reduction in size.....	16
(b) With slight reduction in size.....	21
(c) Without change in size.....	10

Total cases resulting in practical success..... 64

Symptomatic improvement only.....	4
Failure to effect any change.....	6
Made worse.....	1

Total cases resulting in failure to relieve..... 11

The sixty-four successful cases give a percentage of 85.33 per cent. of successes, and the eleven cases of slight improvement and no improvement and the one made worse give a percentage of 14.66 per cent. of failures. The one case that was made worse was a cystic intra-uterine growth, that was improperly treated by electricity before it was generally known that such cases should not be treated by the classical Apostoli method. Future statistics will naturally be clear of such errors of practice; hence it may be said that the practical ultimate results in a hundred cases properly treated by electricity will be at least eighty-five cases successfully and satisfactorily handled, and fifteen cases in which electricity will do no good nor yet any harm, leaving the tumors unchanged for other methods promising greater relief. Of the twelve tumors reported as having disappeared by absorption, this fact was verified by the reader of the paper in but seven instances, the remainder being reported by the patients themselves.

The Bubonic Plague.—The report of Dr. Aoyoma, who was sent by the Japanese government to study the clinical and pathological features of the disease in Hong-Kong, has recently appeared, and has been made the subject of an article by Dr. Simon Flexner, in the *Johns Hopkins Hospital Bulletin*, October, 1896. Dr. Aoyoma contracted the plague himself, but recovered, while the mortality among the Chinese was very great, as shown by the following statement:

	Number Affected.	Number Died
Europeans	11	2
Japanese	10	6
Manilenses	31	1
Urasinese	5	3
Indians	13	10
Portuguese	15	12
Malayanes	3	3
West Indians	1	1
Chinese	2,619	2,447

The symptoms of the disease during the last plague were not, as was stated by most authors, protean, but they were quite simple. The disease began for the most part without prodromata, with a chill, or even in the first instances with pain and swelling of the glands and with succeeding chill and fever. Prodromata when present were usually short and varied in duration from a few hours to two or three days, or perhaps somewhat longer. The symptoms in the prodromal stage are prostration, headache, nausea, vomiting, loss of appetite, vertigo, and only rarely pains in the lumbar region or in the back. In the cases of the affection of the more intelligent population, even before the outbreak of the fever, slight swelling and pain were noted in the glands; whereas in the more obtuse Chinese these slighter phenomena were not noticed. The greater number of cases occur in young males. The temperature rises quickly to 40° C., or higher. Delirium sets in early. The pulse is usually dicrotic, and from 90 to 120 per minute. The urine is dark and contains albumin. The glandular enlargement is characteristic, beginning in one group and involving others in succession. After the swelling the periglandular tissues become involved, and then the skin. There may be post-mortem rise of temperature to 43° C. or higher, and muscular contractions may occur after death, as in cholera. Death occurs from the second to the eighth day. In three cases proven by autopsy to be bubonic, no glandular involvement was to be made out during life. As regards the cause of the plague, it may be said that Kitasato discovered bacilli in the blood and in the lymphatic glands which differed somewhat in their morphological characters but which agreed in their cultural properties. According to Kitasato, the bacillus which appears in the blood resembles the organism of chicken cholera, possesses a capsule, the middle portion staining very faintly; while the bacillus obtained from the lymphatic glands is somewhat longer, has rounded ends, and stains more uniformly than the other. The bacillus obtained by Versin is stated to have rounded ends, to be easily stained with the aniline dyes, and to be decolorized with Gram's method. The ends again stain more uniformly than the middle part. It is suggested by Aoyoma that the forms described by Kitasato as occurring in the blood and retaining the Gram stain may have been pairs of cocci and not bacilli at all. He regards the association of the bacilli and cocci as of great importance, inasmuch as in the greater number of instances the affected glands suppurate. Hence it is considered that the suppuration is caused not by the plague bacilli which are always present, but through the action of pus-producing bacteria which entered along with the former or later than these; and Aoyoma has further found that in suppurating glands the plague bacilli are either much diminished in numbers or have entirely disappeared. The

pest bacilli were also, though not constantly, found in the interstitial substance of the kidneys and in the glomerular capillaries. They were also present in the inter- and intra-acinous tissues of the liver. The mesenteric glands sometimes contained the bacilli in small numbers.

Hygienic Rules for the Eyes.—When the eyes ache close them for five minutes. When they burn bathe them in water as hot as can be borne, with a dash of witch hazel in it. After weeping bathe them in rose water and lay a towel wet in rose water over them for five minutes. When they are bloodshot sleep more. When the whites are yellow and the pupils dull, consult your doctor about your diet.

Remedy for Stage Fright.—The *Lyon Médical*, September 6th, states that, according to *La Médecine Moderne* for August 22d, an American physician advises students to combat the nervous asthenia which paralyzes their faculties and causes them to lose the thread of their ideas, by taking ten drops of tincture of gelsemium three times a day. An English specialist prescribes wine of opium to be taken by actors and singers before going on the stage. From five to six drops, he says, will give to the most timid actress the self-possession of the most spirited old player.

Chloroform in Labor.—Dr. Earle (*Chicago Clinical Review*, No. 7, p. 389) advocates chloroform in labor for the following reasons: 1. Chloroform is safer in the parturient than in any other condition. 2. Its safety is greatly enhanced by proper administration. 3. It diminishes shock. 4. It destroys future dread, and therefore robs childbirth of one of its principal objections. 5. It does not affect the fœtus even in prolonged use. 6. Labor is not prolonged, and the puerperium is uninfluenced. 7. Uterine inertia is not more frequent. 8. Its use is invaluable in normal labor, and positively indicated in all operative procedures.

Uterine Cancer.—The great error so often made is in expecting to find these women emaciated, with marked cachexia, hemorrhage, pain, stinking discharges, etc., as evidences of the presence of malignant diseases. Pain comes on late and is often absent. Bleeding of a profuse character is rare, especially very early in the history of the disease. Foul watery discharges, so often alluded to, are sometimes absent. An irregular flow between the periods is the symptom most often noticed, and is an important one, especially if occurring in a woman past the climacteric, and following sexual intercourse. Many cases are much complicated, and the dangers from the operation much increased from adhesions, the result of delays and tinkering.—*International Journal of Surgery*.

Alcoholism in Europe and Its Relation to Insanity.—Dr. Darin states, in a paper recently published in his *Thèse de la Faculté de Paris*, No. 219, that alcoholism is increasing in Italy and Belgium, and especially in France, while it is decreasing in Norway, Switzerland, and Germany. The number of lunatics in France has also increased. This increase has been chiefly in the two types of insanity known as alcoholic mania and general paralysis. This relation between alcoholism and insanity is shown by the statistics of different portions of the country, insanity being most common where alcoholism is most pronounced. The hereditary effects of alcohol are also striking. According to Legrain, among 814 children of alcoholic parentage, 322 were degenerates and 174 had not sufficient vitality to live. Among the survivors are fourteen per cent. of hysterics and seventeen per cent. of epileptics. General paresis has increased in Paris in proportion to the frequency of alcoholism.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 24, 1896.

THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM.

BEFORE the days of salicin and salicylic acid, no disease more than rheumatic fever or rheumatism of the joints baffled the attempts of the physician to cut short the attack or to keep the patient fairly comfortable while it ran its course.

As Dr. MacLagan says, in the preface to the second edition of his work, which has just appeared: "It was the despair of physicians. For weeks it went on—the agonizing pain, the sleepless nights, the drenching perspirations, the look of misery, the piteous appeals for relief, in response to which we had nothing to give but words of sympathy and encouragement, an occasional opiate, and 'six weeks in bed.'" Surely, a very decided change for the better has taken place since these ante-salicyl days, and still the matter is not so simple as one would believe. The thousand and one remedies of olden days, including blood-letting, of which Sydenham thought so well, cannot be considered as wholly superseded and satisfactorily replaced by the salicylate of sodium. We must remember that in many instances this valuable salt is contraindicated, as in chronic nephritis; and in many others cannot be tolerated by the stomach in sufficient dose to effect its beneficial purpose.

Even when taken in milk or in Vichy water it may persist in disagreeing with the patient. The dose required, for the first days at least, is, according to Morain, eight grams daily; and Germain Sée believes that its administration should be continued in gradually decreasing quantity for a fortnight, in order to secure a lasting effect. Upon the fibrous thickenings left about joints as sequelæ of acute rheumatism, the salicylic group of remedies seems to have little or no effect.

In a paper recently published by Dr. Lee, of Chicago, on "How to Cure Rheumatism," the supply of proper and sufficient nutrition is considered the first indication to be met. Next in order is the restoration and preservation of the normal volume of the blood, its high specific gravity being looked upon as an evidence of deficiency in the liquid element of the blood. This deficiency he would meet by administering from two to four litres of pure water daily. Water applied in various ways to the surface is also advocated. Hydrotherapy does not always receive the consideration

its usefulness warrants. In William Murrell's excellent manual of "Pharmacology and Therapeutics," just published, eight lines are devoted to the water cure. One of these lines says, "It is useful in rheumatism;" and another that "in persons not accustomed to it, it induces a craving for whiskey." Now, as alcohol is considered by many to be injurious in rheumatic affections, it would surely seem too bad if the water in its cure brought forth the habit of indulgence in strong drink, which, in turn, would lead to recurrences of the original evil.

It is probable that treatment will again undergo a modification, as the toxin theory, or the chemico-toxic, or the miasmatic theory of its causation becomes recognized. Many already believe that there is a germ infection to account for the genesis of the affection. Until some radical change in treatment becomes established upon a foundation of plausible theory, we can do no better, it would seem, than to stick to salicylate of sodium or oil of wintergreen as the main remedy for those who can take them without injury, to which may be added, especially for the latter class of patients, such alkalies as the salts of sodium, potassium, ammonium, and lithium furnish, and to which may be further added colchicum for certain cases.

Washing out the tissues by causing the patient to drink large quantities of pure spring water can but be beneficial within certain definite limits, and the scientific use of water externally applied surely has a field of usefulness which has as yet not been exhausted.

THE BUTCHERY OF THE SICK AND WOUNDED.

THE revolution in Cuba furnishes to the world an example of the logic of war, which we could wish might serve as a deterrent to the jingoes of all nations, but which, of course, will not. A war which is waged between two peoples for the attainment of a specific object will naturally not cease until one or the other side becomes too weak longer to contend. To be consistent, therefore, each side should strive, by whatever means in its power—bullets, dynamite, poison, famine—to destroy as many of the enemy as possible. If any of these chance to be sick or wounded, so much the better, for they are then an easier prey. It is on this principle that the war in Cuba is now being waged, by Spain at least, and, if we can trust the Spanish accounts, by the revolutionists as well. Concerning the cruelty of the Spaniards we have abundant testimony of the Cubans, of Americans, and of the Spaniards themselves; and although we have only Spanish accounts of the murder of the sick by the Cubans, it is not unlikely that they are in the main correct, although probably somewhat exaggerated.

The latest evidence of Spain's determination to crush the rebellion by waging war on the sick is furnished us by a correspondent in Havana, who sends a copy of the *Gaceta Oficial* of that city, containing a decree of the governor-general of the island concerning the sending of medicines from the capital to provincial towns. After formulating the conditions under

which pharmacists are permitted to sell drugs, General Weyler says that all who disobey these provisions will be regarded as aiders and abettors of the rebellion, and will be "tried by court martial," which is euphemy for "executed for the crime of rebellion."

Not long ago a physician and his wife were arrested and thrown into prison in Havana for the crime of having bandaged the wounds of some of the rebels. Soon after that a body of Spanish soldiers discovered a hospital near Ininones, and on the order of their commander put to death with the machete the resident surgeon and all the sick and wounded inmates, more than twenty in number, and then burned their bodies, with the house and outbuildings.

A newspaper in Madrid recently contained an account of the murder of a Spanish surgeon, who had been captured by a body of insurgents, after he had been forced to dress the wounds of some of the party; and official telegrams from Havana occasionally contain reports of attacks by the revolutionists upon hospitals. We doubt not that some of these reports are true, for the Cubans can hardly be expected to abstain from reprisals when they have seen their helpless comrades butchered. And, moreover, they are logical. Theorists have sought to establish humane rules for the carrying on of war, to formulate an ethical code for the guidance of men engaged in slaughtering each other; but their efforts are vain. War has been sung by poets and blessed by the Church, but it is hellish.

THE PROPOSED CONGRESS OF LEPROLOGY.

FROM replies received by Dr. Albert S. Ashmead, of this city, to letters addressed by him to many of the leading leprologists of the world, the proposed international congress of leprology would appear to be an assured fact. The only questions that remain to be decided are where the congress will assemble and when. It was suggested that it meet in Moscow in August of next year, during the session of the International Medical Congress; but objection has very properly been raised that the greater would absorb the lesser, and that the work of the leprologists would be buried beneath the overwhelming mass of papers and discussions at the general meeting. If it is worth while at all for students of leprosy to come together from all parts of the world to discuss measures for the suppression of this disease, the assembly ought certainly to enjoy the dignity of an independent congress.

The necessity of a special congress being conceded, it was thought best to meet just before the Moscow congress, so that those who wished to attend both could do so; and it was further proposed to meet in Bergen, the home of Dr. Hansen, in honor of the discoverer of the *lepra bacillus*. Dr. Hansen, however, recognizing the convenience of a more central point for the meeting, has expressed his wish that the congress be held in London; and that seems also to be the choice of most of those actively interested in the project. London would certainly appear to be the place best suited for a meeting of this kind, and we doubt not it will be finally selected by the promoters of the congress.

HOT-WATER BOTTLE BURNS.

LESS than two years ago attention was directed, in the editorial columns of the *MEDICAL RECORD*, to the possibility of most serious injury to patients, especially during recovery from anaesthesia, from the application to the body's surface of the ordinary rubber water bag, even when the water it contained is not excessively hot. Little had been written till then upon the subject, and little has been written since. It is bad enough for a man to have such an unfortunate accident in his practice, without being called upon to publish his mishap broadcast.

The question has, however, been widely discussed in medical gatherings, and since the publication of our warning at least three large hospitals in this city have established the rule that the nurse shall remove the bottle from the bed when the patient is put back into it from the operating-table.

This is an excellent rule, it seems to us, and one which might well be established in every hospital in the land. No harm can come to the patient from heating the bed, and the precaution would act as a constant reminder to the nurse and internes of the element of danger, and would induce watchfulness when in emergencies it becomes necessary to apply heat in this way to other than operative cases. The frequency with which extensive burns have occurred in the past was well illustrated in a recent discussion at the Lenox Medical Society, the members present having, with scarcely an exception, instances to relate of such accidents which had fallen under their observation, or of which they had direct knowledge. Feeling that our previous notice of the matter has not been unrewarded, we do not hesitate again to call attention to it, in the hope that it may save some one from an unpleasant and unprofitable experience, to say nothing of the patient.

News of the Week.

Hebrew Physicians at Moscow.—We have received the following from the executive committee of the Twelfth International Congress: "In reply to numerous inquiries in regard to the conditions under which Israelites may take part in the XII. International Medical Congress, the executive committee hastens to inform those interested that the minister of the interior, with the approval H. I. II. the Grand Duke Sergius Alexandrovitch, has judged it possible to authorize the arrival at Moscow, for the congress, of foreign Hebrew scientists on the same conditions of other foreigners. They will be obliged, therefore, the same as the latter, to have their passports viséd by the Russian consul where they reside. Orders have consequently been given by the minister of foreign affairs to the Russian consuls and ministers in foreign countries, to the effect that the passports of all persons going to the XII. International Congress of Moscow must be viséd without regard to the religious beliefs of these persons." We trust our Hebrew con-

frères will be duly grateful to His Imperial Highness Nicholas Alexandrovitch for this gracious permission to visit one city in his dominions.

The Marine Hospital Service.—There will be held in Washington, D. C., on February 3, 1897, a competitive examination of candidates for appointment to the position of assistant surgeon in the United States Marine Hospital service. Candidates are required to be not less than twenty-one years of age, and no appointment will be made of any candidate over thirty years of age. They must be graduates of a reputable medical college and furnish testimonials as to character. Successful candidates, having made the required grade, are appointed in order of merit, as vacancies arise during the succeeding year. A successful candidate, when recommended for appointment, is commissioned by the President of the United States as an assistant surgeon. After four years of service and a second examination he is entitled to promotion to the grade of passed assistant surgeon, and to the rank of surgeon after a third examination, according to priority, on the occurrence of vacancies in that grade. The salary of an assistant surgeon is \$1,600 per annum, together with furnished quarters, light, and fuel; that of a passed assistant surgeon, \$1,800 per annum; and that of a surgeon, \$2,500 per annum. In addition to these salaries, after five years' service an additional compensation of ten per cent. of the annual salary for each five years of service is allowed medical officers above the rank of assistant surgeon, the maximum rate, however, not to exceed forty per cent. When an officer is on duty at a station where there are no quarters furnished by the government, commutation of quarters is allowed at the rate of \$30 a month for an assistant surgeon, \$40 for a passed assistant surgeon, and \$50 for a surgeon. The successful candidates, after receiving appointments, are usually ordered to one of the larger stations for training in their duties. Full information may be obtained by addressing the surgeon-general of the Marine Hospital service, Washington, D. C.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about \$180, will be made on July 14, 1897, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college on or before May 1, 1897. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga prize for 1896 was not awarded.

The Late Dr. Edward S. Farrington.—At a meeting of the West End Medical Society, on October 3, 1896, the following minute was adopted:

"It is with deep regret that we learn, at this our first meeting of the year, of the death of our esteemed fellow-member, Dr. Edward S. Farrington, who died on September 7th, of typhoid fever. He was a man of fine character, scholarly attainments, and attractive personality, and was held in high esteem by all who knew him. We feel that by his death both the society and the individual members thereof have lost a valuable associate and a good and loyal friend.

"We hereby resolve that these, our expressions of regret and appreciation of our loss, be spread upon the minutes of this society, and that copies thereof be transmitted to his family and to the current medical journals.

"CYRUS J. STRONG, M.D.,

"HOWARD GILLESPIE MYERS, M.D.,

"CHARLES GOOD, M.D.,

"EDWARD L. WILLIAMSON, M.D.,

"Committee."

The Late Dr. William Remsen Taylor.—At a special meeting of the medical board of the Astoria Hospital, held October 6, 1896, action was taken as follows:

"The medical board desires to pay tribute to the memory of William Remsen Taylor, M.D., late president of this institution.

"Whereas, The medical board, in the death of Dr. Taylor, has lost its first executive officer and long-trying friend; therefore be it

"Resolved, That the board causes to be spread upon the minutes of its records these resolutions of appreciation and sorrow.

"Resolved, Further, that the sympathy of the board be extended to the members of his family; also that a copy of these resolutions be forwarded to them and be published.

"NEIL A. FITCH, M.D.,

"JAMES D. TRASK, M.D.,

"CLARENCE N. PLATT, M.D.,

"Committee."

Physician Sued for Pits.—A novel suit has been begun against Dr. Feeney, of Staten Island, by an undertaker, who claims \$5,000 damages for the marring of his facial beauty by small-pox. It is charged that the physician diagnosed as chicken-pox certain cases which the undertaker took charge of after death, and from which he contracted variola. It is reported that when his lawyer presented in evidence the undertaker's face the judge ordered it to be marked "Exhibit No. 1," to which the objection was raised that it had been too much marked already. This is an instance in which the undertaker did not prove the traditional best friend of the physician, who covers up the latter's mistakes. The unusual scene presented by a suit at law being brought by a member of one profession against that of another upon which it feeds, can be accounted for by the fact that the plaintiff combined the function of coroner with that of his other undertakings.

The Modesty of Englishmen offers an obstacle to science which is deplorable. Mr. Jonathan Hutchinson has been giving clinical lectures which were, of course, very popular, and were attended by many women practitioners as well as by those of the sterner sex. It is now announced, however, that only men will hereafter be permitted to attend the clinics, as the male patients express an unwillingness to disrobe and display their lesions in the presence of the ladies.

A Welcome.—Drs. Leith Napier and Ramsay Smith, who were picked up in London by the government of South Australia to take charge of the Adelaide Hospital, from which the regular staff had been driven by the action of the lay authorities, have arrived at their posts. At a special meeting of the Victorian Branch of the British Medical Association, called to discuss the new arrivals, the following resolution was adopted:

"That the Victorian Branch of the British Medical Association desires to place on record its strong disapproval of the disloyal action of those medical practitioners who recently accepted appointments at the Adelaide Hospital in defiance of the protests of the South Australian Branch."

The Water Supply of Philadelphia.—In an article in the *Dietetic and Hygienic Gazette*, on "Typhoid Fever in Philadelphia," Dr. Henry Leffmann shows by statistics and topographical data that the high typhoid death rate in that city is, for the most part, directly due to the use of polluted water, and there is every reason, he says, to believe that if the present water supply of the city were subjected to filtration an immediate fall in the typhoid rate would be shown, and under such circumstances the sanitary condition of the city would be in the front rank of the large cities of the world. During the year 1895 there were four hundred and sixty-nine deaths from typhoid fever in Philadelphia, and, estimating the cost of each one at \$100—a low figure—there was a total expense of \$469,000, "the interest on a sum quite sufficient to filter all the water." If to that is added the cost for the cases which terminated in recovery, there would be a large sum to help pay the first cost of construction of the filtering plant.

Antitoxin Treatment of Diphtheria in Austria.—Professor Paltauf has published statistics of 1,103 cases of diphtheria in which antitoxin was employed, with the result of 970 recoveries and 133 deaths, equivalent to a mortality of 12.5 per cent. He lays much stress upon the early application of the serum, for in the case of injections made on the second day of the disease the mortality amounted to 6.7 per cent., whereas in those made on the third day it amounted to 19 per cent., in those on the fourth to 23 per cent., in those on the fifth to 31 per cent., and in those on and after the sixth to 33.3 per cent. Professor Paltauf makes mention of the epidemic of diphtheria in Ischl, where in December, 1895, all those children died who had not received the antitoxin treatment; whereas in January, 1896, in the cases of 16 children attacked with the disease and treated with antitoxin the result was in every way successful.—*The Lancet*.

Dr. John B. Hamilton, editor of the *Journal of the American Medical Association*, has resigned from the Marine Hospital service, in order to devote himself to his editorial duties and the demands of private practice.

Professor Koch Studying Leprosy.—Dr. Robert Koch has been sent by the Prussian health department to Memel, in Eastern Prussia, in order to study leprosy and the means by which it is spread, and to devise measures by which further spread of the disease in that region may be prevented.

Dr. Irwin, Li Hung Chang's physician, is a genial and talented Irishman. Just as he left Netley eighteen years ago he heard of a good opening for a doctor at Tein-Tsin, so he turned him cheerily to the Flowery Land. In 1879 he was called in to attend a serious case in the imperial yamen. His patient recovered, he was appointed chief physician to the viceroy and the viceroy's family, and ever since his lot has been a happy and prosperous one.—*The Canada Lancet*.

The Doctor's Debts.—A Vienna physician was recently sued for the amount of a bill which he refused to pay. He claimed, and in this was sustained by the court, that the practice of medicine was a privileged profession and not a trade, and that a physician's property could not be seized for the payment of his debts. The case was carried from one court to another until it reached the court of appeals, and in all the decisions were to the same effect, and the creditor lost his money.

Consecration of St. Luke's Hospital.—The new buildings and chapel of St. Luke's Hospital, at One Hundred and Thirteenth Street and Morningside Heights, now nearing completion, were consecrated on October 17th by Bishops Potter of New York, Littlejohn of Long Island, and Huntington of Central New York, assisted by the archdeacon of the Episcopal diocese of New York and the clergy of the city. The board of managers of the hospital, the members of the medical staff, and a few of the patrons of the institution assisted in the ceremonies.

Sir George Murray Humphry, of Cambridge, England, died at his home on the evening of September 24th. He was born on July 18, 1820, and at the age of nineteen entered St. Bartholomew's Hospital, and immediately upon obtaining his qualification to practise, when but twenty-two years old, was appointed surgeon to Addenbrooke's Hospital, Cambridge. He was a frequent contributor to periodical literature, and published several works on anatomical subject. He was chairman of the general committee on collective investigation of the British Medical Association, and himself made and published the results of the investigation on old age. He was among the first to call attention to the fact, which has since come to be very generally recognized, that the aged bear the shock of injuries and surgical operations wonderfully well and that their power of resistance to disease is often as great as that of younger persons. He received the honor of knighthood in 1891.

Helium, one of the newly discovered constituents of the atmosphere, has been divided by Professor Ramsay into two portions, one of which is lighter than the other, although both give the same spectrum.

Dr. B. Meade Bolton, chief of the department of pathology and bacteriology of the Philadelphia board of health, has been tendered the chair of bacteriology in the University of Missouri, and will probably accept the offer.

Gifts to a Hospital.—A number of the summer residents of Long Branch, before returning to their homes recently, started a subscription list for the benefit of the Monmouth County Hospital, and collected a considerable sum for the institution.

A Home for Blind Women.—The Church Charity Foundation of the Long Island Episcopal diocese has made arrangements to open a home for blind women in Maspeth, on November 1st. The building is surrounded by five acres of land, which have been deeded to the diocese. It is stated that there are twelve hundred blind persons in Brooklyn and vicinity, and that only a small percentage of them is cared for in charitable institutions.

"Charaka-Samhita."—The fifteenth fasciculus of the translation, by Avinash Chandra Kaviratna, of this quaint old medical treatise, deals with the properties of various articles of diet and with the perversions of appetite. The physiology of alimentation is considered in a primitive fashion, and the consequences of gluttony are vividly portrayed. The final portions are concerned with epidemics and their origin in the vitiation of the air, soil, and water.

The Hope Hospital in Langholm, Scotland.—A correspondent of *The Lancet* writes that the cornerstone of this hospital was laid, on September 21st, by Miss Hope, of New York. The hospital is one of the results of a sum of £100,000 left by the late Mr. Thomas Hope, of New York, to Langholm, as his native place, the capital to be administered by trustees for the benefit of the inhabitants. The building is to be a very handsome one, and the plans are in every respect drawn on a most liberal scale. The cost is estimated at £17,000.

The Proper Pronunciation of Greek.—The October number of *Education* contains an interesting article with this title, by Dr. A. Rose, of New York. It is a paper which was read by him before an interested audience in the hall of the Academy of Medicine in June last. The same number contains the remarks delivered at the time of the lecture by Professor Orris, of Princeton, and Mr. Botassi, the Greek consul at New York. The arguments advanced against the Erasmian pronunciation are very strong, and should be read by all Greek professors who adhere obstinately to this artificial and indefensible system. Russia and France have, we understand, adopted the correct pronunciation; and if Germany, England, and America could be induced to follow suit, the dream of the adoption of Greek as the international tongue would seem to be nearer realization.

Philadelphia Hospital.—Dr. E. B. Sangree has resigned the position of pathologist to the Philadelphia Hospital, in consequence of the assumption of the duties of the chair of pathology and bacteriology in the Vanderbilt University at Nashville, Tenn.

Slumber Sound in Philadelphia.—The current belief that insomnia is unknown in Philadelphia will be strengthened by an incident related by the correspondent in that city of *The Lancet*. He writes that a hypnotist had been giving exhibitions in one of the theatres, and as a "special feature" he put a victim into a sleep that was to last seventy-two hours, placed him in a store window in a prominent thoroughfare, and offered \$100 to any one who could rouse the sleeper before the time named. One man, anxious to earn the money, failing to make any impression on the victim by tickling, prodding, etc., became desperate and struck him some heavy blows with his fists, without accomplishing his object, however, but injuring him severely. Just at this juncture the "professor" arrived. He was ordered to arouse the man, which he did, when it was found necessary to remove him to a hospital.

Philadelphia County Medical Society.—At a meeting of the Philadelphia County Medical Society, on October 14th, Dr. F. W. Talley read a paper entitled "The Proper Position of Cæliohysteropexy in Gynecology;" Dr. A. O. J. Kelly read a paper on "Essential Paroxysmal Tachycardia, with a Report of Four Cases;" Dr. C. W. Burr read a paper on "The Relation of Anæmia to Chorea," in which, as a result of observations made in thirty-six cases, he came to the conclusion that anæmia is not an exciting cause and not commonly a predisposing cause of chorea; but in many cases it is secondary to the chorea.

College of Physicians of Philadelphia.—At a meeting of the surgical section of the College of Physicians of Philadelphia, on October 15th, Dr. Sprenkle, by invitation of the executive committee, read a paper on "Prolonged Pregnancy," in which he pointed out the dangers to which this condition might give rise, and advised the induction of artificial labor if gestation be prolonged two weeks beyond the normal. Dr. C. B. Penrose read a communication, entitled "Hysterectomy by Combined Operation through Abdomen and Vagina," in which he advocated, in place of following the procedure commonly employed, that the abdominal section be made first and the vaginal manipulations be proceeded with afterward.

Vital Statistics of Philadelphia.—For the week ending October 10th, there occurred in the city of Philadelphia 357 deaths—44 less than during the preceding week. Of the whole number, 104 were in children under five years of age. The following causes were assigned for the largest number of deaths: Pulmonary tuberculosis, 39; heart disease, 24; carcinoma, 21; marasmus, 21; apoplexy, 17; nephritis, 15; pneumonia, 14; inflammation of the brain and its membranes, 14; diphtheria, 14. There were reported during the week 73 cases of diphtheria, 28 of typhoid fever, and 16 of scarlet fever.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Thirteenth Annual Meeting, Held in New York, October 13, 14, and 15, 1896.

DARWIN COLVIN, M.D., PRESIDENT.

THE PRESIDENT called the meeting to order at 10 A.M., October 13th, and expressed pleasure at being called to preside over so important a body.

Report of Committee of Arrangements.—DR. JOHN G. TRUAX made a verbal report, in lieu of the written one left at home, and heartily welcomed members of the association to New York and this annual meeting.

Report of the Council.—DR. E. D. FERGUSON read the report. The library now contained ninety-five hundred and thirty-eight volumes, having been increased by thirty-five volumes during the past year. The total sum in the treasury at the beginning of the year was \$5,330; total disbursements, \$1,992; total amount remaining, \$6,258. A resolution was adopted by the council, and later accepted by the association, in opposition to restriction of vivisection by Congress. In the matter relating to removal of physicians from the Harlem Hospital without cause, brought up by Dr. Manley, the chairman of the council to which it was referred reported that it was a local matter, and he thought the association should not interfere with local matters.

DR. MANLEY could not agree with the report that the discharge of physicians from the hospitals without cause was a local matter. In the present instance it was done at the urgency of the medical colleges, and the action of the faculties of those colleges was in violation of all ethical rules. Dr. Manley moved that the matter be referred back to the council, which should report by the last session.

DRS. J. G. TRUAX, FERGUSON, and others made a few remarks, and the matter was referred as called for in Dr. Manley's motion.

Dr. J. B. Hamilton.—On motion of DR. MANLEY, the following resolution was adopted:

"To the Surgeon-General of the Marine Hospital Service of the United States.

"Whereas, Dr. John B. Hamilton, of Chicago, Ill., surgeon to the Marine Hospital of that city, professor of surgery in Rush Medical College, and editor of the Journal of the American Medical Association, has been ordered to vacate his present position and report for duty at San Francisco; and

"Whereas, Dr. Hamilton, a native of Illinois and graduate of Rush Medical College, occupies the responsible position of editor of the leading medical organ and exponent of medical science in this country; for the great success of which of late years, its enlarged circulation and unparalleled prosperity, for widening the influence of and extending the benefits of the American Medical Association, all must admit, we are chiefly indebted to Dr. Hamilton;

"Whereas, The removal of Dr. Hamilton from Chicago and his withdrawal from the the editorship of the Journal of the American Medical Association would be a great loss to the entire profession (medical) of the United States; therefore be it

"Resolved, That the Medical Association of the State of New York, appreciating the rare qualities of Dr. Hamilton as a scholar, a teacher, and a fearless editor, and his labors in the past in the defence of non-sectarian medicine and his efforts to raise the standard of the medical profession in the United States of Amer-

ica, respectfully petition the President of the United States and the surgeon-general of the Marine Hospital service to reconsider or rescind the above-named order, and permit Dr. Hamilton to continue in Chicago at his post, believing that by so doing the interests of the Marine Hospital service will not be neglected and those of the medical profession best protected."

Functionless Organs. Are There Any? The Use and Disease of the Vermiform Appendix.—DR. NELSON L. NORTH, of Brooklyn, read the first scientific paper. "While thinking how best to present my thoughts in favor of what I supposed to be about the real truth, that the human organism, in its normal condition, was pretty nearly perfect in all its parts, and that all its parts were each peculiarly and specially adapted to accomplish its own portion in the economy of the completed whole, I opened the MEDICAL RECORD and read, under the head 'Rudimentary Organs,' by Cora H. Flagg, M.D., as follows: 'In all of the higher animals we find a large number of structures which are either absolutely useless or of such slight service as to bear little or no relation to the existing life or wants of the animal.' Evolution in the article quoted from has certainly an enthusiastic advocate, and the prize essay of the author is very pleasant Darwinian reading; only we are inclined to think, in running over man's 'rudimentary organs,' that man is, after all, 'a kind of nature's patchwork,' and a great way from a perfect or completed organism, and we are also inclined to exclaim with Shakespeare, though in the deepest irony:

"What a piece of work is man!"

To continue the parody:

"How ignoble in origin!
How infinite in rudiments!
In form and moving
How like his prototype!
In action like an animal!
In apprehension how like a (heathen) god!
The fag end of creation!
The continuation of the (lower) animals!"

"We have not to go far back in medical literature for statements to the effect that so important an organ in the digestive and blood-making process as the spleen is utterly functionless except as a possible reservoir for the blood during congestive conditions. Also with several other of the glandular organs heretofore supposed to be wholly functionless, it is coming to be well understood that, instead, they are hamatopoietic, and hence of singular importance in the assimilative process of tissue building."

Dr. North cited the thyroid and thymus glands as examples: "Even the tonsils, the glandular organs which have borne all sorts of abuse from cauterizations, incisions, and excisions, are beginning to be looked upon as 'guardians of the fauces,' arresting in their follicles marauding bacilli or overtaking them with germicidal secretions, or else bearing in their own bodies the force of the toxins which would otherwise get deeper and attack the citadel of life's forces. So it may be that the poor appendix vermiformis, so often referred to during the last few years as the death-inviting, functionless rudiment of a former existence, may be found to have been created or evolved for a purpose, and not intended to be sacrificed to the surgeon's knife without mercy whenever found in sight or within reach, whether guilty or not guilty of diseased action. It is fairly supposable that, whether man was created instantly by the fiat of God or by the slow process of evolution, the design was to make a perfect being; and it is not fair to suppose—conceding even that the origin dates from the very lowest and first conditions of life—that all through the extended process

of evolution there should be of necessity traces of the changes in the multitudinous rudiments of former conditions, useless for the life that now is and dangerous to that life, in that they so easily take on diseased action and become only 'pathological in their significance.' Rather let us suppose that an almighty God—or the conservative all-powerful force of nature—would have improved at each turn of the evolution processes; and so we should discover that every part of the human organism, however apparently insignificant, has a use, and should not be sacrificed without good and sufficient reason therefor. The numerous follicles or glandular structures of the appendix show evident secretive or secerment action, and it is quite possible that from these, as from glandular bodies of a like character in the lower portions of the ileum, secretions are thrown out which guard this ileo-cæcal valve, and perhaps hinder the passage of the colon bacteria and so tend to preserve the normal condition of the parts. Of course, in a diseased condition, as in appendicitis, all this is changed. Then, again, a careful study of the form, location, bearing, and action of the appendix would indicate its primal use or function as an automatic closer or 'drawstring' to the ileo-cæcal valve; its cavity being filled with gas, it naturally rides upward like the ball valve used by plumbers and so draws the mucous folds of that valve in coaptation—thereby preventing the foul gases of the colon from passing upward. While this valve would prevent regurgitation of gases from the colon, it would not prevent the passage of feces into the colon."

While looking up the subject of the appendix vermiformis, Dr. North had been startled by the number of cases of appendicitis reported and referred to. In seeking the explanation, he had visited the health office of Brooklyn and studied the relative number of deaths for the several years since 1880, from peritonitis, perityphlitis, typhlitis, appendicitis, intussusception, obstruction of the bowels, colic, perforation of intestine, ulceration of bowels, perforation of appendix, and constipation. The percentage of deaths from these combined causes had been, in 1880, 1; in 1883, $1\frac{1}{4}$; and for the successive years to 1895 it had been $1\frac{1}{3}$, $1\frac{1}{9}$, $1\frac{1}{4}$, $1\frac{1}{3}$, $1\frac{1}{2}$, $1\frac{1}{3}$. It was obvious that since there were more deaths from these causes there must be more cases in the aggregate, or else the treatment was faulty. It was not likely surgical technique would much further diminish the death rate from operative interference, and Dr. North thought the difficulty lay in practitioners giving up as soon as a patient complained of pain in the right side and calling in a surgeon, instead of resorting to early local antiphlogistic and internal remedies. Among the remedies which Dr. North had found valuable in the class of diseases named were opium (which was often curative in peritonitis), leeches, ice bag, or poultices, mild cathartics, and rectal injections.

Dr. JOHN CRONIN had seen many cases of what formerly had been called ileus, then typhlitis, perityphlitis, paratyphlitis, appendicitis, recover under local applications and medical treatment. Leeches, ice bag, and poultices were among the remedies—ice bag in the acute stage and poultices later.

Dr. W. M. BEMUS found, in addition to the opium treatment and the ice bag, benefit from rectal injections of cold water.

Dr. HENRY D. DIDAMA remarked that the thyroid gland was once considered useless, but now as a remedy it was taken by the fat man to reduce his weight, it was regarded as a cure of cretinism, etc. Even the suprarenal capsules were put to service—at least he understood such a report came from St. Louis, where most of our things come from. So the appendix vermiformis might be found to have some use—he hoped it would.

A surgeon in the State had told him that he had often been called by physicians to cases of supposed appendicitis, had operated, had often found the appendix all right, closed the wound, and—received his pay.

The President's Address.—DR. DARWIN COLVIN then read his annual address, on "Medical Expert Testimony." It will be published later in full. Some experience was given, showing that the present method of obtaining expert testimony was extremely faulty; in every case so-called experts could be secured for a fee to give entirely conflicting testimony. He favored such change as would make the expert as free from influence by the opposing parties as were the jurors or the judge.

Report of the Committee on Criminology.—DR. AUSTIN FLINT read the report. The committee had been appointed at the last meeting to confer with a committee appointed by the Prison Association of New York, to report on criminology. The two committees met with the executive committee of the Prison Association, December 10, 1895. The chief subject of discussion at this meeting was the question of the amendment to the constitution of the State, prohibiting productive prison labor. The injurious results of such an amendment, enforcing idleness on prisoners, were pointed out during the discussion and in a letter sent by the committee to members of the association. The committee recommended to the president of the State commission of prisons the adoption of the Bertillon system of identification of prisoners. The system was not only useful in the identification of prisoners, but was also of the greatest scientific value, in connection with the study of criminology and anthropology and related questions. The report was signed by the members of the committee, Drs. Flint, Gouley, and W. A. White, on motion was accepted, and the committee was continued.

Prostatic Enlargement.—DR. J. W. S. GOULEY opened the discussion on this subject with a paper in which he propounded the four following questions: 1. What is the nature of prostatic enlargement? 2. How is prostatic enlargement recognized? 3. What are the effects, and how may they be counteracted? 4. When is operative interference indicated, and what operations may be safely performed for prostatic enlargement? (See p. 577.)

Prostatectomy.—DR. SAMUEL ALEXANDER'S paper on this subject will be published in a future issue.

Dr. W. G. BROWNSON, of Connecticut, spoke to one point, catheterization in old men with enlargement of the prostate. By carrying this out systematically and irrigating the bladder when necessary, he had made many old soldiers comfortable and prevented the development of vesical and renal symptoms. The solutions were carbolic acid and glycerin (carbolic acid, two per cent.), boric acid.

The Effects of Prostatic Enlargement and How They may be Counteracted.—DR. DOUGLAS AYERS

read a paper on this subject. He said that, although the prostate had been spoken of as a gland, it might be called a muscle, since so small a portion of it was glandular. The first effect of enlargement was change in the capacity and course of the urethra, followed by obstruction to the flow of urine. Complete retention of urine might occur early, but usually it was one of the latest symptoms. Persons approaching the age at which prostatic hypertrophy was likely to develop ought to be warned by the physician, who should see that the bowels moved daily, that the body was protected by suitable clothing, that the patient partook of suitable food or that which was plain, nutritious, easily digested, not highly seasoned, and took moderate exercise. The amount of residual urine should be early learned and the catheter called into timely requisition. No. 9 or No. 10 of the American scale soft-

rubber catheter would answer in the majority of cases. When the urine became turbid or offensive resort to vesical irrigation should be had. As to medicines, such as the physician's experience had taught him would give the best results should be used. While acknowledging our lack of power to prevent the cause of prostatic hypertrophy, we should employ such means as would lessen the effects and make more comfortable the decline of life.

Method of Retaining the Drainage Tube.—DR. E. D. FERGUSON had found the best method of retaining a drainage tube inserted into wounds or cavities to consist in stitching it to the integument.

DR. H. O. MARCY expressed his pleasure at hearing the very complete and excellent papers read by Dr. Gouley and Dr. Alexander. He recommended to the consideration of the readers an excellent paper on the subject written at his suggestion by his friend, Dr. White, of Boston, in 1887. Dr. Marcy had found vision much aided in one case of prostatectomy performed by him by placing the patient in Trendelenburg's posture. He thought we would come to do away with suprapubic drainage in this operation and rely entirely upon perineal drainage. Alexander's operation was destined to have a wide field of usefulness.

DR. GOULEY, in some closing remarks, said residual urine in enlargement of the prostate was not due to want of expulsive power on the part of the bladder, but to closure of the urethra, which took place long before there was loss of expulsive power. One ounce of residual urine was sufficient to do mischief, and it was not wise to wait until there was more before beginning the use of the catheter. Catheterization, when properly performed, did no harm whatever. In enucleating the prostate he strongly commended the use of the finger instead of sharp instruments in order to diminish hemorrhage. If the proper drainage tube were employed it would not come out, and there would be no necessity for stitching it to the skin. Trendelenburg's posture was the worst of all in prostatectomy, for it was desirable that gravity should act away from the body.

The Treatment of Fecal Fistula, with Report of Cases.—DR. F. H. WIGGIN, of New York, read a paper on this subject (see page 586).

Irritable Stump.—DR. JOSEPH D. BRYANT, of New York, in this paper gave statistics of the late war bearing on the nature of the stump following amputations, the opinions of instrument makers on the subject of irritable stump, and then described a method of amputation in the lower third of the leg which he had employed in a number of cases. The military statistics showed a large percentage of cases with either an unhealed or an irritable stump some months after amputation. He had been unable to secure statistics from surgery in civil life. A visit to a number of artificial limb makers in the city had not resulted in securing all the information which he had desired, but it was learned that irritable stump was recognized by each of them, one manufacturer stating that about ten per cent. of all cases were of that nature. Some were of the opinion that the owners of the stumps were as much at fault as the surgeon. The length of the flap was recognized as important in efforts to secure a useful stump.

Dr. Bryant then gave the history of the first case, that of a military man, which had led him to employ the mode of amputating and described the flap which he had found gave the most serviceable stump, especially in the lower extremity, where he had most frequently applied the method. All told, he had operated in this manner in fourteen cases, and in eleven the stump had been in every way satisfactory. In his conclusions he said: 1. The flap of all pressure-bearing stumps should be equal in length to rather more than

one-fourth of the circumference of the part where amputated. 2. Irregularly formed flaps should be constructed on the same basis, one portion of the flap making up for the deficiency in length of the other. 3. Periosteal covering of the divided end of bone should be made if possible, and when possible the periosteum should be raised apposed to the overlying soft parts. 4. This method of procedure secured the most serviceable stump in amputation of the lower third of the leg.

DR. H. O. MARCY, of Boston, said that many years ago, when he was a medical student, he asked Dr. Bowditch what would be the effect of covering the end of the amputated bone with the lifted periosteum, and the reply was that it would probably produce a lump of bone and cause trouble. Dr. Marcy said further that he was in the habit of suturing the several tissues to their kind and of sealing the wound with iodoform collodion, not employing drainage, and he thought stumps so treated gave less trouble.

DR. DIDAMA thought the point made by the author, not to separate the periosteum from the superincumbent tissues, was an important one.

Hindrances to the Successful Treatment of Diseases of Infancy and Childhood.—DR. J. LEWIS SMITH read the paper. The first hindrance was the disinclination of mothers to nurse their own children. The next was the difficulty of getting a healthy and reliable wetnurse. Before the New York foundling asylum was established about all the babies under city care died. A watch had to be kept at the foundling asylum to-day to prevent mothers leaving their infants at the door and going off without making their identity known. Medical colleges did not give sufficient instruction to undergraduates in the diseases of children, and this want had been only partly met by the post-graduate schools. The habit of attributing all ills to painful dentition, for which, formerly at least, physicians lanced the gums, was a serious fault. Rheumatism was often called growing pains, consequently proper treatment was not adopted and the number of cases of heart disease was greater than it should be. The questions of alimentation, spreading disease at school, and some others had recently been discussed in pædiatric literature, and were therefore passed by.

The Practical Uses of Roentgen's Discovery as Applied to Surgery; with Illustrations.—DR. REGINALD SAYRE, of New York, gave a brief review of the discovery and principles of the x-ray and then projected on the screen a number of photographs so taken of orthopædic cases. It was evident from the demonstration that the x-ray was of value in the location of fractures; in determining whether there had been proper reduction, which could be done without removing the dressings; in locating sequestra and perhaps abscess of bone, in determining whether disease had invaded the joint, and whether there was bony or fibrous ankylosis. It was of less use than might have been supposed in clubfoot of children, for the cartilage was so extensive as to cast a light shadow throughout most of the space. But this fact showed the foolishness of removing tissue by the knife in such cases, since mechanical appliances would readily bring the parts into place. Among the illustrations were some of bandylegs, clubfoot, dislocation at the hip, bony and fibrous ankylosis, fracture, etc.

The Treatment of Otorrhœa and Its Importance.—By DR. EDWARD B. DENCH, of New York. The term otorrhœa was used collectively to avoid technicality. In a given case the physician should inquire how long the discharge had been present; had it been preceded or accompanied by pain; was there a history of previous disease of the ear; had the discharge been continuous or intermittent; had there been any sudden diminution of the quantity of the discharge. If so, had

it been accompanied or preceded by pain. He should observe the character of the discharge—whether serous, sero-mucous, or purulent, whether large or small in amount. A chronic discharge lasting a month, purulent in character, must come from the middle ear, and naturally the membrana tympani must present some opening. A recent purulent discharge might be from the external ear, as in furuncle. Sero-mucous discharge came from the middle ear. Pressure in front of the tragus or traction on the auricle would cause pain if the external ear were involved, and in adults this was a sign of considerable importance; but in children the bones of the ear were not yet formed and the traction would cause pain, as also in inflammation of the middle ear. In many cases patients had a series of attacks, usually following colds, and between the attacks there was no discharge. Here there was either a simple catarrhal inflammation of the middle ear with slight serous discharge, or there had been a purulent discharge with destruction of most of the membrana tympani, the lining membrane being left exposed over a large area, from which serum flowed during congestion. When the membrana tympani was intact pain preceded the discharge, but when it was perforated there was absence of pain. As to furuncles, they were rare in infants, more frequent in adults. Most of the paper was devoted to inflammation of the middle ear.

In simple earache with serous exudate, when the tension became great enough it ruptured the membrane, some fluid escaped, pain was relieved, the process healed spontaneously unless infection took place, and the membrane closed. When suppuration existed it always implied destruction of tissue, and in the middle ear both the soft structures and the bony walls might be involved. The discharge would cease as soon as the necrotic tissue had been separated, but often drainage was not perfect. The first object of treatment was to keep the canal free of discharge, the second was to secure an aseptic condition of the meatus. While much had been said of drainage by iodoform gauze, his own experience had been so unsatisfactory that he no longer employed it. He favored the older method of syringing as often as was necessary to keep the ear free from secretion. Under no circumstances would he stop the ear with cotton, nor should powders be used, such as borax. As an antiseptic douche he preferred bichloride, 1 to 3,000 or 1 to 5,000. Dr. Dench then described two methods of removing necrosed bone when this was present. He preferred curettage through the canal.

The Relation of Affections of the Upper Air Passages to Diseases of the Ears.—DR. FRANK S. MILBURY, of Brooklyn, pointed out in the first part of this paper what he believed to be the frequent connection between some abnormal condition of the anterior nares and postnasal affections which were commonly recognized as the cause of much middle-ear disease. In his opinion in every case of adenoids the Eustachian tubes were involved. The adenoids should be removed and thereby humanity saved much suffering in connection with the ear as well as with the nasopharynx.

The Technique of Intubation in Children; Some Remarks on the Time for Operation and on the After-Treatment.—DR. THOMAS J. HILLIS, of New York, read a paper with the above title. Success depended a great deal upon experience, attention to little points, and on proper nursing of the patient by the parents or friends.

Temperature as an Element in Prognosis.—DR. JOHN SHRADY, of New York, read a very practical paper on this subject, which will appear later.

The Medical Treatment of Inebriety.—DR. T. D. CROTHERS, of Hartford, Conn., read this paper. In-

ebriety, he said, was a more complex disease than insanity. Its progressive degeneration often dated back to ancestors, to defects of growth, to retarded development, or to early physical and psychical injuries. Later the poison of alcohol, by its anæsthetic and paralyzing action, developed more complex states of degeneration, the form and direction of which were very largely dependent on conditions of living and on surroundings. The psychical symptoms showed progressive disease of the higher brain centres, with degrees of palsy and lowered vitality. The medical treatment must be based on some clear idea of what constituted the nature of inebriety and the conditions present in the case to be treated. This required a careful clinical study of the symptoms, tracing them back to causes, and all the varied conditions formative in the progress of the case. Heredity was the most frequent predisposing cause. A second class of cases was due to physical and mental strains or to drains and injuries. The second part of the clinical study was the effect of alcohol. What injury had it caused? How far had it intensified all previous degenerations and formed new pathological conditions and sources of dissolution? What organs had been most affected, and, most important of all, how far was the use of alcohol a symptom or an active cause? Having ascertained these facts, the medical treatment was the same as in other diseases—the removal of the exciting and predisposing causes and building up the body.

The first question was the sudden or rapid removal of alcohol. If the patient was alarmed and intensely in earnest to abstain, he would consent to have the spirits removed at once. If he was uncertain and had delusions as to the power of alcohol to sustain life, the withdrawal would depend on circumstances. The removal of all spirits at the beginning of the treatment was always followed by the best results. The reaction which followed could usually be neutralized by nitrate of strychnine, one-twentieth of a grain every four hours, combined with some acid preparation. Sodium bromide in fifty or one-hundred grain doses every three or four hours would break up the insomnia and cause sleep the first two nights.

The withdrawal of spirits should always be followed by a calomel or saline purge, and a prolonged hot-air or hot-water bath, followed by vigorous massage. Hot milk, hot beef tea, and in some cases hot coffee were very effectual. If the patient persisted in a gradual withdrawal of the spirits, strychnine, one-twentieth of a grain, should be given every two hours, and the purge and hot bath should be given every day while the spirits were continued. The form of spirits should be changed from the stronger liquors to wines and beers. Some of the medicated wines were useful at this time, or spirits served up in hot milk. The two conditions to be treated were poisoning and starvation. Food and tonics were indicated for the second condition, calomel purges and baths for the first.

Dementia, melancholia, paresis, tuberculosis, rheumatism, and neuritis were forms of disease which frequently appeared after the withdrawal of alcohol, and whether they had existed concealed by the anæsthetic action of alcohol, or had started up from the favoring conditions of degeneration caused by spirits, was not known. The therapeutic requirements must reach out to meet all these unsuspected diseases, which might appear at any time.

While the ostensible object of medication was to stop the drink craze, this was as far from being curative as the suppression of pain by a dose of opium. Conditions which caused the disordered nerve force to concentrate in cravings for the anæsthesia of spirits had to be neutralized and prevented before a cure could be expected. The use of narcotics and drugs to check the desire for spirits at the beginning was tem-

porary and always uncertain. Opium, chloral, and cocaine given freely at this time often simply changed the drink craze into a craving for these drugs, which were used in the place of spirits ever after.

Premonitory symptoms of a drink storm could, according to the case, be met with calomel and saline cathartics, prolonged baths, rest or exercise, cinchona and iron tonics free from spirits, or some of the coca compounds. Tinctures of any form were dangerous. The masked character of inebriety made it dangerous to use narcotics beyond a certain narrow limit. Persons who had been subjected to active drug treatment to suppress the desire for spirits were feebler and more debilitated than others. Those who had taken the so-called specifics were marked examples, and, whether they used spirits again or not, they were always enfeebled and pronounced neurotics.

The present empirical stage of treatment should rouse a greater interest and bring the medical treatment of inebriety into every-day practice. Then the family physician, and not the clergyman or quack, should be called in to advise. A new realm of medical practice was at our doors, only awaiting medical study above all theory and exclusively from the scientific side.

The Surgical Relief of Obstruction of the Common Biliary Duct by Calculi.—DR. H. O. MARCY, of Boston, in this paper related the circumstances which led up to his operating in 1884 for the first time for calculous obstruction of the common duct. Prior to that time operation on the common duct had been regarded as impractical. Having attended about three cases before that date which had resulted in death, he made up his mind to operate should another case come under his observation, and this occurred in 1884. However, he was unable in that instance to dislodge the stone in the common duct, and predicted that the patient would some time have another and fatal attack of complete obstruction, although the symptoms were relieved on this occasion; and so it proved. His first entirely successful case was in 1889—a calculus weighing fifty-nine grains was removed, and the woman was living and well to-day. The operation was now regarded as not only admissible but as mandatory.

A New Microtome.—DR. SIDNEY YANKAUER, of New York, described a new microtome, which could be sold for between \$5 and \$10, whereas those on the market cost as much as \$50. He also showed a plaster-of-Paris bandage cutter, and explained on mechanical principles the inefficiency of the knife and scissors.

The Physiological Deductions Regarding the Usefulness of So-Called Animal Extracts.—DR. H. A. HAUBOLD, of New York, in a brief paper considered the possible physiological action of the animal extracts, prefacing his remarks with the statement that their use was not new, for Pliny asserted that the Greeks and Romans ate the testicle of the donkey as a remedy for impotence. The conclusion arrived at by the author was that the animal extracts acted as medicines and not as foods; they, including nucleins and protonucleins, did not furnish the blood with elements from which the tissues could be more readily built up than from elements in ordinary diet. They certainly were not deposited in the system, where they obtained root and grew, unless they were taken through the digestive tract and blood. If not so taken, their action was as that of a foreign material, of which the system tried to rid itself.

One Point in the Treatment of Endometritis.—DR. W. H. ROBB passed hastily over the anatomy of the uterus and then arrived at the object of his paper, which was to direct attention to the value of nitrate of silver in the treatment of endometritis. This was not new, but the remedy had fallen largely into disuse.

He did not wish to be understood as advocating it in all cases or as the sole remedy. Each case must be treated according to its merits. Weak solutions were sufficient in the early stage and in mild cases, while the solid caustic was reserved for chronic granular conditions.

DR. BROOKS said that to his mind there was no fallacy greater than the cure of endometritis with nitrate of silver, particularly with the stronger applications. There might be a temporary result which looked like cure or improvement, but the after-result was likely to be worse than the original condition, as had been pointed out by an eminent gynecologist under whom he had studied.

DR. J. H. CALEF, of Connecticut, had made it a custom to examine the secretions bacteriologically in endometritis, and had found that the congested and thickened lining membrane, with its secretions, made a good culture bed for various germs. A great many of the germs were killed by even a weak solution of nitrate of silver, say 1 to 1,000 or 3 to 1,000.

DR. W. M. BENUS had found the galvanic current valuable in dissolving the mucus adhering to the endometrium in the catarrhal condition, thus enabling him to remove it. Peroxide of hydrogen also aided.

DR. JOHN CRONYN approved of the use of nitrate of silver in some cases, and had not understood that the author made use of it in all. Curetting was a fearfully abused operation.

A Class of Fatal Cases, Presumably Due to Intestinal Ptomaines.—DR. E. D. FERGUSON, of Troy, read the paper. It will appear in a future issue of the MEDICAL RECORD.

Address on Surgery.—DR. CHARLES PHELPS, of New York. "It is proper that we should celebrate with form of words the splendid achievements of our immediate predecessors and of our contemporaries; it is pardonable if our exaltation has been sometimes voiced in too magniloquent and resounding phrase, and not always tempered by a generous remembrance of the struggles and successes of a remoter time. The present supposed renaissance of medical art is but a somewhat sudden increase in the energy of an irregular but ceaseless development. It is unimportant to the present consideration of medical or surgical art to disentangle its history from early fable and mythological romance, to determine to what extent it existed in an epoch of barbarism or in a subsequent era of mediæval superstition, or even to define the period in which it may be deemed to have acquired a scientific basis. From the seventeenth century, at least, the inclusion of medicine in the field of positive, if not exact, sciences is beyond question, and its continued advancement a matter of record. The successive discoveries of the circulation of the blood, of the efficacy of vaccination, and of the possible annihilation of pain by anaesthesia are imposing landmarks along the path which has been travelled. And all through this time the gradual evolution of a rational system of treatment of disease and a progressive improvement of methods of surgical interference are sufficient evidence that the advance has been fairly uninterrupted. In American colleges and universities, even of the higher grades, the extent of classical and rhetorical study demanded has been more and more circumscribed, until undergraduates are now practically permitted to pursue such exclusive lines of work as in their unguided opinion pertain directly to their future occupation. The surrounding condition of mental action, and perhaps the contemporaneous mental constitution, incite to scientific investigation rather than to endeavor in the higher planes of literature. It follows that the arts most sedulously wrought and scientifically developed have been mechanical, industrial, or in some sort utilitarian, rather than æsthetic. The gentler arts of oratory and

poesy and of letters have not only failed of advancement, but have suffered decadence. It is not only natural, but inevitable, in an age characteristically occupied with an improvement of physical conditions, that the art most directly concerned with the integrity and prolongation of life, without which all other material advantage is naught, should command great attention, make great progress, and receive great honor."

The progress of surgery in times of war was then mentioned. The work of bacteriologists since Pasteur's discovery twenty-five years ago had been devoted largely to establishing the dependence of various diseases upon the action of specific germs. "It is evident," the author said, "that the present disposition to direct medical and surgical investigation straight to its ultimate object, the cure of disease, while it has grown out of the mental attitude characteristic of the time, has been greatly strengthened by the fact that the conditions have been made favorable by work previously accomplished. Clinicians and pathologists have so strongly established premises that the time has been ripe for conclusions. The present system of aseptic surgery has resolved itself into an attempt to reach an ideal condition of cleanliness by the employment of specific agencies. The discovery of facts which have reduced sanitation and public hygiene to an almost exact science, and of the laws which govern the inception and development of infectious diseases, have in themselves alone effected a greater saving of human life than have all other recent advances in medicine combined; but an estimate of the progress of therapeutics would be inadequate which failed to recognize the services which have been rendered in other ways, and which are to be accounted only by comparison." In this connection, the author mentioned such measures as the use of Murphy's button, Maunsell's method of circular enterorrhaphy, laboratory and special work.

"The extension of medical knowledge and the perfection of medical art may not now demand the forces of originality or the use of the highest forms of intellectual power, but the vast progress made is not less worthy because the field is open. The conditions of progress are still unchanged. The knowledge gained in the past has not yet been entirely utilized for the purposes of the present, and methods of investigation and of procedure for practical realization of its results which still obtain promise to be sufficient for the immediate future. It is possible that entirely new departures may be taken for incursion into the realms of disease, but the branching of the ways is not yet in view."

About half of the paper related to business methods and ethics of the present age. "The ethical side of the profession is less admirable," the author said, "and less satisfactory as a subject for observation. It is not only the methods and purposes of scientific investigation which reflects the characteristics of the age, but no less the manners and morals of the professional men. The age is pre-eminently commercial, and all phases of life assume a corresponding tinge, especially in America, where manners and modes of thought have remained in an exceedingly impressionable condition. The indispensable condition to business success is to 'hustle,' and it has been largely adopted as a rule of action in the pursuit of medical practice.

"The medical art, when inspired by sympathy and guided by a full sense of its serious responsibilities in the relief of suffering and in the preservation of human life, yields precedence in the sacredness of its mission only to the ministrations of the Church, and is worthy of the chivalric regard of the best of men; but practised as a simple business occupation, and degenerated to a vulgar scramble for the gain it brings,

it is but a carrion trade, and they who practise it are no longer ministers of mercy, but prowlers in the shadow of the tomb, who find their profit in disease and death and fatten on decay."

Two Interesting Cases of Surgery of the Kidney.

—DR. JOSEPH E. JANVRIN, of New York, read the histories of the cases. He said one brought up the question of the proper treatment of pyelitis and abscess of the kidney when the organ was diseased throughout. The first case was one of multiple abscess of the left kidney complicated by Bright's disease with septic symptoms, in which he removed that kidney, but the patient died from sepsis and uræmic poisoning six days after the operation. The case was in a woman who was paralyzed from myelitis and had cystitis. The only question which could arise as to the treatment was whether he ought to have simply drained the kidney after cutting down upon it, or remove it, and to his mind its removal was absolutely demanded. The second case was one of fibro-lipoma which had developed from the capsule of the left kidney, the kidney itself not being damaged. The patient made a good recovery after removal of the tumor, the kidney being left.

The Palliative Treatment of Cancer of the Cervix and Bladder in Women.

—DR. NATHAN G. BOZEMAN, of New York, in this paper confined his remarks to the treatment of cancer of the cervix and bladder in the stage of the disease when an operation could not be considered and any treatment resorted to could only be for the alleviation of suffering. These women complained most of hemorrhage and foul discharge from the vagina. Digital examination frequently caused excessive bleeding. It could be controlled by putting the patient in the knee-chest position and packing with gauze containing an antiseptic powder. This was to be renewed three times a week, and the douche was to be employed for cleanliness. The most difficult cases to manage were those in which the bladder was involved. The first manifestations were severe cystitis, excessive vesical tenesmus, and frequent urination, but when perforation took place the urine found a free outlet, the bladder was given physiological rest, and the painful symptoms disappeared. For these cases Dr. Bozeman had had an apparatus constructed for continuous drainage and irrigation of the bladder. With the catheter introduced through the fistula he connected a rubber tube through which there was a constant (or intermittent) but slow flow of water from a gallon bottle, the tube always being full of water.

Summing up, he said there were three points to be observed: 1. Keep the seat of disease in an aseptic condition. 2. Counteract narrowing of the vagina in front of the disease. 3. When the bladder was perforated, use an efficient method of irrigation and drainage. He used distilled water, and to this one could add, if he wished, some disinfectant.

DR. JANVRIN discussed this paper.

Bromides as a Cure in Diphtheria.

—DR. ROBERT ABERDEIN gave personal experience with bromides in the treatment of diphtheria, he having begun their use in that disease in 1888. Speaking of one case, he said he prescribed two drachms of bromide of ammonium in four ounces of water, directed that the mouth be washed out with warm water, and then with a teaspoonful of the bromide solution, after which a teaspoonful should be swallowed. This was repeated every two hours, and a piece of salt pork was put on the throat from ear to ear. Out of thirty-six cases treated with the bromide he had lost only two, and in the two cases he did not attribute death to diphtheria, as it occurred suddenly and in syncope after the throat had cleared up. He regarded the remedy as almost a specific, and had not found it necessary to resort to antitoxin, although he was not prejudiced against this agent.

Recent Investigations Concerning Eclampsia.—

DR. WILLIAM T. LUSK made some verbal remarks upon this subject. His recollection was that he had read a paper composed by a gentleman in the city stating that by watching the urine and the symptoms it was possible to anticipate every case of eclampsia, and possible with this preparation to prevent any woman having a convulsive attack. It was stated that if the urea fell below a certain percentage, premature labor should at once be induced and convulsions would thus be avoided. Dr. Lusk had seen a patient who had had convulsions in a previous pregnancy. In the present pregnancy she went along four months; then a little albumin appeared in the urine, and in view of past experience it was thought advisable by her physician to bring on premature labor. Digital dilatation was employed, then rapid dilatation according to what he believed was now termed surgical methods in obstetrics. The fetus and placental membranes were removed and the uterus was packed with gauze. Then Dr. Lusk was called to see her because she had most profuse hemorrhage. She survived, but for twenty-four hours it did not seem possible that she could live. This was a case in which there was a little albumin in the urine, but not a single symptom, and Dr. Lusk thought it would have been wise had the physician clung to the old method and left the pregnancy undisturbed.

He had seen a case in which there was a trace of albumin in the urine and was told the urea was two and a half per cent. In the old physiology this amount and upward was a normal average of urea, and the pregnant woman was passing a large quantity of water. But he understood that this patient must have abortion produced, otherwise she would with this percentage of urea finally suffer intoxication, and the wary man always anticipated these things and brought on abortion. But Dr. Lusk did not quite concur; the pregnancy went on, a baby was born at term, and the woman did not have a symptom of any kind.

After relating another somewhat similar case, Dr. Lusk said there were certain things to be borne in mind. First, there were a great many cases of albuminuria which did not have eclampsia. There were a great many cases of eclampsia which did not have anything in the urine. Urea could be injected in quantities without producing convulsions. There were a great many poisons the result of tissue changes, and they were produced in greater quantities in pregnant women, and a small quantity retained in the system might produce serious results. These poisons seemed largely to defy chemical analysis.

Dr. Lusk still preferred the use of Barnes' bags in inducing labor. He had not tried *veratrum viride* in the treatment of convulsions, but thought he would, especially as it received a great deal of consideration at the recent gynecological congress at Geneva, the Italian and also the French physicians having taken it up with much enthusiasm.

DR. SQUIER discussed the action of *veratrum viride*, saying that it, like blood-letting, reduced the arterial tension, and a recent article attributed to high tension alone, even aside from the presence of poisons in the blood, tendency to cause convulsions. He said there was a marked difference between *veratrum viride* and *veratrum alba*, the latter being the drug used in Europe, while the former was found and used in America. The use of *veratrum viride* in eclampsia started with Dr. French, in Brooklyn, and the greatest trouble which had come from its popularity was its administration in too great doses. Five to ten minims of the officinal extract was large enough a dose, to be repeated in ten or fifteen minutes, if necessary, and in less amount at subsequent doses.

DR. FRENCH said there were three brothers of them

at the time *veratrum viride* was first used, and they employed a tincture which they made from the fresh root dug late in the fall or early in the spring, when the root contained a minimum of water. He employed this agent and blood-letting, and should continue to do so as long as he never lost a patient. But he was never called to a case without fearing that he might lose it.

The Duty of the Public to the Physician.—DR. WILLIAM M. BEMUS gave in this paper a review of the facts of the common law bearing on the responsibility of the physician and a part of the statute laws relating to the subject. His attention had been directed in this line by a suit brought against him for a Colles fracture by a charity patient urged to do so by a lawyer who first thought she could sue the city but found suit barred by the expiration of the statutory time. After the plaintiff had produced her witnesses, the judge deemed it unnecessary to hear the defence and directed the jury to find for the defendant. But the patient had no money to pay the costs.

DR. DIDAMA called attention to the fact that at present the plaintiff was required to furnish bonds to pay costs in case the verdict was against him. DR. FERGUSON, DR. HARRINGTON, and other gentlemen made some remarks.

A Plea for the General Use of Measures to Prevent Ophthalmia Neonatorum.—DR. A. A. HUBBELL, of Buffalo, in this paper reviewed statistics on blindness in various countries, showing that a large percentage of the cases originated in purulent ophthalmia of the newly born; mentioned the efficacy of its prevention by different methods, especially Credé's, when employed in maternities and in private practice; referred to laws compelling the use of the Credé method under certain circumstances in this country, and urged its universal use, or the use of some method found by experience to be efficient. In Paris certain doctors had employed insufflation of iodoform powder into the eye of the newly born with, they claimed, better results than with the Credé or nitrate-of-silver method. The latter consisted in dropping one drop of a two-per-cent. solution of nitrate of silver into each eye of the baby just after birth.

Supplementary Notes upon Tendon Grafting and Muscle Transplantation for Deformities Following Infantile Paralysis.—DR. S. E. MILLIKEN, of New York, read the paper, which will appear in a future issue of the MEDICAL RECORD.

Auscultatory Percussion.—DR. LOUIS L. SEAMAN, of New York, read a paper supplementary to one which he had read before the Academy of Medicine some years ago, describing an instrument for auscultatory percussion, more especially for use over the chest, but also over the abdomen. It consisted of a hammer, which made the stroke by action of a spring. It was placed within the cylinder, to which an Edison phonograph sound magnifier was attached. The latter could be used alone, and was being much employed in Europe independently of percussion.

Neuralgia of the Peripheral Nerves, with Special Reference to That Dependent on Trauma or Degenerative Changes.—DR. THOMAS H. MANLEY, of New York. "At the very threshold of this study it becomes necessary that some sort of comprehensive definition be given of neuralgia, in order to demonstrate that such a pathological entity exists at all. From the standpoint of pathology it may be open to considerable doubt, as the groundwork of our views on this malady, which manifests itself through the nervous system, rests rather on clinical phenomena than on anatomical changes of the molecular or corpuscular elements in the cerebro-spinal axis. It therefore follows that as the histopathology of that condition recognized under the name of 'neuralgia' is still involved in great ob-

scurity, anything like a scientific classification of its various pathologic divisions dependent on cellular changes is quite impossible. This difficulty was appreciated when the present contribution was undertaken. My aim has been rather to record clinical observations and curious phenomena than to branch off at length into the domain of speculation or hypothesis.

"Nerve trauma: It has always been an interesting question to me what share of disorganization a nerve sustains in severe trauma, in injuries especially of the major articulations or the members, in entasis, sprain, dislocation, or fracture; what the degenerative power of a damaged nerve is; and what the remote effects on it are which may at an ultimate date follow.

"Nerve degeneration through vascular changes, dependent on tension or compression of the nerve trunks: A large nerve trunk is not a highly vascularized structure; and hence atrophic changes follow rather as a consecutive condition dependent on the vascular elements in the ganglionic centres or the peripheral terminals. But are the nerves alone the media of the transmission of vitalizing influences, of sensation and motion, and of all other vital phenomena connecting the centres of life—the brain and heart—with the extremities and the organs? Or do not the ventricular or meningeal fluids of the brain, with the moving blood current, participate actively in the function of animal magnetism, in the efferent transmission of impulse or sensation? During the past fifteen months in my own researches and experiments on the hæmic elements in the living animal I witnessed such evident influence of the corpuscular elements as to leave no doubt in my mind that a vital nerve must be animated by living blood.

"Anatomy of the nerve trunks: A complete nerve, functionally considered, consists of a root and ganglion—the central source; a shaft, or conductor; and the terminal filaments, or ramifications. All the cerebro-spinal nerves, as they pass out through passages of the cranio-rachidian cavity, occupy openings in the base of the skull and the jointed borders of the vertebral apophyses. All the larger primitive medullated nerve trunks are very rich in a reticulated fibrous stroma. The resistance of these nerve trunks is something quite extraordinary; which goes to show that the generally accepted notion, that nerve tissue is brittle and fragile, is a fallacy.

"Neurectasia, or nerve-stretching, is a very ancient device for the relief of severe neuralgia; but Tillaux and Trombetta have employed it to determine the relative resisting power of the larger nerve trunks. Trombetta's experiments were all made on the living subject. Tabulating his experiments on this topic, he found that it required an average of eighty-four kilograms—two hundred and thirty pounds—to rupture the sciatic nerve. The tough, resisting characters of the nerves are what tend to impart to them their marvellous physical tolerance and enables them to survive the longest after the violent injury of a limb, the nerve being the last to perish. The experienced surgeon, familiar with this fact, well knows that, however hopeful other signs may be, when total abeyance of all neural phenomena is present, the crushed or mangled limb is irretrievably doomed and must be sacrificed.

"Neuralgia of the periphery dependent on senile degenerative changes or structural alteration concomitant with advancing age: The physiological anatomy of the body, from its earliest development to the end of life, embraces evolution and involution, the raising up and pulling down of developmental structures. The infant is born hairless and toothless, probably sightless and deaf, able to digest liquids only, and is guided in movement quite entirely by instinct. During the period of growth, the shape, the relations, the resistance, and the volume of various structures and or-

gans undergo the most radical changes. After maturity the onward course of structural changes varies widely in different individuals, depending on heredity, environment, habit, climate, and occupation. From the twenty-fifth to the forty-fifth year no very marked gross changes are noted in the body; however, degenerative and senile changes are subservient to no unchanging laws, and hence years are not always a criterion of age. The first of the tissues to show signs of atrophic waste are the areolar, the adipose tissue, and muscle; then the bones shorten and harden, the capillary openings between the diploic system and the pericranial plexus of veins are entirely obliterated, the cavernous passages in the bones and all the foramina through which the nerves emerge become contracted and greatly narrowed. This is notably the case in the bones of the head and spine. It is now interesting to inquire what share this reduction, condensation, and distortion may have as a factor in degenerative changes, by a continuous and ever-increasing pressure on the nerve roots. Is it a prominent etiological factor in many of those severe neuralgic seizures? It will hardly do to invoke neuritis as a cause, inasmuch as a primary inflammation of nerve substance is denied by many prominent pathologists. There can scarcely be a doubt but this senile shrinkage, in embarrassing the vascular current and compressing the nerve elements, leads to other ultimate degenerative changes and well-marked functional disorders; in fact, it requires no stretch of the imagination to comprehend the relations of cause and effect in the degenerative changes here enumerated. After middle life, reversion of outline with a progressive diminution in length of the spine is obvious, when it is commonly said that the individual has "grown smaller." At this period the human machinery begins to show signs of wear, and the whole nerve structure suffers.

"In the above brief notes my purpose has been to revive an interest in the study of the peripheral neuralgias. The subject is attended with great difficulties, because the physiology of the complex nerve functions is yet in many important particulars unsettled. In the types of neuralgia here considered, the degenerative or senile theory enunciated may account for at least one important etiological factor, emanating from mutations attending the process of involution. It affords a material basis for inductive reasoning, which may open the way for a more rational therapy."

Temperature an Element in Prognosis.—DR. JOHN SHRADY read a paper entitled "Temperature as an Element in Prognosis," in which he discussed somewhat at length the various phases of heat phenomena, particularly in relation to the attribute of force. He drew attention to the interchangeability of the terms applicable to electricity, motion, and last, not least, chemical affinity. He regarded man as a walking laboratory—which, indeed, was by no means an original view—since his functions would be inoperative without elementary changes, the outward registry of which was justly entrusted to the thermometer. It could not be gainsaid that every phenomenon, both organic and inorganic, was governed by fixed laws, the operation of which was often misconceived, although the analogies of heat, light, and electricity aided somewhat by the present vogue of their study. The only trouble, as pointed out by Paget, was that we became embarrassed by numerous exceptions, through failure of making the law sufficiently comprehensive. Much yet was to be learned in the language of temperature, and such language could be gained only in the comparative school in connection with other branches of science. For this reason, all on account of the unchallenged appeals to the eye, he could do nothing else but accept the thermometer as the greatest of the instruments of precision. What is called science is

the court of last resort, and it will adjudicate between the claims of the organic and inorganic, on the basis of a compromise between force and resistance. In all these cases of disputed sovereignty, heat more than rhetorically represents the fury of the battle. At all events, thus far observers and experimenters have won glory as strategists of the campaign, without founding a new empire. The same immutable laws prevail, notwithstanding their unsatisfactory interpretation and application. Yet, because investigation has been without very material result, should it therefore be abandoned? The phenomena of heat, therefore, should be studied on the basis of the laws which govern material force. He quoted from trustworthy authorities many high temperatures in acute diseases, and corroborated in the main the view that in themselves they were not especially fraught with danger or in general portentous of evil. The involvement of special nerve centres, or, as Musser has been pleased to style it, the thermo-toxic apparatus, does not bring much hope or consolation, nor give much time for any but reminiscent measurement. The temperature peaks, sharp and precipitous, explode at a very high apex with a dismal chasm at the end of the range. In many and by far the most numerous cases, the gauge marked intensity only. It was the brisk, crackling fire, and not the low, smouldering one, on point of extinguishment through abstraction or loss of material, which gives the glow of comfort. In these last cases of the subnormal, care should be taken to observe both the central and the peripheral temperatures, for even a chill may be misleading, as many have been surprised by the per-rectum test with readings of 107° or 108° F., recovery not therefore on that account to be un hoped for. It is the subnormal temperatures which are really alarming, those, in fact, obtained after the precautionary shakedown of the thermometer, at least, say, to 95° F.; the normal thin red line will not answer. The extreme ranges, zigzag and with short curves, constitute the stenographic writing upon the walls. Of course, the respiration and circulation are not to be unstudied, nor conditions, environments, and the teachings of bacteriology; but as careful engineers it behooves all to watch well the heat-gauge, or, at least, the stop signal of the track walker, for the thermometer does not well brook contempt. It has its revenge in uncanny dooms. Above all, let not the prophet entirely despise the honors which may be his due.

Officers Elected.—*President*, Dr. Charles Phelps, of New York; *Vice-Presidents and Members of the Council by Districts*: 1, Dr. R. N. Cooley and Dr. John P. Shearer; 2, Dr. E. M. Lyon and Dr. T. H. Hannon; 3, Dr. Robert Aberdein and Dr. L. J. Brooks; 4, Dr. A. A. Hubbell and Dr. W. M. Bemus; 5, Dr. C. E. Denison.

Correction.—By a mechanical transposition a portion of the proceedings of the section on surgery of the College of Physicians of Philadelphia in the *MEDICAL RECORD* of October 17th, p. 560, was included in the report of the meeting of the Schuylkill County (Pa.) Medical Society.

Rise in Temperature after Labor.—Dr. Machure (*The Canadian Practitioner*, August, 1896) says: "For twenty-four or thirty-six hours after labor the temperature may be elevated as the result of fatigue, but if the subsequent temperature should be above 99° F., its cause should always be promptly investigated. It may be due to (1) constipation, (2) mammary disturbances, (3) intercurrent non-obstetric disease, or (4) sepsis."

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 6, 1896.

B. SACHS, M.D., PRESIDENT.

A Contribution to the Study of Motor Aphasia.—

DR. B. ONUF read a paper with this title. He said that during the last few years the writings of various authors had shown the necessity of harmonizing the conclusions of the two principal methods of studying language. He was of the opinion that the strictly anatomical and psychological theories must be blended with one another. The following case of cortical motor aphasia was then reported:

Mrs. S. D.—, twenty-three years of age, had an attack of acute articular rheumatism three years ago, during which she probably acquired an endocarditis with valvular lesions of the heart. On June 7th, after a miscarriage, she had an attack of embolism, followed by hemiplegia of the right side and involving the right arm, and particularly the hand and fingers. She said that the understanding of spoken language was unimpaired, but this statement should be taken with some allowance. He had first seen her on April 3d. At that time there was slight disturbance of motor speech—*i.e.*, slight difficulty in finding the words, and an occasional misuse of words, or an improper construction of sentences. She had difficulty in giving the name of common objects presented to her. Aside from these disturbances there was marked defect of the faculty of reading and writing, individual letters of the alphabet being frequently mistaken. She found it, as a rule, easier to read the word *in toto* than to spell it. The word "one," for example, was pronounced correctly, but spelt "won." In the writing, which was done with the left hand, the patient used printed characters, both in copying and writing from dictation. The auditory impressions received from loud reading undoubtedly helped her understanding, and enabled her to read words which she could not otherwise. There were absolutely no visual disturbances—no hemianopsia and no narrowing of the visual fields. Apparently there were no gross lesions of memory.

The author then referred to the researches of Bianchi on the removal of the frontal lobes of monkeys. He concluded that the frontal lobes were, so to speak, the centre for intelligence and constituted the organ in which the various sensory and motor images became co-ordinated and fused. The destruction of this portion of the brain results in the destruction of the anatomical basis upon which judgment and the reasoning faculties reside. Until recently, Broca's centre had always been considered, he said, as motor, and its anatomical position would not contradict such a view; but, on the other hand, the function of this centre is so much more complex than that of the parts composing the motor district proper that one hesitates to place it under this head. Broca's centre, the reader said, is a centre of the higher order, presiding over the functions of the larynx, tongue, and lower part of the face, and probably also has at the same time the function of fusing sensory and motor elements, and must be considered as a part of the frontal lobe in the sense of Bianchi's definition. This view found further support in his own observations. He reported a case of a man whose speech had been suddenly affected, so that he spoke very thickly and could hardly be understood. There was no real aphasia, for he knew what he was going to say, and always succeeded in saying it, but the words were very much blurred. Five days later he died with symptoms of congestion of the lungs. On post-mortem examination, a blood clot was found at the level of the lower part of the ascending frontal and ascending parietal

convolutions of the left hemisphere. Almost all the cortical substance of these convolutions had been destroyed, but the third frontal convolution had been left intact.

With the exception of the old theory of Wernicke, of the existence of a special speech tract connecting the speech centre directly with the nuclei of the medulla, a pure type of subcortical aphasia could not be conceived. Wernicke had himself abandoned this theory. He compared the process of acquiring speech to a reflex process, but the part which visual, tactile, or muscular sensations might play in the acquisition of speech were not at all considered by this author. Careful analysis, however, showed that the tactile and muscular elements had a much more direct influence than the visual. The acquisition of such sounds as could be learned by watching the motion of the lips was the easiest of all. The auditory element informs the speaker as to whether the utterance is what was intended, while the tactile elements help to make such utterances possible and more and more correct. It must be assumed that Broca's centre takes part also in this process. Each innervation of Broca's centre is conveyed to the centre of the auditory word images, but each innervation of the auditory centre is not necessarily carried to Broca's centre. The child is taught to associate a certain letter with an effort necessary to enunciate the proper sound. A direct association between the auditory and visual image is not absolutely necessary for the mental act of reading; it is very probable, on the other hand, that a direct association forms between the visual and the psycho-motor image, which latter innervates the auditory image. When we read, we have a distinct impression that the psycho-motor images are first aroused. The faculty of reading depends upon the intactness of Broca's area equally with the intactness of the centre of auditory word images; hence, a lesion of Broca's centre must cause not only motor aphasia but alexia. On the contrary, subcortical motor aphasia leaves internal language and the faculty of mental reading intact. The motor conceptions can be acquired without any association with the speech organism. The writing of a word implies the ability to spell it. Only for the writing of single letters at dictation the possibility remains that the auditory image affects directly the graphic concept. Cortical motor aphasia implies not only alexia but also agraphia. Bastian distinguishes three states of lessened excitability of the centre, viz.: (1) That in which it does not respond to volitional excitation, but can be excited by association from one centre to another; (2) that in which the centre responds only to direct sensory stimuli; and (3) that in which even these direct sensory stimuli fail to excite the centre to activity. If there were a contiguous and continuous zone of language, as some have thought, then any lesion within this centre ought to cause actual aphasia. The fact that a lesion within the centre of language causes no aphasic disturbances speaks against the continuity of this zone.

In the case reported in the paper it was easy to understand, Dr. Onuff said, the occurrence of motor aphasia with alexia and agraphia, if we supposed that Broca's centre was involved. This view found further support in the fact that many cases of motor aphasia with alexia had been reported in which the aphasia had been almost entirely recovered from, while the alexia had remained. He could not answer, however, the question, why in this and many other cases the aphasia was recovered from sooner than the alexia. The observations in this case would go to show that most of the words are read as a whole, and not by spelling. It was certainly not possible in the English language, because of the variety of ways in which certain groups of letters are pronounced in different groups. In

learning Russian he had himself begun to read before he had been entirely familiar with the letters of the alphabet. Although to a certain degree he had to read the language "spellingwise," he still recognized many words by familiar combinations of letters and by the sense. He believed that the reason his patient used printed characters solely was that there was a loss of motorgraphic memories. The visual memories for printed signs are usually much better established than those for script, for the reason that reading is chiefly done from printed characters. That muscular sensations play a very important part is shown by the fact that we can write with the eyes shut. If we are warranted in speaking of a motor speech centre, we must be justified in speaking of a physiological apparatus in which muscular graphic memories are stored. Loss of these memories does not imply absolute impossibility to write, as visual memories may supply the deficiency. It is not supposed that the lesion may destroy the motorgraphic memories only and leave intact the other motor faculties connected with the hand and finger muscles. A patient with a lesion of Broca's centre can understand what is said to him, but he has lost the power of inwardly repeating what has been said. The motor speech centre forms such an important factor in the evolution of the higher mental processes that its lesion cannot remain without damaging influence on the mental activity.

Discussion.—DR. JOSEPH COLLINS said that he agreed for the most part with the views expressed by the reader of the paper. Certainly the paper served still further to confirm the views expressed by Bianchi. Personally, it seemed to him that all that a study of aphasia could do was to help the pedologist. We could do a great deal for psychology by working in the field of aphasic disturbances. He could not agree with Dr. Onuff that a person having pure motor aphasia had complete inability to read. It did not seem to him that it was necessary in order to read to translate what we read into articulated words, and he thought he had one or two cases under observation at present which would abundantly substantiate this statement. One patient was completely aphasic, yet he could write prolifically, and was able to read understandingly both his own writings and those of others. He certainly both read and understood these writings; hence, the speaker said, he could not believe that with pure and complete motor aphasia there is necessarily alexia. He did not think there was any objection to subdividing the motor speech centre into an articulo-motor centre and placing adjacent to it the centres for phonation, labial movements, and buccal movements.

THE PRESIDENT said that his individual experience with aphasia had been a rather curious one. At first, he had been impressed with the writings of Jackson and Bastian. Then had come the German school with all sorts of mechanical theories, and now we all felt the need for returning to a mixture of the psychological and the mechanical theories. On the whole, he was in entire agreement with the views expressed by the reader of the paper. Recently he had observed the progress of a case in which aphasia was the sole symptom of a cortical tumor. The manner in which it progressed would seem to justify fully the subdivision of the motor speech centre, and also to show that speech is not the function of any one centre or any series of centres, but that it is really the result of a very close union of these centres by distinct association tracts. If this were not so, a relatively small lesion could not explain the variety of symptoms observed in a single case. The case referred to was that of a lady who had been carefully observed by her brother, who was a physician. The first thing noticed was an apparently slight apathy, but this was really

due to a difficulty in speech. When first seen by Dr. Sachs, about three months after this, it was found that she had lost the faculty of using nouns, so that she could not give the names of those persons best known to her. After a while the difficulty of speech became more distinct; there was great difficulty in finding words. Toward the end only was there a distinct deficiency in the understanding of language. From the very first her brother had noticed a distinct difficulty in reading, and a still greater difficulty in writing. He had never seen a patient able to speak so much and yet be unable to name or even to copy single letters. She could, however, write a whole name fairly well. Such a case seemed to show the necessity for a further subdivision of the motor area. The paper of the evening was of value as a corroboration of Bianchi's views. It showed that we were gradually turning to larger divisions rather than to the small localization areas which we employed as a result of the teachings of Ferrier.

DR. OXFORD, in closing the discussion, said that he distinguished two forms of aphasia—cortical and subcortical motor aphasia. The latter was also called pure motor aphasia. In cortical motor aphasia it was assumed that the cortex where psycho-motor images of speech are deposited is affected. Subcortical aphasia is one in which there is an impossibility of loud speech, but internal language remains intact; hence such persons can read and write perfectly. He believed the cases referred to by Dr. Collins were examples of subcortical motor aphasia.

The Commitment of Patients and the New Insanity Law.—DR. G. W. JACOBY read a paper on this subject. He said that under the name of "the insanity law" there went into effect a new law in July of this year. In his opinion the framers of the law had totally failed to unite the postulates of jurisprudence with those of medicine—indeed it would seem that they had intentionally ignored, as far as possible, the medical side of the subject. The medical certificate no longer serves for the temporary detention of the patient for five days. The responsibility for the commitment has been removed from the shoulders of the physicians to those of the judge, and a matter which is essentially medical has been transformed into one chiefly legal. This law also provides that at least one day before the physician presents his application to the judge the patient is to be informed of the proceedings. This personal service can be omitted under certain circumstances, according to the discretion of the judge. After all the necessary legal preliminaries have been taken, the superintendent of the institution to which the patient is committed may refuse to accept the patient on the ground that he does not consider the person insane, or that the papers are not made out properly. There is also a provision for an appeal from the decision of the judge and a trial by jury. The old law was much better, particularly on account of its provision for temporary detention. The provision which takes away every method of procedure except appeal, when the application is refused, is a particularly objectionable feature. Personally, he would not be satisfied with an insanity law which would not allow of the temporary commitment of the person on the strength of medical certificates by two qualified physicians, one of whom should have special psychiatric qualifications.

DR. CARLOS F. MACDONALD said that he wished at the outset to disclaim any responsibility for the framing of the new law. It had its origin with a member of the statutory committee of revision. He was the only physician in this State who had opposed the bill before the legislature. During the past seven years, as commissioner in lunacy, he had examined thousands of cases of alleged illegal commitment, and he had

yet to learn of a single case of a sane person being committed through corrupt collusion or through intent, although he had occasionally known of instances of mistaken diagnosis, such as might occur in connection with any disease. He thought that as a rule judges would waive the notice of personal service upon the patient or friend, and it seemed to him a distinct advantage to make the commitment a judicial order rather than a judicial approval, as in this way it relieved the medical profession of much responsibility and the danger of suits for damages. In his judgment, the weakest point was the absence of any provision for temporary detention. A determined effort should be made this winter by the medical profession to amend the law in that respect. Curiously enough, laymen consider themselves fully as qualified as physicians to diagnose insanity, and this new law is an outgrowth of that feeling.

DR. C. L. DANA said that his views were entirely in harmony with those of the reader of the paper, and the society should make it clear that it appreciated the absurdities and many faults of the new law. It had caused an infinite amount of trouble to the city physicians, and the ordinary process of commitment had in consequence become tedious and expensive—so much so that physicians had found it advisable to commit insane persons, as far as possible, to institutions outside of this State.

DR. F. PETERSON said that the new law was objectionable in that the paper must be fully made out and approved by the judge before the patient could be sent to an asylum, and because of the possibility of other difficulties arising in practice, such as had been mentioned. In his own experience, however, the judge had in every instance dispensed with the personal service.

DR. GRAEME M. HAMMOND said that he agreed with the views presented in the paper, and now that the evils had been pointed out it was our duty to consider the best remedy. He hoped the society would take an active interest—for instance, by appointing a committee charged with the duty of urging proper amendments.

DR. L. C. GRAY said that he thought the law was not only absurd but an outrage. It was ridiculous that physicians should submit to lawyers about a matter involving the question of a disease of the brain.

DR. COLLINS said that according to the new law the physicians certified to the insanity of the person, and the judge committed him. This was no infringement upon the rights of the medical profession. He did not think that the gloomy view and the objections presented in the paper were well founded. It was true there were some objectionable features, but they did not appear to him to be of vital importance. The new law offered unusual opportunities for a trial of the home treatment of the insane, so strenuously advocated by some.

DR. L. F. BISHOP said that the new law had given him less trouble than the old law.

DR. HIRSCH said that this law had no counterpart in any other country, for not only the disposal of the lunatic, but the decision as to his insanity was made by the judge, the physicians only giving their testimony. This testimony was given on special blanks which made it far from scientific. It was remarkable that a judge must tell us whether a patient is fit to live with his family, or must be deprived of his liberty because of his being insane and a menace to society. Persons having small-pox or cholera were often forcibly removed from their homes, but in these instances the decision was made by a physician, as it should be, and not by a judge. He thought that the personal service provision was objectionable, and sometimes produced a bad mental impression on the patient.

DR. M. ALLEN STARR said that according to the new law the judge acted entirely upon the testimony given by the two physicians—the physicians' rights were more fully protected than by the old law. He urged that the society should not take an extreme view, but should simply ask that one or two features, which were generally admitted to be particularly objectionable, should be amended.

THE PRESIDENT said that the worst feature was the lack of provision for temporarily detaining acute cases. One result of the new law would probably be the establishment of many private institutions for the care of the insane, which would not be under the control of the State. He had found that it took about four hours to have a certificate signed in this city.

DR. JACOBY, in closing the discussion, said that he did not look upon the new insanity law as an unmitigated nuisance. The judges now take the certificates of the physician simply as testimony additional to that of the petitioner. If an appeal should be taken from the decision of the judge, it was not clear that adequate provision would be made for the patient.

DR. HAMMOND then offered the following resolution, which was unanimously adopted:

Resolved, That the president appoint a committee of five to report to the society such measures as it may deem expedient for securing the amendment of the present lunacy law governing the commitment of the insane."

OUR LONDON LETTER.

(From our Special Correspondent.)

OPENING OF WINTER SESSION—INTRODUCTORY LECTURES—DEATHS OF SIR G. HUMPHRY AND DEAN COPEMAN—A DANGER FOR SANITARY BOARDS—JUBILEE OF ANÆSTHESIA—MALE PATIENTS AND FEMALE PHYSICIANS.

LONDON, October 2, 1896.

THE winter session of our medical schools opened yesterday. In some the time-honored addresses were omitted, as has been the case for several years; in the others the old custom was observed. The addresses were certainly worth listening to by practitioners as well as students, far more so, in fact, than the after-dinner speeches that in some instances have supplanted them. The dinner which was to have been held by the alumni of University College was omitted, in consequence of the death of Sir J. Erichsen. But there was an address by Prof. S. Martin, who expressed satisfaction at the rate of progress of scientific medicine, and that we have passed from the darkness of the sorcerer and herbalist into a clearer knowledge of the processes of disease, and, therefore, the means of counteracting them. The great change that has taken place has been from the speculative to the real, he said, and added that in not a few cases treatment is an experiment—intended, it is true, to benefit the patient, but still an experiment, since all the conditions present in the body are not known, and we watch the result to ascertain new facts. Much treatment is empirical, but not to be despised, since it often gives a clew to the experimental investigation of the morbid process. The lecturer then spoke of bacteriology, which, he said, has taught us the cause of tuberculosis; and he saw no reason why, as knowledge advanced, we should not destroy the sources of infection and deliver mankind from the scourge of centuries. So, too, there is hope that in time cholera also may cease to be a scourge to the race.

At St. George's Hospital, Mr. A. Frost regretted

that a number of men commenced medical study who were really unfit for the profession, and he thought the standard of preliminary education should be raised. Then, as to surgery, some men had no manual dexterity, whereas they should in many cases be ambidextrous. Much clumsiness is due to the ridiculous custom of teaching children to do everything with the right hand—a relic of pagan superstition. The lecturer then passed to the subject of vaccination. Students, he said, should remember that Edward Jenner was a pupil of St. George's. His discovery had saved millions of lives, had stood the test of a century, and its value was admitted by all who were capable of weighing evidence. But its opponents had added the proof of a gigantic experiment upon human lives, with a result so appalling that it should not be forgotten; and, curiously, this experiment was conducted in Jenner's own county, Gloucester—an illustration of the proverb, "A prophet hath no honor in his own country." The royal commission had reported, and although they could not agree whether they should compel people to protect their children from small-pox, or should ask them not to increase the prevalence of small-pox unless conscientious scruples led them to do so, or whether they should have as absolute control of their children's lives as over their chattels, all sections of the commission agreed that vaccination is a preventive. The road indicated by Jenner had been followed by Pasteur, Lister, Koch, and others, and it now remained for students to discover whither it led.

Mr. Morton Smale was the lecturer at St. Mary's Hospital, and a marked feature of his address was an exposure of so-called "patent medicines," on which the British public squanders two and one-half millions of pounds a year. He thought the governmental stamp misled many ignorant persons to believe in these nostrums, and therefore should be abolished, while drugs should be supplied only by qualified pharmaceutical chemists, and no combination of drugs should be sold or dispensed even by such pharmacists except on the prescription of a qualified practitioner.

At the Middlesex Hospital Dr. Essex Wynter first reviewed the course of study, and asked his hearers to think over the important period of their lives in which their studies were to be carried on—a period which covered the transition from dependence on others' guidance to freedom and the assumption of more than ordinary responsibility, including the chief period of physical, intellectual, and moral growth, and of great influence on their future social standing. They must develop their senses, acquire manipulative skill, cultivate capacity for deliberation and prompt action in most disturbing circumstances, and, above all, the habit of patience, kindness, and tact, remembering that

"We are not ourselves
When nature, being oppressed, commands the mind
To suffer with the body."

One after another our friends are passing over to the majority. Just after I had dispatched my last letter, telling you of Erichsen's death, I received the news that surgery had lost another veteran, viz., Sir George M. Humphry, the Cambridge professor who did so much to raise the medical school of Cambridge that he was sometimes spoken of as having created it. He represented the university in the General Medical Council from 1869 to 1889. George Murray Humphry was the son of a barrister and was born in 1820. He was one of the elected fellows of the Royal College of Surgeons in 1844, and practised at Norwich before he went to Cambridge to become surgeon to the hospital and professor in the university, of which he took the M.B. in 1852, and M.D. in 1859. Among the numerous honors he received may be named the honorary membership of various societies, British and foreign,

the degrees of LL.D. and D.Sc., the presidency of the anatomical and pathological societies, and the much prized F.R.S. He was knighted in 1889. Perhaps his most esteemed work was that "On the Human Foot and the Human Hand," but his "Treatise on the Human Skeleton" runs it a close second. Besides "Lectures on Surgery" and numerous contributions to societies and journals, he was the author of "Observations in Myology," "Observations on the Limbs of Vertebrate Animals," and an essay on "The Coagulation of the Blood in the Venous System during Life." Besides these and other works, you will remember his Hunterian oration of 1879, "On Old Age and Changes Incidental to It," which created no small interest in a subject which the distinguished orator was known to have carefully studied.

Another notable death is that of the Rev. A. C. Copeman, honorable canon of Norwich, where, like Sir George Humphry, he practised in his earlier career as a surgeon. He was a member of the College of Surgeons in 1845, and M.B. of the London University in 1848. He became a clergyman and was promoted to various offices in the Church, and continued at Norwich until his death last Sunday. Though he left the profession he retained much interest in it, and on the hospital committee, as well as chairman of the board of guardians and in other positions, gave much attention to the welfare of the sick and the poor. He was in his seventy-fourth year, and the oldest of the beneficed clergy in Norwich except one.

A sum of £2,875 has been awarded by a jury as damages to the representatives of a gentleman who was alleged to have died through the escape of sewer gas into his house, from a flue in the chimney stack erected under the superintendence of the surveyor. This method of ventilating the sewers must necessarily be risky, and as the local sanitary authority has to pay these heavy damages, to say nothing as to costs, other boards will doubtless adopt better methods and forbid their officers to permit this dangerous one.

The Society of Anæsthetists have initiated a movement for the celebration of the jubilee of anæsthesia, and, of course, invite the co-operation of the profession at large.

In consequence of the objections of patients to undressing before women, Mr. Hutchinson has been obliged to exclude female physicians from the demonstrations at his museum. Of course, the attendance of patients is voluntary, and their objections must be respected or their cases could not be exhibited.

DISEASES OF THE AGED—A SPECIALTY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Now that childhood has been fenced off as a possible specialty and is being prospected by careful observers as to its probable yield to one who works it faithfully, it is time that we should turn to the other extreme of life, and consider whether it, too, may not be worthy of intensive cultivation.

The physiological processes of old age and its pathological changes are certainly deserving of more thorough study than they have yet received. The senile heart has been the theme of some very able essays and even volumes. The digestion of the aged would be an interesting subject for observation and analysis. The brain changes of age—their nature, their causes, their possible prevention—would, when understood, form a very valuable contribution to that store of knowledge upon which the wise therapist bases his remedial efforts.

The food, clothing, exercise, sleep, and occupation of old age must be thoroughly comprehended, not in a faddish way, but as a part of the education of every

physician, if our race is to advance in longevity as in culture and comfort.

If this is true, it is not difficult to believe that in future the practitioner who wishes to bring his patient who has already passed seventy safely and happily to the eightieth, ninetieth, and even one hundredth milestone of his earthly journey, may be glad to turn for counsel and consultation to one who has made the care of the aged a special study.

Why do old people die? How do the changes occur, and in what organs or functions are the subtle processes located which cause so many aged persons to detach themselves painlessly, quietly, without evident disease, sometimes apparently by a simple exercise of the will, from the parent tree of humanity? An author tells us that it is failure of nutrition which gradually extinguishes the life flame of such persons. If so, how necessary is it that the nutrition of the latter half of life should be minutely studied! And how dangerous an experiment it must be, unless for grave reasons, to tinker with the diet and digestive habits of the aged! Then the promotion of nutrition must be the ultimate goal of every therapeutic effort. All progress in this direction is gain; all disorder of nutrition, by however excellent a drug, is perhaps irrecoverable loss.

So, as the patient gradually passes farther and farther on the way whose distant stretches so few of us may hope to tread, the wise physician should, for ordinary ailments, steadily lessen the doses of the more powerful remedies, drop the dangerous drugs and those which are trying to the stomach, and place his reliance more on rest in bed, with simple and abundant food. Even aperients are sparingly administered, the bowels being coaxed rather than compelled to their duty.

Yet even the most experienced general practitioner, as he stands in an attitude of respect before that aged frame which has weathered the storms of nearly a century, must at times, dreading lest his well-meant efforts should add to its perils, long for the counsel of a professional brother who, to his own long acquaintance with his patient's peculiar needs, might contribute a deeper scientific knowledge of the processes of age, its pathology, and its therapeutics.

A study of the thought processes of extreme age would be no insignificant portion of the training of such a specialist. Why is it that the mental faculties of some persons deteriorate with the onset of advanced age, while those of others, apparently no more healthy, are preserved clear and alert, though of course not so hardy as in middle life? Is this preservation dependent upon bodily nutrition? or is it the reward, as some would have it, of the habitual ingestion of healthful, pure mental food throughout life? Does the brain cell thus fed on the best of social intercourse and literary pabulum win the reward of intellectual longevity? What would the specialist on old age have to say upon this point?

Apart from the gradual brain deterioration which affects so many among the aged, there are numerous disturbances of its mentality which call for study. Is there not a melancholy which is the result of age changes? If so, what is its cause? Has it to do with digestive errors? Or is it the result of a failure of excretion, as by the kidneys? Sometimes it seems due to insufficient sleep, and occurs in otherwise healthy individuals.

Shall old age have its specialists and its special journals? Or can it be merged with pædiatrics into a specialty which embraces both extremes of life? A startling suggestion, yet one which is not destitute of reason. Both extremes of life involve frailty of organization, and demand wise supervision of diet, clothing, and exercise. Both call for lessening of drug medication. In both the main reliance must be placed on

the power of the body to right itself, time being a cheap commodity. Both need for their medical guidance the same type of physician. He must be thoroughly equipped with professional lore, yet must add to this extraordinary patience and gentleness, and a love for philosophical reflection which shall ensure deep insight and great breadth of view.

There are many men of this type and capability, failures in the fierce elbowings of ordinary practice of medicine or surgery, who might find a congenial and profitable field in these departments of "inner medicine," both of which contain rich mines of research, awaiting development by a master worker.

A. K. BOND, M.D.

BALTIMORE, Mo.

TUBERCULOSIS AND BACTERIAPHOBIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Some five or six years ago, when Dr. Koch first brought out his tuberculin claim, I wrote you a brief note which was published in the *MEDICAL RECORD*, stating that "tuberculosis is a disease of malnutrition, the result of a defective organization, either hereditary or acquired; and hence is incurable when once fully established in the pulmonary organs."

In that brief article I also warned the profession against what appeared to be the coming craze named as the latter part of the title to this article. Since that time, in spite of the bacteriaphobia which seems to have seized upon the great and learned medical men of the whole earth, I am more than ever confirmed in the truth of that statement. That this form of disease is the result of malnutrition, its own common English name clearly indicates. It is a consumption, a wasting away. Why do its victims waste away? There is but one answer to this question; they waste away because they are badly nourished. Nutrition is defective. Does this grow out of the condition of the lungs? Are the lungs the primary organs of nutrition? Do the lungs make blood? The truth is that pulmonary tuberculosis is not the primary, but the secondary condition. So also are all the local manifestations of the disease. The primary condition is found in the blood-making organs. The organization fails to make a full supply of pure and perfect blood for its own absolute needs, and the result is a dyscrasia: bad blood, defective blood, autotoxæmia. Such blood contaminates the whole organism and specially the lungs, and more especially the upper lobes of the lungs, because the whole blood stream courses through these organs and the toxins entangled in the lung cells are retained there and become the foci of pulmonary irritation, inflammation, and ulceration; "more especially in the upper lobes," first, because there the circulation is weaker and more easily obstructed.

The real seat of the disease is in the chylipoietic viscera and is organic; that is, it has its origin in defective digesting and assimilating organs. They fail to convert the food into healthy blood in sufficient quantity to maintain a normal physiological condition. This is the root of the disease, and what is called the tuberculous bacilli are the outgrowth of it after it becomes seated in the lungs, where the atmosphere has access to the deposit and comes in contact with it. These are from without and not from within.

The first symptoms of the disease are connected with the abdominal organs and are manifested in the form of indigestion, constipation, congestion, eructation, borborygmus, etc., followed by headache, a slight intermitting fever, and finally by cough, etc. Sometimes the first suspicion of the disease is aroused by a pulmonary hemorrhage bursting forth from heavily congested lungs, the result of the dyscrasia which has

been gradually creeping upon the patient so insidiously that it is not suspected. There had been no thought of tubercle, but only of a general malaise attributed to want of exercise, or indigestion, or some of the other premonitory symptoms. During this premonitory period, this malaise stage, a careful inspection will manifest a periodicity of action in the system, with temperature normal or subnormal at some period between midnight and midday and above normal at some part of the period between midday and midnight. This periodicity generally continues and increases to the end; unless indeed the disease is subdued or greatly mitigated. Fistula in ano and appendicitis are both indications of an organic predisposition to tuberculosis; so also is typhoid fever, but when it is successfully passed through, it seems, for a time at least, and perhaps forever in some cases, to immunize the organization against any further tendency to tuberculous deposition. The root of this fever we all know to be enteric. The same may, in some measure, also be true of appendicitis, fistula, and tuberculous joint.

If the above intimated theory of this dreadful enemy of the human race be true, or chiefly so, the practical uselessness of all prevailing modes of treatment will be manifest, and specially those founded upon the bacteriological theory. Tuberculin injections have been demonstrated a failure; so also has the creosote treatment, and indeed all methods may be said to have come to naught. Now let us do better. How? Abandon all bacteriaphobia and come down to a rational method of treatment. Let all high-flier theories like bacteriology, specific medication, and all such foolishness go, and come down to rationalism, which is the only scientific and successful form of medication known to man. Rational medication is the outcome of man's highest faculties. It results from the ability in all cases to trace the symptoms manifested back to their origin, the cause of the disease, and the present systemic condition resulting from that cause. To this end the successful physician must not only understand the significance of all manifested symptoms, but be able by his learning to trace them back to their origin in the organization. If the patient has a fever he must be able to reach the cause of that fever and remove it, if possible, or, if not possible, then to conduct or aid the natural forces of the organism in their struggle to restore the lost physiological condition. I have sometimes said that physicians know everything that can be known, except how to cure disease. The reason for such a remark grows out of the fact that their remedies are not well directed to this end. They are too often impelled by the thought that something must be done, and something too that must produce clearly manifested results, whether these results are toward the normal or the abnormal. Homœopathy should have taught us long ago to beware of too clearly manifested results, unless we are absolutely sure that they are in the physiological and not the pathological direction. I knew of a case that occurred in your great city of New York, where a very prominent gentleman, like most city gentlemen a high liver and of very full habit, though only forty-four years of age and of strong constitution after dining out in the evening, was taken in the middle of the night with a bad fit of indigestion and a "big doctor" was called in to relieve him. The patient's heart was dreadfully oppressed from plethora and general stagnation of the circulation, accompanied by abdominal pain. The doctor injected hypodermically one-half grain of morphia, which soon relieved the patient, who fell asleep and never awoke any more to the things of this world! This was a case of irrational medication, and well illustrates by contrast what I mean by rational medicine.

All cases of irrational medication are not so clear

as this one was, but the antiseptic treatment of tuberculosis is almost or quite as much so, because the remedies are irrationally applied. They are applied to an effect of the disease and not to its cause. The cause is malnutrition, and is usually the result of a defective organization, either inherited or acquired by bad habits of living. All our efforts should be directed to restoring the lost functions of the blood-making organs. This is the direction in which now all our efforts at cure should be directed. Everything that we now know to be beneficial in these cases is in this direction—best climatic conditions, exercise out of doors, tent life in suitable climates, proper food suitably prepared, and every other means that operates to promote healthy blood-making in the organization.

J. S. PRETTYMAN, M.D.

MILFORD, DEL., September 8, 1896

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 17, 1896:

	Cases.	Deaths.
Tuberculosis.....	117	85
Typhoid fever.....	33	15
Scarlet fever.....	53	1
Cerebro-spinal meningitis.....	0	3
Measles.....	38	2
Diphtheria.....	157	17
Smallpox.....	0	0

The Society of Medical Phonographers of England now has over two hundred and fifty members.

Intestinal Fermentation.—In a study of the various foods as to their putrefactive tendencies, Gilbert and Dominici are quoted in the *Texas Medical News* as experimenting with milk upon a healthy man. Two and five-tenths litres of milk were given daily for five days. Before beginning with the milk diet the faeces showed sixty-seven thousand bacteria per milligram. On the second day of the milk diet the faeces showed fourteen thousand bacteria; on the fifth day, twenty-five hundred. By the use of sterilized milk the number was still further reduced. From this the inference is drawn that milk is the ideal diet in typhoid fever and other enteric diseases, it being less fermentative than meat and other albuminous materials.

Dangers of "Scorching."—A patient whose case illustrates the subjective dangers of "scorching" was recently under the treatment of Dr. Hansell in the hospital. A young man, who had imperfectly convalesced from a severe attack of typhoid fever, exercised violently on his bicycle for two or three successive days in direct opposition to the advice of his physician. After his last run, he noticed a defect in his visual field. It was found that he had sustained a circumscribed local detachment of the retina from hemorrhage into the choroid. A somewhat similar case was recently reported by an English ophthalmic surgeon. In his patient the hemorrhage was due to the rupture of a retinal vessel. Another accident, occurring in the person of the writer, is thus far unique in the literature of bicycling. After a hard and hilly ride over stones and ruts the contents of the bladder were found to be, in large measure, blood. In the next micturition but little difference was noted and in twelve hours the urine had regained its normal color.

Examination of urine subsequently passed showed the presence of large numbers of blood cells and some bladder epithelium. The hemorrhage was therefore probably from a small vein in the bladder wall. Accidents of this and like nature should be widely reported, in order that bicyclers, who constitute so large a proportion of the young and middle-aged, may regulate their exercise according to their physical powers and endurance, and they should accept these instances of threatened blindness as warnings against immoderation.—*Philadelphia Polyclinic.*

The Weaning of Infants.—Dr. Louis Fischer (*Pediatrics*, July 15, 1896) says that when a child reaches the age of six months it is well to think of weaning. Gradual weaning is usually very successful. Begin by feeding from six to eight ounces once during twenty-four hours. Each succeeding month withdraw one breast feeding and substitute an artificial feeding, so that by the ninth month the infant is weaned. Complete weaning should take place about the tenth month, unless it is midsummer or there exists some other special condition. For artificial feeding, Dr. Fischer recommends three ounces of cow's milk, and if the bowels are regular, three ounces of barley gruel, and about ten-fifteenths of a grain of ordinary table salt and half a lump of cane sugar. He says that if the increase in weight is not five or six ounces weekly, a careful chemical and microscopical examination of the breast milk should be made.

Subcutaneous Alimentation.—In a communication to the *Münchener med. Woch.*, August 4th, Fritz Voit reports some experiments with subcutaneous alimentation. Leube had before injected melted butter in the dog, made lean by restricted diet, and at exploratory laparotomy found that it had been laid up in the form of fat. This fat in states of the system with insufficient heat was completely used by the economy, thus sparing the albuminoids. Leube had no success, however, with sugar in large amounts, but Voit, observing that animals and man did not react alike, injected grape sugar in the latter with success. Of a ten-per-cent. solution used with due antiseptic precautions, he found that he could inject subcutaneously (in the thigh) ten, one hundred, or one thousand cubic centimetres without inconvenience. As much as sixty grams of grape sugar could be injected without a trace of it being found in the urine subsequently. Lévrose and galactose could be used as well as dextrose, but lactose and cane sugar reappeared almost entirely in the urine. Sugar could not be used for alimentary purposes by direct injection into the veins of animals, as it was excreted at once with the urine.

Physiological Albuminuria.—Dr. Zeehuisek (*Centralblatt für innere Medizin*, January 11, 1896) has examined the urine of one hundred and forty-four supposedly healthy individuals. His examinations were made from the standpoint of the clinician and only that substance was regarded as albumin that was coagulable through heat. He concludes as follows: (1) Many cases of albuminuria in young people (five per cent. in the one hundred and forty-four) are caused by affections of the renal parenchyma. (2) In another series of cases the albuminuria in the young is of extra-renal origin, i.e., accidental (red blood corpuscles, leucocytes, spermatozoa, etc.). (3) Functional albuminuria was not observed in the one hundred and forty-four cases examined. (4) In the persons examined, no trace of a "physiological albuminuria" was discovered. (In 71.5 per cent. of the one hundred and forty-four cases the most delicate reagents failed to disclose the faintest trace of albumin.)

MYXEDEMA: A CASE TREATED BY THYROID EXTRACT.

By JOHN WOODMAN, M.D.,
NEW YORK CITY.

It seems advisable, on account of its advanced character, to report the following case, so wonderfully and quickly relieved by small doses of thyroid extract, aided by the ingestion of large quantities of water:

Mrs. F—, aged thirty-eight, married. She has six children, the last of which was born in 1893. Family history good. She had always been well. She menstruated at fourteen years; the flow was always profuse. She was constipated all her life. Her present illness began nearly eight years ago. She first noticed that the left side of her face and the left eyelid were swelling slowly. Soon the swelling extended to the other side of her face, and then slowly involved the entire body, it being most marked about the upper eyelids, scalp, and supraclavicular spaces. The eyes could scarcely be opened. With the swelling a gradual weakness developed and a general malaise. The face became very broad and the nose markedly flattened. The lips were swollen, pale (at times bluish), and the lower one especially tended to be everted. The tongue was much swollen and protruded, making it difficult for her to shut the mouth; it was also very dry, so that swallowing was difficult and accompanied by a gurgling sound. The arms, wrists, and hands were swollen, so that the hands could not be tightly closed. The abdomen became very large. The feet were swollen, especially at the inner and the outer arches and on the dorsal surfaces. She wore No. 3 shoes eight years ago, and in January, 1895, she wore No. 7. The feet also became very tender. There was no pitting of the edema on pressure until in December, 1894. The tumefaction was not evenly distributed, but seemed to be in rolls between the muscles. It was spongy and elastic to the touch. Her head fell forward, probably on account of weakness in the posterior cervical muscles. Her weight increased from one hundred and twenty pounds to two hundred and forty pounds. She had not sweated since she began to notice the swelling. The skin was hard and dry. In 1892 she had an attack which was diagnosed as jaundice. The conjunctivæ and skin were very yellow. This discoloration lasted about three weeks, when the conjunctivæ became normal. The skin never returned to its normal color, but turned a darker yellow, then brown, and finally almost black. There was pigmentation all over the body, especially on the exposed parts and on the neck and chest. The skin became harder and more indurated after that attack, and seemed adherent to the underlying structures. There were deep wrinkles all over the face, especially on the forehead and about the mouth. A fine scaly desquamation was present over the entire body.

The hair fell out entirely from the axillæ and pubes, but not very much fell from the scalp, though the hair there became very coarse, dry, and brittle. The nails on the hands did not change, but on the feet they were thickened, brittle, and deeply striated. Different joints would swell and become painful, and then the swelling would disappear, leaving stiffness.

The gums were swollen, spongy, and sore, and nearly all the teeth fell out. There was marked lachrymation. There was dribbling of saliva at night, but the mouth was dry during the day. The breath was foul and the tongue often coated. The appetite was poor; she wanted to eat only certain articles of diet. She had more or less nausea all the time, and she often vomited. She was constipated nearly all the time.

She had a cough all the time, but it was much worse during the winter, with expectoration of whitish sputa. She could not breathe through the nose, so the mouth was open all the time. She snored at night. There was also great dyspnoea at night. She could not lie on the left side, and often had to sit up to breathe. She had marked dyspnoea at all times on exertion, and on account of the dyspnoea and extreme swelling of the tongue and lips she could speak only in monosylla-

FIG. 1.—Mrs. F., January 4, 1895.

bles, and the speech was hesitating and muffled. There was palpitation of the heart, at first at night and then marked on the least exertion. Often she had syncopal attacks. The heart upon examination was found enlarged to the left and downward, with a systolic murmur at the apex, which was transmitted to the axilla but was not heard in the back.

She noticed, soon after the appearance of the swelling, that she did not pass as much urine as formerly. Sometimes she had severe pain after micturition, and at other times she would pass urine unconsciously. The urine was repeatedly examined and was always found to be acid; the average specific gravity was 1.020; albumin varied from a mere trace to as high as twelve per cent., and was always present. There were no sugar and no tube casts.

She never had headache, but would have vague neuralgic pains in the lumbar region, radiating to the lower extremities and around the scapula. She had cramps in her leg frequently. Her disposition completely changed. She was apathetic, and no longer felt any interest in life around her or in her family. She

FIG. 2.—Mrs. F., February 1, 1895.

felt as if she could not cry, but wanted to be alone all the time. She was content to be alone and to sleep all day in a chair; she often had bad dreams, and would get frightened in her sleep. Within the first year of her illness she began to have hallucinations. She would see rows of people's faces, and would think she was being followed as she walked about her house. She never thought she would be harmed, but felt as though some one was always near her. She would not leave the house alone, for fear of getting lost. She had some inco-ordination of her feet, and it would seem to her as if she was walking on slippery ice. Memory failed, and she could not recall events of two weeks before. The eyes became very weak, and finally she could scarcely see. Marked deafness developed on the left side. There were marked mental slowness and dulness of comprehension. She was always cold. She felt more comfortable in summer than in winter, but even in the hottest weather she felt uncomfortably cold.

Three children were born during the eight years, and during the pregnancies all the symptoms were much exaggerated. The children were born healthy and were breast fed. The first, born about a year after her pronounced symptoms appeared, is now strong and well. The second died of erysipelas at four months. The third is now two years old, and seems bright and intelligent; but six months ago it had a convulsion, after which a hemiplegia developed, which has continued to the present time. A ventral hernia developed during one of the pregnancies.

During the eight years she was treated, at different times, for Bright's disease and for dyspnoea and palpitation, with apparently good results each time, but with no permanent improvement. The treatment by thyroid extract was begun on January 4, 1895, and five

grains daily were given at first. Later the dose was increased to ten grains daily, but it produced so much dyspnoea and palpitation and such a rise in temperature that it was reduced to the original amount and was continued at five grains daily until she regained her normal condition. While taking the thyroid extract she drank large quantities of water. Within the first week of treatment the symptoms began to ameliorate, and there was a steady improvement up to the time of her recovery. The oedema began to disappear almost immediately, the fulness in the eyelids, face, scalp, and upper extremities disappearing first, the oedema in the lower extremities being the last to disappear. The tongue, lips, and gums became normal, and she could soon speak perfectly well without dyspnoea. She could walk up and down stairs, and sleep on either side without discomfort. Her appetite improved, and she no longer had palpitation.

February 12, 1895, she began to perspire, and the skin after that time began to resume its normal character. Desquamation took place in large scales. Flakes could be stripped off, leaving normally smooth skin beneath; and the pigmentation was removed with the superficial layer of epidermis which desquamated.

The skin was no longer thickened and adherent, but soft and smooth. The hair in the axillae and on the pubes began to grow, and the hair on the scalp became much softer.

The symptoms of diminished urine and incontinence disappeared, and albumin was not found in the urine after the middle of February. The apathy disappeared, and she became bright and cheerful. She had no hallucinations of any kind and slept well at night, but had not the great tendency to sleep that she had formerly. Her memory became perfectly clear, and her eyes and ears regained their former acuteness. March 1, 1895, she had lost thirty-one pounds, and about May 1st her weight had been reduced from two hundred and forty pounds to one hundred and eighty.

The thyroid extract has evidently supplied the sub-

FIG. 3.—Mrs. F., March 1, 1895.

stance from lack of which so many serious symptoms developed, and she has continued to take the extract in five-grain doses every other day since her recovery to normal condition. She will undoubtedly have to

continue supplying the lost substance by means of the thyroid-extract preparations, for, since the great swelling about the neck has disappeared, it can be plainly seen that the thyroid gland is completely atrophied.

She continues well to the present date.

I am indebted to Dr. M. Allen Starr for seeing the case in consultation, and to Dr. Elizabeth D. Dixon for assistance in arranging the history for publication.

223 EAST TWENTY-FIFTH STREET, October 1, 1896.

THE BICYCLE FOR SCOLIOSIS.

By OTTO G. T. KILIANI, M.D.,

NEW YORK,

INSTRUCTOR OF CLINICAL SURGERY IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

SINCE the etiology of scoliosis and the static laws governing the same have been studied more closely, both the prophylaxis and the treatment of lateral curvature of the spine have progressed considerably in this country as well as abroad. The former is still

If our therapeutic efforts should enable us to correct these three cardinal points, or, still better, to over-correct the position by transforming the scoliotic curvature into the opposite curve, when the static laws would exert their influence upon the vertebrae in the reverse sense, and if, finally, we could keep the vertebral column in this corrected or over-corrected position for any length of time, we would be able to cure a scoliosis just as well as the severest cases of club-foot, as Hoffa sets forth so ably in his "Lehrbuch der orthopädischen Chirurgie." But as yet we are far from having achieved anything of the kind.

First of all, we have to strengthen the general constitution of scoliotic children, and especially their weak muscles.

Then we have to reduce the contraction of the column by mobilizing the spine.

I do not intend to enumerate all the different methods by which we strive to achieve this end, but presume that they are known and selected for the case in question according to the predilection and personal experience of the physician or orthopædist in charge.

FIG. 1.—Artificial curvature of normal spine, caused by handlebar lowered on right side.

FIG. 2.—D. F., scoliosis, age 13, standing.

FIG. 3.—D. F., sitting on an ordinary bicycle.

somewhat neglected here, as all the public schools and a great many of the private schools fail to furnish benches answering the requirements for preventing the development of scoliosis in children. The incorrect position of the pupils is partly the direct result of the method of writing, and we sincerely hope that the inclined handwriting will shortly disappear entirely from our schools.

In well-developed habitual scoliosis of the usual kind, with dorsal convexity to the right and lumbar convexity to the left, we find in the so-called second stage the following symptoms:

1. The vertebral column is shortened.
2. The whole spine is displaced to the right.
3. Besides the angular deformity of the ribs, the spine is twisted, so to speak, around its longitudinal axis, so that the right side of the thorax stands considerably farther back than the left.

If my impression is correct, a good many of the physicians treating scoliosis have given up to a great extent the apparatus in the form of plaster-of-Paris corsets and braces, intended for correcting the abnormal curvature of the spine and keeping the same in this corrected position.

My personal opinion is, that all modern treatment for scoliosis should culminate in the endeavor to correct the curvature as much as possible, and then, instead of trying simply to keep it in this position, to exercise the muscles in this corrected position, so that they will be able to hold the spine in it, if the altered anatomical conditions will permit.

Before describing my new device to achieve this purpose, it seems hardly necessary to state that I consider it only one link in the long chain of therapeutic efforts, and nothing would be more wrong than to rely solely upon the one in question.

FIG. 4.—D. F., treading on modified bicycle, with left pedal high.

FIG. 5.—D. F., treading on modified bicycle, horizontal pedals, left foot forward.

FIG. 6.—D. F., treading on modified bicycle, right pedal high. Spine practically straight.

FIG. 7.—D. F., in same position, on bicycle with ordinary handlebar.

FIG. 8.—D. F., treading on modified bicycle, with horizontal pedal, right foot forward.

FIG. 9.—D. F., combination of inclined seat with modified handlebar.

Bicycle exercise constitutes such a perfect combination of active and passive motion, by means of an exactly constructed machine that it suggested itself to me to make use of it in the treatment of scoliosis. The oft-repeated accusation that the bicycle tends to develop forward curvature of the spine (kyphosis)

was, of course, of no weight, and, if so, it would rather have induced me to make use of this quality.

I shall now endeavor to describe the photographs published with this paper, and thus lay the question before the profession for its judgment.

No. 1 shows a sculptor's professional female model,

whom we may consider of perfect figure, even lacking the otherwise normal slight scoliosis brought about by the use of the right arm in manual work. She is seated on an ordinary ladies' bicycle held fast in a home-training machine, which enables the rider to practise at home, while the machine stands still. The saddle is raised a little more than is customary with women riders, to bring the weight of the body partly on the handlebar. The latter is arranged in a way to be described later, which allows either half to be raised or lowered to any degree desired.

In our pictures the right handlebar is lowered to some extent, as is clearly shown by the position of the

FIG. 10.—Modified Handlebar.

two hands. The line of the spinous processes is painted on the skin with a dermatographic blue pencil.

It is immediately apparent that the woman shows a left convex dorsal and a right convex lumbar scoliosis of noticeable degree. Any one who will repeat the experiment can convince himself of the conditions to be named: first, the line of processus spinosi shows clearly the bending or lateral curvature of the spine. This line is in cases of true scoliosis very often misleading, as is well known, and should not be relied upon too much. Secondly, the thorax is decidedly twisted, so to speak, around its longitudinal axis in an ascending spiral from left to right; the right shoulder is lowered, the median edge of the left scapula stands out; the curve of the ribs of the right side is flattened; in short, we have the position we try to produce in a case of common habitual scoliosis (with dorsal convexity to the right).

If it is possible to influence the normal body in the manner described by the use of a handlebar lowered on one side, it will be interesting to see how a case of scoliosis will be altered.

Fig. 2 shows a little patient of mine, thirteen years of age, in standing position, with a scoliosis which needs no comment.

Fig. 3 shows the same patient seated on an ordinary ladies' bicycle, with arms hanging straight down. Here the scoliosis is still more marked than in standing, as the weight of the body comes into play. The right dorsal curvature is just as plain as the left lumbar curvature. Now we put on the handlebar, lowered on the right side, and go through the different motions and positions in the revolution of the wheel.

In Fig. 4 we begin with the left thigh in flexion, the left pedal high. We have to consider the spine fixed at about the first lumbar vertebra; the dorsal and cervical parts of the spine are pulled down and bent to the right, with the natural result that the spine is straightened out.

Fig. 5.—The left leg begins to go down till the pedals form a horizontal line, with the left foot for-

ward. The spine is nearly straight, the scapulae showing clearly the influence of the position on the thorax.

Fig. 6.—The left leg goes still farther down and brings the right thigh correspondingly in flexion.

The patient's spine is almost straight, the angular deformity of the ribs is straightened out considerably, and the position is as nearly as possible the ideal one.

For comparison, we show in Fig. 7 the same patient on a bicycle with the usual handlebar, in the same position, namely, the right pedal up.

Finally, Fig. 8 shows her with the right foot coming down to the line of horizontal pedals. This constitutes one revolution of the pedals, and treading begins anew.

It seems evident that muscular action in this corrected position, achieved by such simple means, ought to be beneficial. For any one conversant with the treatment of scoliosis it is needless to say that I cannot speak yet of any results produced by this treatment, although I have at present four patients, two boys and two girls, using my adapted bicycle. I would not venture to utter until several years have elapsed any definite judgment on its possible value, but rely on the apparent rationality of the idea, and hope that other physicians may give it a trial.

Another important feature is that, with the untwisting, so to speak, of the spine by the position of the arms, we can add the inclined seat, by raising one-half of the saddle upon the proper side, as shown

in a primitive way in Fig. 9. Any of the saddles in the market with separate lateral sections that can be padded higher on one side, answer the purpose well. In one of these there is a contrivance by which one side may be raised by means of a screw which acts on a steel plate upon which the cushion rests. This of course would answer only for training at home, as balancing would be seriously impaired by the inclined seat. The lowered handlebar alone does not interfere with it at all, as I know by personal experience in riding on such a bicycle myself for the sake of trial.

Conceded that the ideas set forth in this paper are right, we only have to mention briefly the advantages of the treatment. First, a good many of the patients to be treated are in possession of a bicycle. Even for those who do not own one, the expense is relatively slight in comparison with that of other orthopaedic apparatuses. Secondly, it affords a physical exercise to which the patients will take kindly and which they will therefore carry out faithfully. This is a decided point of advantage, as the execution of gymnastic exercises always demands an unusual amount of patience and perseverance on the part of both patient and physician.

Finally, it only remains to describe the simple device by which either handlebar can be adjusted in any desired position. The handlebar used by me (as shown in Fig. 10) is sawed apart in the middle, and the two parts are adjusted by means of a screw and thread, fitting one into the other (the two necessary pieces having been soldered into the tubes). The circumference of the two pieces is grooved and held in place by a wedge with corresponding teeth, the latter being tightened by a screw with nut, fastening the jaws of the head, pointing toward the rider. The thread mentioned will allow the lowering of either side of the handlebar to any degree desired, while the two halves of the handlebar will still be held firmly together. The wedge with its corresponding teeth will hold all the parts absolutely firm when pressed in against the handlebar by the tightening screw and nut. Any skilled mechanic will be able to alter any han-

dlebar in the desired way. I personally am indebted to Robert Linder for faithfully carrying out my intentions.

133 EAST FIFTY-SEVENTH STREET, NEW YORK CITY.

DIPHTHERIA OF THE NASO-PHARYNX.*

By WALTER J. FREEMAN, M.D.,

PROFESSOR OF LARYNGOLOGY, PHILADELPHIA POLYCLINIC; LARYNGOLOGIST TO THE ORTHOPÆDIC AND CHILDREN'S HOSPITALS; CONSULTING LARYNGOLOGIST TO THE PENNSYLVANIA INSTITUTION FOR THE DEAF AND DUMB, ETC.

ALTHOUGH we find brief mention here and there of the occurrence of diphtheria in the naso-pharynx, its importance in this position has by no means received the recognition it deserves. Guthrie¹ says that "nasal diphtheria is very common in children, and may often escape recognition, for membrane . . . may be found above the soft palate and in the posterior nares." Moritz Schmidt² says that the formation of membrane in the vault must take place very frequently, but dwells upon it more in its aspect of causing destructive action in the ears. Seibert,³ Rosenburg,⁴ and many others regard it simply as an extension from a faucial diphtheria, overlooking apparently the fact that the recognized tendency of this process is to extend downward. Bosworth,⁵ likewise, calls attention to the fact that "the primary deposit occurs at times in the pharyngeal vault or some other portion of the upper air tract," but he does not take the position that this is a very frequent seat, for he states in another paragraph that "the diphtheritic membrane primarily makes its appearance, in the very large majority of cases, on the face of the faucial tonsil, where it is open to direct inspection. . . . In rare instances," he goes on to say, "it makes its appearance on the pharyngeal tonsil, where it can be inspected only by the rhinoscopic mirror," adding that "this last resource is unavailing in most cases in children." In my opinion, however, it is a mistake to assume that the disease first makes its appearance on the faucial tonsil simply because it is first recognized there, and also to state that the vault can be examined only by means of the rhinoscopic mirror, and that this is unavailing in most cases in children.

The period of incubation of diphtheria is given by the majority of writers as about four days. When, however, the disease has been surely traced to infection, as in the not uncommon instance of a physician's receiving the expectoration directly in the face while examining a patient, the incubation is found to be but twelve to thirty-six hours. This, as has been experimentally determined by the inoculation of the ptomain in the lower animals, is probably the true period of incubation. It is, therefore, reasonable to believe that, in those cases in which the period of incubation has been extended for days or even weeks, the infection has been less in amount or less virulent, and has needed time to develop. Nowhere could this more easily take place than in the nose, or in the crypts and folds of the various tonsil groups, especially those of the naso-pharynx, where no mechanical cleansing takes place as in eating and drinking.

The literature of the subject of diphtheria is vast, and I shall not enter into a detailed account of the history of the disease. I feel, however, that a brief synopsis is not amiss, that a more perfect understanding of the points to be discussed in the paper may obtain. The microbic origin of diphtheria was first recognized in 1868 by Oertel,⁶ who thought that in a micrococcus he had found the specific germ. It was not, however, until sixteen years later that Klebs⁷ announced the discovery of the true bacillus of diph-

theria, which has since that time been called conjointly by his name and by that of Loeffler,⁸ who a year later first proved that the bacillus was pathogenic and obtained cultures. The Klebs-Loeffler bacillus is of about the same length as the tubercle bacillus, but is much thicker and is somewhat bent or curved. It is irregular in outline, due to its beaded or granular appearance, and is motionless. Its chief characteristics are the rapidity and peculiar appearance of its growth on culture media, which, according to Park,⁹ distinctly differs from that of any other mouth bacteria, except—notice this—the so-called pseudo-diphtheria bacillus, and in its taking the stain in a peculiar way, the granules and the ends, one or both of which are clubbed, being more deeply colored. But it must be remembered that many circumstances, such as different culture media and other influences in growing, alter the shape of the germs very markedly, so that, for instance, instead of having the club-shaped ends, these may even be pointed. The theory that the Klebs-Loeffler bacillus is the cause of diphtheria is now firmly established, as firmly as in the case of any of the germ diseases, but we also recognize that pseudo-membrane may be formed by other germs and possibly even by inflammations not microbic in origin. Loeffler¹⁰ in 1887 announced that a bacillus closely resembling that of typical diphtheria existed in apparently harmless pseudo-membranous inflammations, which from their mild clinical course could not be distinctly classed with true diphtheria. Its chief points of difference, he says, are that it is not pathogenic, that its ends are not so often club-shaped, and that it does not grow so characteristically. The life of the so-called pseudo-diphtheria bacillus is extremely short, and in this corresponds with the degenerated form of the bacillus of true diphtheria found in membranous rhinitis and other cases of mild diphtheria. The vitality of the Klebs-Loeffler bacillus, on the other hand, is very great. Park states that some membrane on cloth still gave cultures after six months. Von Hoffmann¹¹ has isolated a bacillus which, except for its non-pathogenic properties, cannot be distinguished from the bacillus diphtheriæ. This he found also on apparently healthy mucous membranes.

In view of these facts, it is not surprising that so much doubt and confusion should arise as to the differential diagnosis between diseases exhibiting pseudo-membrane as their earliest and most pronounced symptom. Since such diseases exist, so alike in their most prominent symptoms, the one very fatal, the other apparently innocent, it is of the utmost importance that the most searching analyses and every means of diagnosis at our command should be employed to enable us to arrive at a correct diagnosis. Roux and Yersin,¹² and Abbott,¹³ have asserted, and as I think on good grounds, that the pseudo-bacillus above mentioned is but an attenuated form of the Klebs-Loeffler bacillus, and may under certain conditions recover its virulency. While the so-called pseudo-bacillus gives rise to symptoms differing clinically from the Klebs-Loeffler bacillus, the difference is more in degree than in kind, and Abbott¹⁴ has found that the same pathological changes follow, though in less degree. The characteristic symptoms produced by typical diphtheria arise too late in the course of the disease to serve a practical purpose in affording us means to differentiate the two. Often the occurrence of diphtheritic paralyses or of albuminuria has been our only means of knowing that the patient has had true diphtheria, the course has been so mild, resembling in so many ways that of pseudo-diphtheria. Hardly one of us but has seen cases of true diphtheria, proved such by the typical sequelæ above mentioned, run their course with hardly a constitutional symptom, and again we have all had most

* Read by title before the American Laryngological, Rhinological, and Otological Society, New York, April 15, 1896.

threatening cases, causing us no end of anxiety and doubt, recover in a few days. When we think of the mild cases, even simulating simple lacunar tonsillitis, which give rise, as has been proven by reliable authorities, to diphtheria of fatal termination and also to infection to others, we begin to appreciate the responsibility resting upon us, and are taught to regard with a certain amount of gravity all pseudo-membranous exudate wherever formed. This was brought most forcibly to my mind during the years 1893 and 1894, when Abbott and Ravenel were carrying on their bacteriological investigations in membranous rhinitis, upon the results of which they based their brochures and presented the largest summary of cases published up to the year 1895. Of the thirteen new cases Abbott¹⁴ and Ravenel¹⁵ reported, in all of which Klebs-Loeffler bacilli were found, nine had been reported from my clinics at the Children's and Polyclinic hospitals. Until that time such cases had been treated as are those of dispensary patients and seldom submitted to bacteriological examination, because there were so few constitutional symptoms to cause any suspicion of gravity. Finding that several cases of infection undoubtedly arose from these, no more cases of this disease have been permitted more than the one visit to the dispensaries, and have been immediately reported to the board of health as cases of nasal diphtheria.

Although the anterior nares are so easily examined, such a location for diphtheria has been recognized only for a few years, and no one can doubt that the naso-pharynx, although hitherto examined even less frequently for diphtheria, forms a much more likely field for the lodgment and growth of such pathogenic micro-organisms. The recognition of pathological processes here, although at times attended with much difficulty and requiring much patience, will amply repay the pains taken, as it is an axiom that the earlier the diagnosis of a disease the better the prognosis.

Notwithstanding Bosworth's statement to the contrary, I feel convinced that in a large majority of children it is possible to examine the naso-pharynx. In those cases in which the examination with the rhinoscopic mirror cannot be made successfully, there still remain to us other methods of examining this region, namely: (1) inspection through the anterior nares, and (2) bacteriological culture from the vault, with one of which we can ordinarily attain our end. Thus, of three hundred and eighty dispensary patients between two and twelve years of age, I could study the vault in two hundred and thirty-four, in many only through the anterior nares. I acknowledge that in many subjects suffering from diphtheria the examination would be more difficult, but not if undertaken early. The accompanying cut, taken from an article in the *Polyclinic Journal*,¹⁶ shows an easy method I have used for holding children for throat and nose examination, though in most cases of severe diphtheria any forcible methods are unadvisable.

No one will deny at this date that diphtheria is a local affection, and gives rise only secondarily to constitutional symptoms by the absorption of the toxalbumins generated by the bacillus. It has been proven that the membrane deprived of its germs produces the diphtheria by the action of its ptomain, a ptomain so poisonous that "one-three hundredth of a grain is fatal to a full-grown guinea-pig." If we can, therefore, detect the disease clinically at the point where the infection is just taking place, that is to say, at its strictly primary seat, where the thin smoky film of fibrous exudate is only beginning to form, and slight constitutional symptoms exist, much can be done to arrest its progress. For "we may hope," as Bosworth says, "by the first application to rob the local progress of much of its infective potency and limit its

capacity for extension." Recognizing this, we should examine with the most thorough scrutiny not simply the pharynx and larynx, as is usually done, but also the nares and naso-pharynx, and not merely in cases of suspected diphtheria, but in all our patients, even those in whom some evident cause of sickness exists. The procedures are so easy of accomplishment in a large number of instances that it should be a rule for general practitioners also to adopt them as one of their routine methods of physical diagnosis. We would then seldom have the statement that the disease is constitutional "because the symptoms precede the local manifestations."

The Easy Method for Holding Children for Throat and Nose Examination.

As the whole course of diphtheria is only a few days, if we can gain even a few hours in the recognition of the disease the balance will probably turn in our favor. Bacteriology has done much in enabling us to tell whether the pathological process is diphtheritic. Time gained in controlling the disease is, however, only to be obtained by discovery of the primary seat or true origin before the pseudo-membrane is well formed, and therefore before absorption leading to symptoms of toxæmia has begun to take place. Diphtheria is a disease which overwhelms patients so suddenly that, except at the very beginning or when it is quite mild, cases of it comparatively rarely come to the dispensaries. They are struck down and feel so ill that the throat symptoms sink into insignificance and the general practitioner is called, so that, although the laryngologist may be called upon to exercise his peculiar skill in diagnosis or treatment, it is, unfortunately, not until the disease has made considerable progress. Thus it is that our dispensary cases of diphtheria are mostly made up of membranous rhinitis or of diphtheria just commencing in the naso-pharynx, fauces, or larynx, in which there are few and

light constitutional symptoms, and the patient comes because of some merely local discomfort.

CASE I.—Aged nine years. Taken sick November 25, 1893. Pseudo-membrane in naso-pharynx and covering both Eustachian prominences. Klebs-Loeffler bacilli found. Pseudo-membrane disappeared December 1, 1893. Only sequela was a slow pulse (50), thus showing the unmistakable diphtheritic toxæmia. At no time was the pseudo-membrane elsewhere than in the vault.

CASE II.—Physician, who for two weeks had been treating a case of diphtheria in a child, with Klebs-Loeffler bacilli present, and albuminuria, ciliary and other pareses. The physician developed sore throat with headache on November 21, 1895. Examination showed slight exudate in the naso-pharynx. Next day, in spite of all antiseptic measures, there was increase of pseudo-membrane in the vault. Dr. Harrison Allen was called in consultation; decision, probable diphtheria. Antitoxin injection November 22d. False membrane absent November 26th. Isolation, however, continued, because of persistent presence of Klebs-Loeffler bacilli. Recovery uneventful: no sequelæ. At no time was the pseudo-membrane present elsewhere than in the naso-pharynx.

CASE III.—J. C.—, aged eleven years. March 24, 1896, vault simply lined with pseudo-membrane. None elsewhere. Clinical diagnosis, diphtheria. Culture taken and examined, with report "contains some doubtful bacilli." Second day merest trace of membrane on left Eustachian prominence. I considered the patient practically well, and the diagnosis a mistake, but he returned to the clinic March 28, 1896, after having been sick two days. Vomited, and on the third day had acute otitis media sinistra. Examination of the vault showed the pseudo-membrane still present on left Eustachian prominence. Another culture taken April 3, 1896, and answer returned April 6, 1896, "Case is one of true diphtheria." House quarantined and patient sent to Municipal Hospital. No pseudo-membrane at any time elsewhere than in the vault.

CASES IV. and V.—M. N.—, aged four and a half years. July 20, 1893. Apparently simple rhinitis. One week later membranous rhinitis and pseudo-membrane in the fauces. R. N.—, her brother, aged eight and a half years, at the same time had pseudo-membrane only in the naso-pharynx.

I have observed numerous other cases of pseudo-membranous deposit in the vault, which, however, I have not been able to follow.

It is of importance to call attention also to two interesting cases reported by Holt.¹⁷

(1) Rachitic child, aged two years. January 7, 1890, had profuse nasal discharge. No pseudo-membrane visible for two weeks, then a minute spot on one tonsil and four days later on the other. Death finally resulted.

(2) An infant, six months old, exposed to this one, had nasal discharge of mucus and blood for twenty-nine days without other symptoms of diphtheria. Then œdema of the extremities occurred, followed by death on the thirtieth day as a result of nephritis. There was no visible membrane at any time. Autopsy showed a patch of diphtheritic membrane one inch in diameter in the naso-pharynx, and a smaller one in the pharynx near the epiglottis. No bacteriological examination was made.

In presenting these cases, although they are few in number, we take into account the infrequency with which, for the reasons mentioned above, we see diphtheria in the dispensaries. I regard them as sufficient in number and importance to warrant the claim that the naso-pharynx is very frequently the starting-point of the disease. That there was no extension of the

pseudo-membrane, and that the cases ran such a short mild course, are due, I believe, to the early and thorough methods of cleansing the naso-pharynx.

A CLASS OF FATAL CASES PRESUMABLY DUE TO INTESTINAL PTOMAINS.¹

By E. D. FERGUSON, M.D.,

TROY, N. Y.

SOMETHING over twenty years ago a case occurred under my observation that created in me a profound interest and became the subject of considerable thought and reading. The patient, a man about forty years of age, had the appearance and history of robust health. I had known him for several years and his sturdy figure had impressed me with a favorable view as to his ability to resist disease and his chance for many years of life. He was taken quite suddenly with abdominal pain and became rapidly very ill, so that on the second day I saw him in consultation. From the condition and clinical history, we could fairly exclude intestinal obstruction and peritonitis, but vomiting, which had begun early in the trouble, had continued, and instead of becoming offensive in odor, as would have been expected in obstruction, was of a watery material which later showed small brownish flakes which gradually grew darker. The vomiting was frequent but not violent, and at times was rather a regurgitation than a vomiting. His pulse was rapid, the countenance anxious, the complexion somewhat "muddy," although he had naturally a dark skin, and the sclerotic lost its pearly clearness, although not to a degree to lead me to pronounce it colored with bile. The movements of the bowels did not throw much light upon the case, but the color, though dark, was not a healthy brown, neither was it a green or a black. There was quite a degree of tympanites, but no notable tenderness.

The man was evidently "sick unto death," though he retained his mental faculties in a fair state during the greater part of his illness. The vomited material grew darker, finally almost a "black vomit;" his pulse became very rapid, and just before death the temperature rose to a very high point—over 105° F. No post-mortem examination was made, nor do I now think that any positive result could have been obtained

¹ Read at the annual meeting of the New York State Medical Association, on October 14, 1896.

from one, in view of the limited knowledge of pathology then in our possession.

Here was a case that I was unable to classify. That it was not a common disease was evident; nor could I assign it to any of the recognized forms of fever or local inflammations. That it was toxic in its origin seemed the only rational explanation, but none of the mineral or alkaloidal poisons would furnish a similar clinical history. The animal poisons seemed the more probable basis of explanation, and I recall my disappointment, when, some few years thereafter, I read Boehm's article on sausage, fish, and cheese poisoning, in Ziemssen's "Cyclopædia," without securing definite aid in unravelling the tangle. I had awaited the appearance of that volume with this case in mind, and, though disappointed in the hope of definite aid, my opinion that I had seen the work of some animal poison was strengthened in a general way.

However, I had been unable to secure evidence that the patient had taken any food likely to cause the trouble, or different from that taken by other members of the family. Hence I finally evolved the idea that his was a case of auto-infection, though the conclusion was based upon a process of exclusion rather than any reliable evidence from pathological investigations.

About ten years thereafter I witnessed a similar course of events in a girl about ten or twelve years of age. The onset was sudden, there being considerable abdominal pain, fever, and vomiting, with rapid failure in the vital forces. The vomiting was possibly more regurgitative in character than that of the first case, but the colored and finally "coffee-ground" appearance of the material from the stomach recalled the former case and led me to anticipate the fatal issue, which occurred in slightly less than three days from the time of onset. By this time some progress had been made in the chemistry of decomposition. Alkaloids had been secured from animal tissues, and a presumption was beginning to take reasonable grounds in favor of the intervention of bacteria in the process. The work of Selmi, of Bologna; Gautier, of Paris; and Brieger, of Berlin, had begun to throw a degree of valuable light upon this somewhat obscure field, so that rather definite notions were possible, and I began to speculate somewhat on the various links in the chain represented by my two cases. The dark or coffee-ground vomit had impressed me as an important element in the evidence, for I felt that I could exclude upon reasonably good grounds the presence of gastric ulcer in any of its forms as the source of the hæmatemesis. In piecing together the more prominent signs and symptoms as I have related them, I came to the conclusion that the first step was due to the presence and functional activity of some micro-organism in the intestinal canal; that thence resulted some ptomain or toxin which was absorbed into the intestinal veins and reached the liver, where it induced a rapidly progressive and diffuse parenchymatous hepatitis with its attendant systemic and local phenomena, among which was the hæmatemesis. To a certain extent, the process seemed analogous to acute yellow atrophy of the liver, or even yellow fever, though the cases did not show notable icterus. The analogy was sufficient, however, to induce the opinion that when another case occurred an autopsy would show profound hepatic changes.

Not very long after the second case I was requested to see a child about four years of age, which was thought to be suffering from peritonitis, with a view to opening the abdomen in the hope of finding the cause and removing the same. Though the child's abdomen was somewhat tympanitic, the evidence of peritonitis did not seem clear enough to warrant a surgical procedure, and the fact that regurgitation of a watery

mucus with small brownish flakes had recently occurred, together with the rapid development of the symptoms, led me to conclude that the case was similar to those just related, and that "black vomit" would occur and death follow. Such proved to be the case, the patient perishing after about three days of illness. The autopsy showed no peritonitis. The bowels were distended with gas, were quite hyperæmic, and contained a rather dark and somewhat grumous material. The liver had undergone notable changes; a portion being somewhat swollen, rather nutmeg-like, with brown and yellow mottling on section and softened in consistence, while the remainder was shrunken, the capsule was wrinkled, rather yellow in color, and was flexible with a rather leathery feel while handling without breaking the capsule.

A year or so after this case I saw a man, about forty-five years of age, who was also supposed to be suffering from peritonitis. The history showed abdominal pain, not localized, though apparently intestinal; very moderate distention with gas; rapid development of symptoms of exhaustion; rising fever; vomiting of a glairy, rather watery fluid; and slight icteroid tinge of the sclera. I ventured the opinion that the patient would have "black vomit" and would perish within a short time, which proved to be the case, for he died on the following day. A post-mortem examination showed the same condition of the abdominal organs that was found in the case of the child, the remaining organs of the body showing no evidence of disease.

So far I had encountered only cases of spontaneous origin, though they were not the only ones I had seen in which I had believed the same or a similar morbid process existed, yet they presented a more pronounced and typical course.

I now turn to a series of cases having a relationship that rendered them of even greater importance, for from them it seems reasonable that some practical conclusions may be deduced.

One evening three or four years ago, I was requested to see a young man who had just been shot in the abdomen. The bullet was believed to have penetrated the abdominal cavity. There was sufficient shock to justify a presumption that visceral injury had occurred. The usual preparations were made, and as early in the following day as the light would allow the abdomen was opened and a wound of the intestinal canal was found and closed. The patient progressed without serious symptoms for about two days, when he began to have abdominal pain and regurgitation of a watery material, which finally began to show brown specks but was not offensive. I felt that we were dealing with another case of poisoning by intestinal ptomains, and that a fatal issue would soon supervene. This proved to be the case, and the autopsy showed an absence of peritonitis aside from the adhesive peritonitis that was connected with the Lembert stitches and which had progressed only to the conservative degree that had resulted in the efficient closure of the wound in the bowel. The liver had undergone changes similar to those described in the foregoing cases, and there was no obstruction of the bowels.

In the spring of 1895, I operated for the purpose of suspending a retroverted and retroflexed uterus in a patient about thirty years of age. She had been under my care for about ten years, and persistent efforts by the use of pessaries had failed to restore and support the womb. She was in perfect physical health, and, measured by our present views of abdominal surgery, the risk was as near to zero as could be expected. The operation was simple and brief—a short incision gave ready access to the parts, and the uterus was brought into a forward position and fastened there. No severe shock was manifest, and the

patient for twelve hours gave no evidence of any trouble. On the morning following the operation she was comfortable, but had regurgitated a small amount of watery material. This fact made me anxious, particularly as she showed some fever not accounted for by evidence of trouble in the operative field. On seeing her again in the evening, the regurgitation had increased and, though no brown color was yet present in the vomited material, her evident tendency, as shown by quickened pulse, rising temperature, and muddy complexion, was to enter upon the course of the other cases I have related. On the following day the vomit became dark, nearly black, and she died a little over fifty hours after the operation.

Not long after this case I operated for the removal of a large uterine myoma in a woman about fifty years of age. The patient was in fair general health, probably better than the majority of such patients, and the removal of the uterus was unattended by unusual difficulties or any accident. The magnitude of the operation, however, resulted in considerable shock, but the reaction was satisfactory. For the first eighteen hours all went well, when regurgitation began, and the now somewhat familiar picture was reproduced, she dying about forty-six hours after the operation.

Again, in February of this year, I operated on a woman about thirty-five years of age and in good physical condition, removing both ovaries, which were cystic and presented papillomatous growths. The cysts were each about the size of my two fists and were firmly bound in the pelvis. The operation was difficult but no accident occurred, and the shock, which was moderate, soon passed off. For the first twenty-four hours all went as satisfactorily as could be wished. She was comfortable and cheerful and the bowels responded satisfactorily and thoroughly to the saline cathartic given on the morning following the operation. During that afternoon, however, the regurgitation began, but without notable abdominal pain and no distention. The bowels continued to move until death, the discharge becoming dark colored toward the end. The vomit finally became black, and she died about sixty hours after the operation.

Here are eight cases presenting a sufficient number of signs and symptoms in common to indicate a similar origin and to justify placing them in a class by themselves. The conditions common to all the cases were: a sudden onset and rapid course of the trouble; the reference of subjective symptoms to the abdomen, such as pain and nausea; the presence of fever in each instance, the fever usually becoming very high just before death; the occurrence of coffee-ground, or black, vomit as the cases progressed; the absence of the usual signs of peritonitis; the absence of evidence of intestinal obstruction; the dusky or muddy hue of the countenance some hours before death, with possibly moderate yellowness of the sclerotic; and finally, the evidence furnished by the three autopsies made in the series of eight cases as related. Only one explanation has seemed to me tenable, and that was the presence and activity in the intestinal canal of some organism capable of producing a toxin which could not only give rise to pain in the bowels, but was capable of profoundly disturbing the function of the liver so as to induce a parenchymatous hepatitis with rapid softening and absorption, resulting in an acute atrophy. Of course this process may have been located in the liver more particularly than in the bowels, but that point did not allow of determination by any means at my hands.

• There were four medical and four surgical cases in the series, and the clinical history removed them from the category of any ordinary infective process. Neither could we invoke the idea of some special micro-

organism of a contagious nature, for the cases were isolated and not associated with similar cases either by time or locality, nor were they subject to unusual conditions or causes of disease, either in food, domicile, or other element of environment. The fact now recognized that the products of bacterial life are varied by certain conditions, in some instances a pathological micro-organism failing to give virulent products, while a change of conditions will result in a full establishment of its malign properties, seems to me pregnant with significance in many ways. It must be accepted that bacteria exist in the intestinal canal in all persons, and under certain yet unknown conditions some of them may become capable of inducing disease, though usually the tenancy is harmless. The bacillus coli communis is a familiar example. The only logical explanation of this fact lies in the assumption that usually the functions are so discharged that the enemy is either inhibited from pernicious activity, or the special material upon which it depends for action is not at hand. In a general way, this may be represented by the terms immunity, resistance to disease, and the like; nor are these idle terms. They represent ideas that should command our attention with a view to practical deductions. It is not probable in the light of our present knowledge of pathology that these eight patients at remote intervals and places received into their bodies any micro-organism or toxin from which all other persons in the vicinity were exempt. It is more logical to suppose that they had become specially susceptible to the influence or activity of something present in the persons of others as well as of themselves, where, however, it either was not functionally active, or its products were neutralized. In the surgical cases it requires but little strain on the medical imagination to conceive that the shock attendant on opening the abdomen could have a notable influence on the chemistry of the intestinal canal. The subject has lately received considerable attention from other standpoints, and we are quite familiar with such terms as "stercoral empoisonment," "intestinal ptomaines," etc. We can conceive of no other explanation, particularly of the fever, for all now accept that fever is usually the result of the presence of some toxin, whether the toxin results from the bacillus of diphtheria or typhoid fever on the one hand, or from the staphylococcus present in a furuncle. Just what constitutes the essential condition of vulnerability and reaction in each case, why some are made ill and others escape, is the problem that offers itself. Myriads of typhoid bacilli are swallowed without pathological results. Most of us have received the diphtheria germs in our bodies. Staphylococci are constantly gaining access to the crypts of the skin in each one of us without producing suppuration.

In many instances we can gather a clew to some of the conditions favoring infection. No extraordinary care is required to prevent local infection at pressure points in patients confined to bed with a fever, but when paraplegia exists all our best-directed efforts will probably fail to prevent a bedsore. In this instance a profound interference with innervation has evidently contributed to the creation of a local susceptibility to certain pathogenic germs. A review of the question of immunity has impressed me with the varied conditions under which it may exist, and the important fact that it may be lost.

In our surgical experience it is notorious that whatever diminishes the condition known as vital force—a term we can hardly dispense with as yet—increases the susceptibility to pathogenic organisms. Diabetics, drunkards, in fact all those who are below par by their own fault, or through diseases, do not present the same chance for successful surgical work as do those in good condition. A few pus-producing germs will

usually fail to incite suppuration if in contact with healthy tissue, but even if in a healthy person they be present on or in tissue locally disturbed, as in tissue tightly ligatured, we can safely count on infection. We know, too, that a contagious disease will fail to infect some members of a family while others are attacked, and yet those who escape may contract the disease at a later exposure, and this without any physical change or deterioration in general health that we can note. The immunity of the negro to yellow fever is a fact for which we have no adequate explanation, any more than for our inability to engraft syphilis on the lower animals; but all these facts have a lesson which we should note and utilize so far as we can. In interpreting the phenomena connected with the cases I have related, it seemed fair to conclude that the result in the surgical cases was not due to the introduction of infection at the time of operation. This conclusion was justified by the absence of pathological changes in the operative field, together with the fact that the clinical history corresponded with those cases in which no operation was performed. If this conclusion is justifiable it adds another reason to show us that at present, much as has been done to diminish the hazard of severe surgical procedures, there remain some conditions involving risk to life which are as yet beyond our control, and which should prevent us from assuming that even an exploratory opening of the abdomen is free from risk. Previous to the case of suspension of the uterus, I had surgically entered the abdomen in a series of over twenty-five successive instances without a fatal result, and this simpler and apparently safer case than any in that list succumbed.

In explanation of the process, as before indicated, it seems reasonable to me to invoke the aid of shock under the influence of which germs within the intestinal canal were able to produce toxins, which under ordinary conditions would not have been the case. So far as the preparation of the patients was concerned by examination in reference to the bodily functions, including the kidneys, etc., by the use of salines to "clean" the intestines, and by a proper diet in each instance, all that reasonable requirements could demand was done. It is not to be forgotten also that the usual history in these cases was previous good health, in some instances specially so. The speediness with which the condition developed and progressed to a fatal issue is also one of the important facts.

In discussing these cases with some of my medical friends, I learn that similar cases have occurred under their observation, but, while I find that most surgeons are inclined to credit them to acute "stercoral poisoning," they usually have ascribed the origin of the trouble to obstruction of the bowels, either by adhesions or the paralysis connected with peritonitis. In my cases, the evidence so far as it is available is opposed to such a conclusion; nor does the clinical history correspond with that of intestinal obstruction. In some of my cases the bowels were moved, and, in the last one, the passages continued free to the end. That there should be a parietic condition of the bowels in a portion of the cases is not remarkable.

In a series of cases presented by Dr. H. O. Marcy at the recent meeting of the American Medical Association, and printed in the *Journal of the American Medical Association* for August 8, 1896, I find that he has assigned intestinal obstruction as the cause of the trouble in all his cases. In some of them it is clear that such was the explanation, but in others it is not so clear. The following is one of the cases:

"Mrs. D—, aged forty-two years. Very nervous organization, but in fair general vigor, although for some years a sufferer from a retroverted, adherent, enlarged uterus, cystic ovaries, and diseased tubes.

The bowel had been freely evacuated; only fluid food in small quantities, often repeated, given for some days before the operation, with as large quantities of water as could be easily taken. Operation, March 18, 1896. It was difficult, owing to the embedding of the diseased adnexa in the pelvic cavity. After the removal of the diseased structures, the enlarged retroverted uterus was brought forward and sutured upon each side to the abdominal wall. The pelvic peritoneum was reformed by lines of buried tendon sutures, leaving only a small portion of the fundus of the uterus uncovered, which was partially denuded of its peritoneum owing to old adhesions. The small intestines were covered by the omentum with great care, the fundus of the uterus was dusted with sterilized aristol, and a vaginal drain of iodoform gauze carried through the posterior cul-de-sac into the vagina. Patient rallied well from the ether. The night following the operation was comfortable. Nausea and vomiting ensued on the morning of the 19th, with a singular weakening of the heart's action, followed by a rapid elevation of temperature, reaching before death 107° F. The skin was mottled with dusky patches some hours prior to death. These conditions were believed to be due to intestinal obstruction. The gauze drain was withdrawn and an effort made to examine the pelvis through the opening, but without avail. Regardless of every effort, the patient died about forty hours after the operation. The autopsy showed a loop of the lower part of the small intestine attached to the fundus of the uterus, which was separated with the greatest ease. The intestine above was filled with several pints of a very fetid dark-colored fluid, believed to have undergone decomposition prior to death."

It is manifest that this case does not correspond to the usual history of intestinal obstruction, nor does the recent adhesion "which was separated with the greatest ease" amount to an obstruction, for it is certainly common to have temporary adhesion of the bowels after abdominal section and in cases of peritonitis, without serious trouble. The course and termination of the case, and the presence in the bowel of "several pints of a very fetid dark-colored fluid," speak strongly for the existence of some condition which was more important than even the possible obstruction, which we may probably assume was not occlusion. In our classification of cases it is important to seize upon some essential element for the assistance to be derived therefrom in our consideration of the clinical histories, and this is accomplished in placing to the front the idea of intestinal ptosis. I do not deny that intestinal obstruction may be present in addition. What I do wish to call attention to is that obstruction of the bowels without concomitant changes in the intestinal contents is usually a quite chronic condition, a fatal issue occurring at times only after many weeks. No doubt the obstruction is occasionally so prominent and important a factor as properly to entitle it to become the designating feature, but in many of the cases it is a minor element, and in still others does not exist.

It would give me pleasure to present a full *exposé* of the life history of the micro-organism to which the process is due, but no light has been thrown on that part of our subject.

In conclusion I must place my title in error by relating a case that recovered, and I do so with some hesitation, for the account is so remarkable that it still seems to me like a "traveller's tale." Nearly two years ago I was requested by telephone to go to a neighboring town prepared to operate for obstruction of the bowels. I learned over the telephone that the patient had given birth to a child about two days before, that she had failed to have movements of the

bowels, was somewhat tympanitic, was vomiting a dark fluid, had fever and abdominal pain, and was very much prostrated.

As it would be some time before I could reach the place, and as cathartics had been tried in vain, it was agreed that awaiting my arrival copious enemata of water should be given. The treatment was diligently pursued. A large bag of water was emptied into the colon, and as it did not return, was followed by another—in fact by several others. In the mean time, the vomiting had increased in quantity and in frequency, and finally became fecal in odor, which was at first regarded as confirmatory of the diagnosis of obstruction.

On my arrival I found feces in fairly good-sized pieces in the recently vomited material, while some of that vomited at an earlier date was odorless, but contained sediment nearly as dark as charcoal dust. The patient was in a very weak condition, but she had begun to perspire moderately and her pulse was slightly less frequent, and the fever had fallen. Though I believed she would die, the idea occurred that possibly the poison could be removed in this unusual manner, and the washing was continued until the vomited material was quite clear. In order to maintain the action of the heart, strychnine was given hypodermatically in heroic doses, being guided by the pulse. She hovered between life and death for several days, then rallied somewhat, but developed a broncho-pneumonia and its attendant pleuritis, which placed her in great peril again. She finally recovered, and I believe has remained well. It is manifest that this treatment cannot be applied as a rule, but the lesson it carries is patent.

The arguments that have been made to explain the condition by the presence of a special microbe seem to me to lack sufficient fulness to entitle them to stand as final. Various organisms have been found in the intestinal canal—in cases of "stercoral empoisonment," even the pus-producing staphylococci—particularly in puerperal cases in which the pelvic organs were free from pathological changes. The problems are too recent and too complex to allow of definite conclusions on that phase of the question. In view of what is known of the behavior of micro-organisms under varying conditions, it is not improbable that we may finally arrive at two conclusions. First, the condition may be due to a special ferment, either a bacterium or an enzyme, and this may be present in the body without pernicious influence until a favorable combination of circumstances arises. This is favored by what is known of such organisms as the bacillus tuberculosis, the pneumococcus, etc. Second, it seems quite probable that the process may not depend upon one special organism, but circumstances may render one of several the offending agent.

This last supposition would involve the idea that the trouble is not dependent upon a constant cause, and, as a corollary, it would follow that the intermediate steps may not be the same, or in other words, that we now class together several distinct processes on account of certain striking features in common. Such a conclusion seems to me probable, for the variation in the signs and symptoms of the cases noted, as well as in others I have not reported, seems to me to justify the assumption that similar but not identical processes were to be expected in the final explanation. However, the personal element of the equation may prove more important than is suspected.

There is still another hypothesis that is not entirely untenable. It is manifest that the chemistry of the

digestive process is to a positive degree under the influence of the nervous apparatus, not only as to the rate of the process, but quite probably as to various details of it. Hence it is entirely possible that, given the usual elements of material and mechanism, if the nervous influence is sufficiently disturbed, products may result that could prove highly deleterious. The disturbance in digestion that occasionally comes to most people when under depressing emotions is a matter of common observation, and the limit of that disturbance has not been defined.

Concerning the measures which we may rationally take to protect our surgical cases from this danger, it is manifest that whatever will place the intestinal canal in a state of relative freedom from vitiated food products and micro-organisms would be reasonable measures to adopt. This can probably be best accomplished by a diet of plain articles of food, as milk, fish, etc., for three or four days before the operation, with the use of one or more doses of calomel, to be followed by Epsom salts on the day before the operation. It is quite possible that calomel has a special usefulness for this purpose. The free use of water also, to aid in the elimination, particularly through the kidneys, is important.

Still, do what we may, it is to be feared that for some time to come we will occasionally encounter one of these sad cases, and, as we advance in a series of successful operations, we should not flatter ourselves that we have mastered all the perils attendant upon surgery, or that the day of "capital operations" has passed.

THE PHONENDOSCOPE.

By HERMAN B. BARUCH, B.S., M.D.,

MT. SINAI HOSPITAL, NEW YORK.

This instrument was devised by Bianchi, of Florence, Italy, with the aid of the celebrated physicist Bazzi.

It has been extensively used in Europe for several years, and Schwalbi, of Berlin, from whom I quote below, commends it highly.

Following is a description of the instrument, which will be made clear by referring to Diagram 1. It consists of two principal parts:

1. The resonator.
 2. The conducting tubes of soft rubber.
- The resonator is composed of three parts
- A. The resonator proper.

FIG. 1.—The Phonendoscope.

B. A removable membrane.

C. A staff of metal tipped with a hard-rubber button. This staff screws into a thread in B and can be removed with it.

The resonator consists of a capsule having its sides and top of metal. The bottom is made of an ebonized plate which is pushed forward from within by a small spiral spring. The plate is held in place by a metal rim. The top of the metal capsule is perforated by two converging apertures. Between these the spiral spring is situated, inside the capsule. The second membrane, also ebonized, may be attached to A by two slits in the metal rim surrounding it, which re-

ceive two projecting metal points on *A*. Into *B* the small staff above described is screwed.

The soft-rubber tubes are tipped with metal points which are received in the converging canals in the top of *A*. The other end of the tube is armed with a small ear-piece which is self-retaining.

I have modified the instrument by attaching the distal end of the rubber tubes to the ear-piece of an ordinary stethoscope. This is found to be more satisfactory for prolonged and repeated use of the instrument, as the tips originally provided have to be introduced too far into the meatus auditorius for comfort, and often fall out of the ear. These rubber tubes may be multiplied to any extent for the purpose of affording to a number of students the means for simultaneous use. The whole instrument weighs about eight ounces.

To use the instrument the rubber tubes are connected to the resonator, the ear pieces are inserted, and the capsule is laid on the surface of the body. The instrument is most sensitive when used without the outer membrane and when both tubes are used. It is least sensitive when the staff and outer membrane are both attached and only one tube used.

I have thus carefully described the instrument, because only by accurately understanding its construction can one realize its capabilities without actually testing it. The inventor claims, and his claims have been borne out by practical experience, that the phonendoscope is of great practical utility in the following directions: 1. The instrument enables us to appreciate the normal and pathological sounds emitted by the organs of the body. Many acoustic phenomena which are not audible by ordinary means of auscultation are rendered clear and appreciable. The instrument enables one to hear the respiratory murmur, the pitch and quality of the sounds of the circulatory apparatus, of the organs of digestion, of the ear, both in health and disease; also of muscles, joints, and bones (fractures, dislocations, etc.), of the pregnant uterus and fetal heart, and even of the capillary circulation. He also emphasizes the ease with which "comparative auscultation" can be made, using two instruments upon corresponding areas and using a tube from either resonator. By squeezing the tube from one instrument and then the other, an exact comparative study of acoustic phenomena may be made. This is of especial importance in tracing the direction and extent of the transmission of cardiac and aneurismal murmurs, and in deciding fine points in pulmonary diagnosis.

2d. It may be used to great advantage to determine the form, position, thickness, and relations of separate viscera, thus replacing percussion. For this purpose we use the resonator with staff and second membrane attached. The button of the staff is firmly pressed upon the skin over the organ to be examined and generally only one tube is used. As the index finger of the right hand gently strokes the skin near the button, a distinct vibratory sound is elicited. This varies according to the thickness and extent of the organ examined. The ear soon becomes so trained that it recognizes the slightest grades of change in intensity and quality of this vibration. The stroking should be done with a regular oscillating motion of the finger, care being taken not to vary the amount of pressure used. Proceeding from the button to the periphery, the stroking is continued until a decided change in the quality of the sound is heard. This is very readily appreciated and indicates a change in the conducting medium beneath. Marking the point at which this change is heard, we go on with the stroking in another direction, marking as before. Thus we outline by dots upon the skin, with great exactness, the underlying organs. The trained ear may not only

recognize the boundaries of underlying organs, but also distinguish gross changes in structure and texture. The following is a translation of the directions of the inventor for outlining the various organs; by referring to diagrams 2 and 3, the points of election will be readily seen:

Anterior Portion of the Body.—Lungs: Place the phonendoscope above, upon, and below the clavicle for the upper lobes (1-2); in the third intercostal space for the (4) middle lobe; in the fourth for the lower (5). Do not stroke too hard. In this way you can readily distinguish the beginning of the lung, its divisions into lobes, and the overlapping of the same. When a pleuritic effusion is present, put the instrument in the same positions and, after examining in the upright and reclining positions, place the patient first

FIG. 2.—1, Upper lobe of lung; 2, upper lobe of lung; 3, middle lobe of right lung; 4, lower lobe of right lung; 5, Heart—(x) right ventricle, (1) right auricle, (2) left ventricle, (v) large vessels (aorta, etc.); 6 and 7, liver; 8 and 9, stomach; 10, ascending colon and cæcum; 11 and 12, transverse colon; 13, descending colon; 14, bladder (uterus); 15, kidneys.

on the right and then on the left side, to ascertain the variation in the level of the fluid. Stroke vigorously.

The heart: To determine the position of the heart, place the instrument in the left parasternal line, fourth intercostal space; for the right ventricle a little lower to the left, for the right auricle a little lower to the right; for the left ventricle, a little higher to the left; for the large vessels, a little higher to the right (arch of aorta, etc.); vigorous strokes. In this way we can determine the exact size and boundaries of the heart, its division into ventricles and auricles, and the position of the large vessels.

The liver: Place the instrument in the following positions successively: Beneath the xyphoid appendix in the right mamillary line, in the seventh intercostal space; in the ninth intercostal space over the mid-axillary line. Vigorous strokes.

The stomach: Place the phonendoscope in the seventh intercostal space, left midclavicular line, and then on the linea alba near the left free edge of the ribs. When the stomach is full, place the instrument just below the greater curvature. We can thus distinguish the pylorus, cardia, the coils of the intestine, and the nature of their contents, whether fluid or gaseous, and also the change in place and form of the organs when the position of the patient is shifted. Stroke vigorously for fluid, and lightly for gaseous contents.

The colon: For the cæcum and ascending colon place the instrument in the right iliac fossa, beneath

the free border and in the anterior axillary and mid-axillary lines. For the transverse colon, on two or three points, according to the breadth, above a line which passes from right to left over the umbilicus and strikes the left free border between the midaxillary and posterior axillary lines. For the descending colon, beneath the left free border in the midaxillary line and also near the anterior superior spine of the ileum. Stroking varies with the nature of the contents.

Bladder: Place the instrument in the linea alba above the symphysis pubis. Stroke gently when the bladder is empty, vigorously when it is full of fluid.

Ascitic fluid: Place the phonendoscope on either side in the anterior axillary line and in the linea alba on a level with the umbilicus, having the patient change from the upright to the reclining position, and even stand on his feet. Stroke vigorously.

New growths, also deeply situated organs, as the kidneys and spleen, can be outlined by placing the instrument over the centre of the organ and stroking the overlying region. Enlarged glands can be studied in the same way.

Posterior Surface of Body.—**Lungs:** Place the phonendoscope on either side in the scapular line at a

FIG. 3. 1, Upper lobes of lungs; 2, lower lobes; 3, spleen; 4, kidney; 5, liver; 6, kidney.

level between the first and fourth dorsal vertebrae for the upper lobes, and between the seventh and tenth for the lower lobes.

Liver: Place the instrument in the right scapular region at the level of the twelfth dorsal vertebrae.

Spleen: Place the phonendoscope on the left side in the posterior axillary and midaxillary lines and in the interspaces between the last ribs.

Kidneys: Place the instrument just within the semi-scapular line, immediately below the regions of the liver and the spleen.

My experience with the instrument extends to about one hundred carefully examined cases. I have examined patients with the naked ear, then with the stethoscope, and with the phonendoscope. Heart sounds have been especially studied. In cases of myocarditis, when the heart sounds could not be distinguished with the stethoscope, they have been distinctly heard with the phonendoscope, and this through several thicknesses of clothing. Murmurs which are inaudible to the unaided ear are so magnified and distinctly

reproduced as to be recognized with great ease. This will be a very substantial recommendation to physicians whose hearing is unfortunately defective. It is remarkable that there is so little disturbance and distortion of sounds when we listen through several thicknesses of material. Even fine crepitant râles may be heard with distinctness through the ordinary clothing. The heart can be examined with accuracy without disrobing the patient. I have several times detected even faint murmurs in this way and my diagnosis has been confirmed by my colleagues by observation with the stethoscope.

Another great advantage will be found in its use in the clinical lecture room. The tubes can be multiplied to any number and many students can listen to a heart or other organ at the same time, while the instructor demonstrates.

I am convinced that the phonendoscope is as great an improvement over the stethoscope as the latter was over immediate auscultation, and that we have in it a most perfect aid to accurate diagnosis.

NEW YORK, September 17, 1896.

THE VISUAL DISTURBANCES DUE TO NERVOUS DISEASES.*

BY WARD A. HOLDEN, A.M., M.D.,

NEW YORK.

IN beginning these remarks it may not be inadvisable to devote a few words to the theory of the tests of the visual field, inasmuch as it is chiefly these tests that give us information as to the location of the nerve affections causing disturbances of vision.

The light sense, as respects the power of distinguishing between two different light intensities, is most acute in the centre of the field of vision and gradually diminishes in the periphery, although even at the limits of the field slight differences in light intensity can be recognized. The color sense, as respects the ability to recognize a particular color, diminishes in the periphery of the field much more rapidly than the light sense, and at the limits of the field for white, colors of ordinary intensity in areas of moderate size are not recognized at all. If from any cause the conducting power of the optic nerve is interfered with uniformly, we find, first, that the acuteness of central vision is diminished, so that an eye with vision $\frac{20}{20}$ has now perhaps only $\frac{20}{40}$; we find, second, that the light sense is diminished in the entire field, so that a patch of pale gray which the normal eye could distinguish from a white ground at 60° in the periphery can now perhaps only be seen up to 30° in the periphery; and we find, third, that color perception is diminished, so that the field for blue is small, for red is smaller, and green is recognized only near the point of fixation. The condition then is one of relative loss of all functions in the entire field.

If we suppose the conducting power of the optic nerve to be still further interfered with, the acuteness of central vision will be further diminished, the color fields will be further contracted, the perception of green being perhaps lost altogether, and the power of distinguishing differences in light intensity will be much diminished in the entire field and altogether wanting in the periphery, where objects will not be seen. We have now not only the former relative loss of function in the entire field, but also an absolute loss of function in the extreme periphery of the field. The usual perimetric tests with a large white object will reveal only absolute defects in the field, but by using as a test object a pale gray patch or a small black point that can just be distinguished from a white

* Read before the Academy of Medicine, October 15, 1896.

ground by the normal eye at the limits of the field, the test becomes much finer and relative defects in the periphery can be made out. By using a paler gray patch and a smaller black point, or by using colors, relative defects in the intermediate and central zones will be revealed. In congenital color blindness with normal acuteness of vision the light sense is unaffected and functional tests may be made with the gray patches or black points, but in every case of acquired color blindness the color defect is accompanied with a light-sense disturbance, so that the functional tests may be done indifferently with colors or with grays and blacks.

The nature of a defect in the visual field is readily made out by standing eighteen inches from the patient and having him fix the finger held half-way between his eye and the observer's, while a card with a similar test object on each surface is brought in from the periphery in various directions, the point where the test object is first recognized by the patient being compared with the point where it is first seen by the observer, the patient's abnormal field thus being compared with the observer's normal field. For determining the exact extent of the defects and for recording them a perimeter is required. Since the field varies somewhat with fatigue, and since the errors of observation may be considerable when the fields for the different colors are mapped out successively, the relative extent of the color fields is best determined by holding a blue patch side by side with a red or a green patch and noting which color is first recognized as the two are brought in from the periphery at the same time. The normal eye will recognize blue first, red next, and green last, and this will also be the case in the contraction from optic-nerve atrophy and in other relative defects. But if there is a sharply limited absolute defect, as in hemiopia, the colors will all be recognized simultaneously at the margin of the defect; and it will sometimes happen that the red is recognized earlier than the blue, indicating a reversal of the sequence of the color fields. This reversal is due to imperfect adaptation of the retina, which is the physiological cause of the night blindness that accompanies retinitis pigmentosa and other diseases affecting the pigment epithelium. This reversal is also a symptom of hysteria.

When a colored test object is placed upon a white ground the colored patch will be seen beyond the limits of the color field as a dark spot on the white, and when it is placed upon a black ground as a light spot on the black. This renders it very difficult for the patient to say exactly where the color is first recognized. The difficulty, however, is largely done away with by putting each colored patch upon a gray ground having the same light intensity as the color. The patch will then not be seen as it is brought in from the periphery until the color is recognized, and in a scotoma for that color the card will appear uniformly gray.

In these ways we can most delicately determine the degree and the extent of defects in the visual field, and, since so many nervous diseases have visual disturbances among their first symptoms, the early determination of defects in the visual field may be of great value in diagnosis.

• In discussing the various types of visual disturbance in their connection with the lesion causing each, the subject naturally resolves itself into three parts, for some types of visual defect are characteristic of affections of the optic nerve, others of affections of the chiasm, and others still of affections in the visual path behind the chiasm. Disease of one nerve causes a visual defect in one eye only, but a single lesion in the chiasm or farther back in the visual path must cause symmetrical defects in the two eyes.

I. Diseases of the Optic Nerve.—With a diffuse

degeneration of the optic nerve, the ordinary atrophy, there is gradual failure of central acuteness of vision and peripheric contraction of the visual field, more or less concentric, the color fields being also contracted but preserving their normal sequence. The optic disc grows pale in its temporal half and later in its nasal, and finally the entire disc is white and excavated and the retinal vessels are narrow. This simple atrophy is most frequently due to a diffuse degenerative nervous disease, such as tabes, paralytic dementia, or disseminate sclerosis, and is often one of the earliest symptoms, and in tabes it is thought by some that the early occurrence of optic-nerve atrophy is an indication that the spinal lesions will be less severe and longer delayed in their development. Simple atrophy may be unilateral, but in most cases atrophy in the second eye follows later. This same peripheric contraction of the visual field occurs in post-neuritic atrophy of the optic nerve. An optic neuritis may, however, pass off without atrophy, and it is not unusual for a low degree of neuritis, probably dependent upon a meningitis, to persist for months or years without seriously affecting vision, and even the intense optic neuritis or choked disc which is a remote symptom of brain tumor may exist in a high degree without visual disturbance, but when vision is once affected it fails rapidly. This neuritis generally passes off after trephining, even though the tumor is not removed. In post-neuritic atrophy for a considerable time the outlines of the disc remain blurred and the retinal veins large. The disc is grayish-white in color and it is swollen instead of being excavated as it is in simple atrophy. The final appearance of the disc after neuritis does not always indicate the degree of visual disturbance, and occasionally after meningitis in childhood the same picture of post-neuritic atrophy is found in both eyes when one has good sight and the other is blind.

Entirely distinct in its pathology from peripheric contraction of the field is central scotoma. In the pure form there is diminished perception for red and green in the centre of the field, while blue is recognized here and the peripheric limits of all the color fields are normal. The cause of this symptom is an interstitial inflammation of the papillo-macular bundle of the optic nerve, that bundle which occupies the infero-temporal third of the disc and is then distributed to the macular region of the retina. As the inflammation advances, after a transient reddening of the disc its infero-temporal third becomes white and later excavated, while the remainder of the disc is of normal color. The pale sector remains sharply defined, so that it cannot be confounded with the diffuse temporal pallor of incipient general atrophy. The pure chronic form of this retro-bulbar neuritis of the papillo-macular bundle is usually due to tobacco and alcohol poisoning. There is never peripheric contraction of the field and until very late the central scotoma is only relative.

Central scotoma is found occasionally with disseminate sclerosis, with hereditary optic-nerve atrophy and with the acute retro-bulbar neuritis following grippe, etc. In these cases there is often an absolute central scotoma and frequently also some contraction in the periphery of the field. In simple atrophy vision once lost is usually never recovered, but in neuritis, particularly when limited to the papillo-macular bundle, lost vision may be entirely restored. In simple atrophy vision is best in a bright light, in neuritis in a subdued light.

The visual disturbances in hysteria, neurasthenia, and simulation are similar and cannot be sharply differentiated. All resemble the types of disturbance due to affections of the optic nerve. In extreme cases there will be total blindness in both eyes, of sudden

onset, although more frequently total blindness is limited to one eye. In the usual cases there is slight disturbance of vision for distant objects, more marked disturbance of vision for near objects, and concentric contraction of the field, or rarely a central scotoma. There is also fatigue of the visual field, the limits of the field varying with successive tests and gradually becoming narrower, and accompanying this there may be a reversal of the order of the color fields, that for blue being narrower than that for red. When the loss of vision is merely relative, the central acuteness may often be brought up to the normal by patiently urging the individual to read the letters lower down on the test card and by putting indifferent glasses before the eye. When there is apparently total blindness in one eye the tests for simulation will show that there is vision in each eye.

Before passing to the symmetrical disturbances in the two eyes, the unsettled question as to the existence of crossed amblyopia should be at least alluded to. Some British neurologists believe that a single lesion, presumably in the angular gyrus, can cause amblyopia in the eye of the opposite side with marked concentric contraction of the field and slight contraction of the field on the same side. Nothnagel has denied the existence of crossed amblyopia and many others have doubted it. Gowers, who is one of its chief advocates, reaffirms his belief in crossed amblyopia in his Bowman lecture of last year. He explains the amblyopia by supposing a lesion to exist in a hypothetical cortical visual centre higher than the half-vision centre in the cuneus. "Impressions seem to pass," he says, "to this higher centre in each hemisphere from both half-vision centres in the occipital lobes in such a way that in each higher centre both fields of vision are represented, but that of the opposite side in greater degree." In support of the existence of such a centre he adduces, first, hysterical amblyopia (which is now thought to be due to cortical disturbances), with which hemianæsthesia is frequent, but with which hemiopia is never found, the contraction of the fields being concentric, as would be expected if the amblyopia were due to involvement of the hypothetical higher visual centre. He adduces, secondly, the subjective visual spectra in the aura of epilepsy and in the scintillating scotoma of migraine. These visual disturbances are symmetrical in the two eyes but not necessarily hemiopic, sometimes more than half the field being involved, sometimes less, so that it is difficult to believe that they are due to involvement of one half-vision centre. The whole matter, however, is still vague, nor is it likely to be soon definitely settled.

II. Diseases of the Chiasm.—Pressure on the chiasm in front or behind, as well as pressure above or below, if near the median line, affects only the crossing fibres which are distributed to the nasal half of each retina and receive impressions from the temporal half of each field. The characteristic visual disturbance in chiasm disease is therefore bitemporal hemiopia. If the chiasm is cut through, all the crossing fibres being divided, the result is the absolute loss of the entire temporal half of each field, which is called complete absolute bitemporal hemiopia. If the chiasm is cut part way through so that only a portion of the fibres is divided, the result is the absolute loss of a portion of the temporal half of each field symmetrical for the two eyes, which is known as partial bitemporal hemiopia. If the chiasm is subjected to pressure that is sufficient to diminish but not abolish the conducting power of the crossing fibres, the result is loss of color perception in the entire temporal half of each field, while for large white objects the field is normal, which is called relative bitemporal hemiopia or hemiachromatopsia. Careful tests in this condition will reveal not only a color defect in the temporal half

of the fields but also a light-sense disturbance, pale gray patches and small black points not being perceived. Chiasm affections may thus give rise to a variety of visual affections, all corresponding to the type of bitemporal hemiopia. The simplest case is when the chiasm is slightly compressed by hemorrhage or exudation, or by the enlarged pituitary body, as we have it in acromegaly. There will then be produced a complete but relative bitemporal hemiopia. Central vision will be normal or nearly so; the field for large test objects will be normal, but colors and small test objects will not be seen in the temporal fields. If the pressure increases, the bitemporal hemiopia will become absolute, central vision will be diminished, and the optic discs will grow pale from atrophy of the optic nerves. If a malignant tumor of the pituitary body involves a portion of the chiasm, there will be at first a small absolute defect in the temporal half of each field, which will increase in extent until the bitemporal hemiopia becomes complete. The extension of the tumor involving the lateral bundles, the infero-nasal quadrant of one field is lost and later the supero-nasal quadrant, so that the eye is totally blind. Later the nasal half of the other field will be gradually lost and both optic discs will present the picture of complete atrophy.

III. Diseases of the Visual Path Behind the Chiasm.—Homonymous lateral hemiopia, the loss of each right or each left half of the visual fields, may be relative or absolute, partial or complete. It is rarely recovered from, although the defect may become smaller in the first few days. Central vision is usually normal. Homonymous hemiopia may be due to an affection of the optic tract, when the crus is likely to be involved, causing hemiplegia. It may be due to an affection of the internal capsule, when it is frequently associated with hemianæsthesia. And it may be due to an affection of the optic radiation of Gratiolet or of the cortex in the region of the calcarine fissure, when it is usually unaccompanied by other focal symptoms. If the lesion is peripheral to the primary optic ganglia, the tract atrophies and the discs grow pale. If the lesion is central to the primary optic ganglia the optic discs do not atrophy. It is also commonly stated that in lesions central to the primary ganglia the pupillary reaction to light will be normal, while in lesions of the tract there will be hemiopic pupillary inaction. But it must be said that Wernicke's symptom has not the great importance it is supposed to have, because in cases in which theoretically there should be hemiopic pupillary inaction it is often impossible to make it out with certainty. Ophthalmologists indeed have for the most part denied its existence altogether, and almost all of the cases reported have been seen by neurologists. Cases of homonymous hemiopia from tract affections are rarely seen, but bitemporal hemiopia from chiasm lesion is not rare, and most of the reported cases of hemiopic pupillary inaction, among them Seguin's often-quoted ones, were cases of bitemporal hemiopia. Here the determination of the presence of the symptom is interesting but of no diagnostic value, since the bitemporal hemiopia locates the lesion in the chiasm. In three cases of this sort I was not once able to elicit hemiopic pupillary inaction, though possibly the light was not thrown into the eye from a point sufficiently peripheric. In reading the report of Seguin's cases later, I find he states that when light reflected from a mirror was thrown into the eye at an angle of 90° to the temporal side of the line of vision no reaction occurred, but when the mirror was brought forward until the beam of light fell into the eye from an angle of 70° or 60° reaction occurred. Nor in this extreme peripheric field of 20° or 30° was reaction always completely wanting, but sometimes only less

marked than when light was thrown into the eye from a corresponding portion of the nasal field. Henschen, among others who have occasionally elicited the symptom, also describes it as being often only a less marked reaction and not complete inaction. When light is thrown into the normal eye from the extreme periphery of the field, pupillary reaction is never very marked, and often may be entirely wanting. Again it may vary greatly in the same individual, in the same conditions, and at one time be more pronounced from the nasal side and at another more pronounced from the temporal, the size of the pupil changing with the patient's constantly changing accommodation and the accuracy of the results obtained by the ordinary tests being exceedingly questionable. In order to eliminate errors due to changing accommodation and to Haab's cortical pupillary reflex, Heddaeus has recently proposed that the patient shall fix a test letter at two metres' distance, accommodating constantly for this, while two shaded lights, one to the patient's left and one to his right, are exposed alternately, and any difference in the degree of pupillary reaction noted. And it may be that, when performed with such refinements, the test for hemiopic pupillary inaction may give results sufficiently accurate to be of value in diagnosis.

There have been reported a few cases of relative homonymous hemiopia or hemiachromatopsia in which colors are not recognized in homonymous halves of the visual fields, while for large white test objects the fields are complete. Since in these cases coarse tests have not always revealed light-sense defects, it was supposed that, the cortical perceptive centres for form, light, and color being distinct, the color centre was here alone involved, or the color centre and the form centre only. Hence until recently it has been positively stated that homonymous hemiachromatopsia always indicated a cortical lesion. However, the careful examination of such cases has revealed light-sense disturbances also. In the only case that I have personally had an opportunity of examining, a patient referred from the nervous department of the Vanderbilt Clinic, there was a partial absolute homonymous hemiopia, and besides the absolute defect there were larger relative defects of different sizes for different colors, the defect for green being a complete hemiopia. But in each color defect there was a light-sense disturbance equivalent to those which accompany defects for the different colors due to lesions of the optic nerve. And there is little doubt but that light-sense defects will be found in every case of homonymous hemiachromatopsia, as they are found in every case of bitemporal hemiachromatopsia. It is difficult to suppose that a cortical lesion of two different centres could so exactly correlate the defects in color and in light sense, and it seems much more likely that further observations will lead us to the extreme opposite conclusion, viz., that hemiachromatopsia accompanied by a hemiopic light-sense disturbance must be due to an affection of the fibres of the visual path and not of the ganglion cells of the cortex. Nor does the only autopsy yet made in a case of this sort disprove this supposition.

45 WEST THIRTY-NINTH STREET.

Eating.—Children should be trained to eat slowly, no matter how hungry or what important business is pressing. Much safer a little food well ground than a hearty meal swallowed in haste. Cold food is even more difficult to digest than hot, if taken too rapidly. The normal temperature of the stomach is about 98° F.; food has to be raised to this temperature before digestion can take place.—*Medical Council.*

Progress of Medical Science.

Retropharyngeal Abscess.—Dr. Ambler says (*Cleveland Medical Gazette*) this affection is more commonly met with in children than in adults, and when occurring in the former is generally associated with a strumous diathesis.

Symphiseotomy.—Dr. Mayariet (*L'Obstétrique*, January, 1896) says that the most recent statistics are as yet somewhat discouraging. Neugebauer gives a maternal mortality of 11.1 per cent., and that of the child 19 per cent. The operations of M. Pinard and his followers in the last four years have given a mortality of 10.14 per cent. for the mothers and of 11.59 per cent. for the children. Perhaps this mortality would diminish considerably if all operators were careful and abstained from interfering whenever any unfavorable condition exists in mother or child which would compromise the success of the operation.

Bacteriology of the Hair.—Dr. L. Brocq (*Journal of Cutaneous and Genito-Urinary Diseases*, September, 1896) says that when the bacteriology of the hair is taken up various microbes are found in it. Six are, however, discovered quite constantly. These are: (1) a white fungus; (2) a yellow fungus; (3) a bacillus subtiliformis; (4) a bacillus in the form of a boat, staining with difficulty; (5) a special micrococcus, which Sabouraud designates provisionally under the name of micrococcus cutis communis; (6) the spore of Malassez, the flask bacillus of Unna, which he calls the bacillus asciformis. These two microbes, which appear to be the most important, are found in seborrheics who are not attacked with alopecia areata. No one of these microbes would have the importance of a causal agent in the disease.

Thoughts on the Origin and Spread of Contagious Diseases.—Dr. Faulds (*New York Medical News*) summarizes as follows: 1. That non-virulent microbes exist in all parts of the habitable globe. 2. That they were made disease producing in the case of cholera, small-pox, syphilis, diphtheria, and tuberculosis, in the thickly populated centres of the old world, through overcrowding and bad hygienic conditions, such as have never been known to us. 3. That the virus is always derived from a previous case, and is spread, either directly or indirectly, through human intercourse. 4. That increased vital resistance renders persons immune only in tuberculosis and other exceptional instances. 5. That if virulent bacteria could be prevented from finding a lodgment in human tissue, they would, for want of nutritive pabulum, soon return to their primitive dormant state. 6. That isolation, quarantine, and disinfection, under the direction of bacteriologists, are the only means by which we may hope successfully to prevent the spread of contagious and infectious diseases.

Suture in Veins and Arteries.—Dr. Sabanyeff, of Odessa, reports two cases of this kind. In the first the suture was applied to the femoral vein wounded during incision of the inguinal glands; in the second to the femoral artery. In the latter case the patient died from the original disease, and Dr. Padalka found by microscopical examination that the healing of the wounded artery took place from without inward. Dr. Heidenhans (*Centralblatt für Chirurgie*) cites two previously recorded cases, one involving the common femoral and the other the common iliac. He reports an instance in his own experience, in which in removing cancerous glands from the armpit an incision was made in the main artery. The bleeding was arrested by digital compression, and the edges of the arterial wound

were brought together by a continuous suture of catgut. Bleeding was thus completely arrested. The lumen of the vessel was not apparently diminished. The sutures held in spite of strong arterial pulsation. The patient made a good recovery. The axillary artery could be felt pulsating along the whole extent of the armpit.

Infection by Pets.—Cats have been suspected of conveying the infection of diphtheria, and scarlet fever has been traced to them. To this may be added the unwelcome news that a health officer has reported a case of small-pox which has been brought about in the same way; that is to say, by a cat from an infected house entering a neighbor's.—*Popular Science*.

Cerebral Concussion.—Kramer's study of cerebral concussion is summarized as follows in the *Lancet-Clinic*: A blow on the head produces a momentary increase of intracranial tension and consequent compression of the brain as a whole. The effect of this compression is to cause an interference with the blood supply to the entire brain, and this is sufficient to account for the primary symptoms of cerebral concussion. The so-called syncopie death, after severe concussion, is produced by a paralysis of the respiratory centres, the cardiac centres remaining intact. This fatal result may, in many cases, be prevented by the prompt institution of artificial respiration.

Seminal Vesiculitis.—Dr. Eugene Fuller (*Journal of Cutaneous and Genito-Urinary Diseases*, September, 1896) describes several operations, and draws the following conclusions: 1. Chronic non-tuberculous cases of seminal vesiculitis can be successfully and satisfactorily treated by extirpation of the sac. 2. Such an extreme measure, however, should be reserved for extreme cases, associated with serious or severe subjective symptoms. 3. Before resorting to extirpation the patient should have the benefit of the stripping treatment, if his circumstances allow it, and extirpation should be advised only in case the stripping treatment proves unsatisfactory. 4. In performing the operation the Kraske incision is the method advisable.

Cystitis in the Female.—Dr. Hersler's plan of treatment is thus outlined and recommended as giving the best results: (1) To remove any discoverable source or sources of irritation which act through the medium of the urine. This may be effected by a milk diet and a discontinuance of the use of acids, pepper, etc. Any mechanical source of vesical irritation should receive appropriate treatment. (2) The urine should be rendered bland by the use of a milk diet, the ingestion of considerable quantities of water, the administration of potassium citrate if the urine be too acid, or of boric acid and salol if it be alkaline. (3) Pelvic congestion should be relieved by hot vaginal douches, placing the patient in the knee-chest position, and the correction of constipation. (4) The inflamed cystic mucous membrane may be relieved by the administration of boric acid, sandalwood oil, copaiba, or creosote by mouth; or the use of injections of boric acid, carbolic acid, or nitrate of silver in suitable strengths. (5) The patient's general health should be improved by tonics, etc. (6) Rest in bed, especially in all acute cases, is absolutely imperative. While advocating direct local treatment for cases of cystitis which do not readily respond to ordinary therapeutic measures, I must advise that it should be employed with judgment and caution.—*American Journal of Surgery and Gynecology*.

Treatment of Ileus.—Naunyn (*Separat-Abdruck d. Mittheil. aus d. Grenzgebiet d. Med. u. Chir.*, I. Bd., 1896) gives the following set of rules for the treatment of ileus: 1. The prognosis of the operative treatment

of ileus is most favorable on the first and second day of its existence; it is markedly worse on the third day. 2. Seventy-two per cent. of the recoveries are obtained in those cases in which obstruction is due to a rupture, not including cases of strangulated hernia. 3. In primary peritonitis, this condition and not the resulting ileus must determine the operation. 4. (a) In chronic intestinal stenosis the necessity for an immediate operation does not often arise; (b) the seat of obstruction can usually be made out exactly, if it is located in the duodenum, descending colon, sigmoid flexure, or rectum; otherwise it can only be guessed at; (c) strangulation can often be diagnosed, and demands immediate operation. 5. An exact diagnosis of ileus is possible when it is caused by foreign bodies, e.g., gall stones, volvulus of the sigmoid flexure, and intussusception. Of treatment other than surgical, Dr. Naunyn says: 1. Avoid cathartics. 2. Large enemata of water or injections of oil, five to sixteen ounces, are better. Injections of air are less serviceable. 3. Opiates should not be given in large doses. 4. Washing out the stomach is recommended whenever there is faecal vomiting or the stomach is overdistended. 5. Food and drink should be reduced to the minimum. 6. Puncture of distended intestinal coils is of doubtful value.

Anæsthesia.—The *Medical and Surgical Reporter* gives the following instances in which chloroform is the preferable anæsthetic: 1. Chronic endarteritis occurring in those advanced in years. 2. Chronic inflammatory affections of the respiratory tract and advanced pulmonary disease. Of course, acute catarrhal affections of the respiratory tract are equally forbidding to the use of ether: but a patient suffering from such an acute inflammation should, unless delay were hazardous, be cured of his catarrhal condition before being subjected to any operative interference requiring a general anæsthetic. 3. Renal disease, acute or chronic. 4. When there is a history of ether having been taken badly at some former operation. 5. Chronic alcoholism. 6. Those cases in which the galvanic cautery is to be used in the neighborhood of the mouth or ear passages. 7. Cerebral tumors or abscess. 8. In old age. 9. In puerperal eclampsia where an immediate effect is required. 10. Night operations with artificial light. 11. During labor. 12. In military and naval practice, on the field of battle, its use seems to be at times justified, although strongly contraindicated.

The following conditions are looked upon as peculiarly unsuited for its administration, if not, indeed, prohibitive: 1. Surgical shock. 2. Epilepsy. 3. Spina bifida and hydrocephalus (Morton). 4. When there is a tendency to syncope. 5. Fatty heart and chronic valvular disease. 6. Acute alcoholism: Delirium tremens (Sansom). 7. Fatty liver. 8. It is unsafe to give chloroform to a patient already under the influence of chloral, whether in obstetrical practice or otherwise.

Curettage as a Method of Inducing Abortion.—Dr. Puech presents the following conclusions in the *Annali de Gynecologia et Obstetrica*: 1. Curettage should have a place among the approved methods of artificial abortion. 2. Before the fourth month it is efficacious and free from danger. 3. It should be adopted, particularly whenever rapid evacuation of the uterus is indicated. 4. It should be adopted whenever economy of blood is especially indicated—in anæmia and feebleness from any cause. 5. In intractable vomiting; particularly is it indicated for two reasons advanced—rapidity in performance and economy in blood.

MENTAL THERAPEUTICS.

THE wonderful influences of the mind on the complex nutritive processes and on the various diseased conditions of the body are readily acknowledged by every observing physician. The old saw, faith in the medicine and confidence in the doctor, has not only a foundation in fact, but an explanation in science. The more we think on the possibilities of mental therapeutics, the more we become convinced of its wide range of practical application. So much advantage, however, is taken by quacks and other pretenders of the well-known credulity of their victims, that the truly scientific observer has been loath to investigate the subject in the calmness of a judicial examination or with the unprejudiced aim of a seeker after fundamental truths. That the general subject deserves more earnest attention at our hands must be apparent to every thoughtful man who endeavors to explain certain nervous phenomena of almost daily occurrence, but which on casual examination appear beyond reasonable comprehension. Such, at least, is the conviction of Dr. A. T. Schofield, who, in an address on "Mental Therapeutics," published in a recent issue of *The Lancet*, strives to aid investigators in this new and attractive field of study. It will not be necessary for our present purpose to do more than offer in outline some of the main points upon which he bases his argument in proof of the intimate correlative agencies affecting mind and body and their direct bearing on both the natural and the perverted nervous tendencies. He starts with the assumption that the conscious mind, or ego, is but a very small part of the vast subconscious mind upon which it rests. The former has its seat in the cortex only, governing reason, feeling, and volition, while the latter "is connected with—or may we not say is the active principle of?—all life that lies below, including reflex action." While it is not possible to be conscious of any vibrations that do not reach the surface of the brain, the vast majority of impressions are directly and uninterruptedly transmitted through it to the subconscious mind, which thus becomes the storehouse and registry of all those intricate and complex energies which make up the responsive vital reflex of our varied and impressive environment. Although full consciousness is the result of the combination and interaction of the two conditions named, the conscious mind so-called becomes

a party to the impression only when the latter is focussed on the cortex by the direct attention of the individual affected. To go a step farther, the author assumes that the cortex not only receives impressions from without in a primary and direct way, but is also subjected to like impressions secondarily and indirectly from the subconscious mind. In the one case, there is an immediate and easily understood recognition of the impression, while in the other the phenomenon is not only without explanation to the individual, but is entirely beyond his control. In the latter category are mentioned unconscious habits, unconscious cerebration, and the like. The conscious mind, when it wills, dominates the unconscious, and thus in its own imperious way interprets sensations to suit its purposes, diverts normal processes into abnormal directions, changes the rhythm of vital processes, disarranges the nutritive machinery of the body, and even tampers with the pain signals in its mad misrule. Dr. Schofield says truthfully:

"The cortex, or surface of the brain—the seat of conscious mind—is a special factor for good or evil in every disease. Every organ and function is represented there, and there brought into vital unity. Professor Laycock says: 'The hemispheres, as the organ of thought and mental action proper, are in unity with all the processes of life whatever, whether they be termed vegetative or animal.' Indeed, the unity of the body and to a great extent of the 'ego' is formed in the cortex. Bain shows that all tissue nutrition is influenced from this great centre, and most physiological acts can be arrested mentally by its action. It controls unconsciously anabolic and katabolic cell action; and there is no doubt that a sound, cheerful mind, acting through it, is a great protector against disease of all sorts, and if disease has a hold a cheerful mind can often cure it. Mental therapeutics can be applied to the body in one of three ways: (1) By the unconscious mind directly—in spiritual or physical influences and surroundings; (2) by the unconscious mind acted on by the conscious indirectly—in rousing faith in persons, remedies, or places, etc.; and (3) by the unconscious mind acted on by the conscious by direct effort—in determination to get well, to shake off illness, ignore pain, etc. With regard to the ailments for which mental therapeutics is useful, it is a powerful means of cure in all organic and inorganic diseases, while in hysteria and allied neuroses it is the only reliable means of permanent efficacy."

He then gives several interesting instances of the influence of mind, conscious and subconscious, in ordinary disease and on the natural habits of thought and action in the human organism.

"A patient suffering agonies with toothache was told by her medical man to apply to the tooth a silver coin wrapped in silver paper. Believing it to be infallible, she did so several times and was relieved. One day, however, she was told the remedy was wholly mental, and at once it was powerless. Here is an instance of the pernicious effects of the conscious mind inhibiting after first aiding the subconscious. Unzer, in 1771, says: 'The expectation of the action of a remedy often causes us to experience its operation be-

forehand.' I have just received a remarkable illustration of this, that, however, goes beyond this statement. A colleague of mine gave a patient the other day some opium pills to produce sleep, but forgot to mention their object. Last week he found the pills had acted well each morning, but the patient had had no better sleep. Another patient thought she had taken a large dose of rhubarb as a remedy for constipation, and the thought was effectual. Hunter says: 'By my will I can fix my attention on any part until I have a sensation in that part;' while Müller affirms that it may be stated as a general fact that any state of the body which is expected with certain confidence will be very prone to occur as the mere result of that idea. It is easy to produce symptoms by suggestions. If, for instance, you press some particular part of the spine of a neurasthenic and say, 'Do you feel any pain here?' he may say, 'No.' But if you persist in your suggestion for half a dozen times, and the nervous centres are at all susceptible, he will say, 'Yes,' and the pain suggested by you will be felt. Now this is true with regard to producing cures as well as in producing diseases. The action of the subconscious mind in presenting a fact to the conscious mind is remarkably illustrated in a recent story of Sir R. Quain's. He was sent for by a man, aged forty years, who had a delusion that his body had a most offensive smell, and he even covered up his pictures lest they should be tainted. No smell could be perceived, but a most fetid iliac abscess was found and opened. His idea, therefore, was not a delusion, but a recognition through his subconscious mind of his condition."

By way of illustrating the power of suggestion in the treatment of so-called imaginary troubles, he mentions the value of the time element in connection with the watching of the mantel clock for indications of dosage:

"The real value of the clock in this, as in other cases, is truly scientific, and depends for its potent effects on rapidly formed accurate psycho-physical habits, or artificial reflexes, in the brain. A woman about seventy years of age came to me in deep distress about her obstinate constipation, which was so severe that every enema and pill had failed and mechanical evacuation was the last resource. This condition had continued for some years. The patient was of exceptionally powerful mind and will and remarkable intellect. Seeing this, I relied upon the clock as an efficacious aperient. I explained the power of an exact habit over the bowels, and told her she would be cured if at 9:30 A.M. exactly by the clock on the mantelpiece she sought relief each morning. She was at first aided artificially at the exact hour, but after a few mornings when 9:30 A.M. arrived, and she was taken out of bed, the bowels began to act, only she sometimes wanted to relieve them before the hour. This was never allowed; she was told that to be too soon would prevent the result as much as being too late. At the end of six weeks the bowels were duly relieved without medicine at half-past nine exactly, by the power of subconscious habit, and at the end of six months she had never missed a day. She has now no further trouble."

It is probably within the experience of many of our

readers that similar cases are to be found, in which the method of dosage was more than the dose itself, the placebo more powerful than the real drug, and, best of all and at the bottom of all, the belief that the doctor understood the case and knew exactly the best remedy to give. It is fair to assume, if the range of psycho-physical ailments is great, there should be an equal power of mental therapeutics to cure them. The highest recommendation for mental therapeutics is that it is not dangerous, that it is susceptible of further profitable cultivation, and that it may serve in many obscure and apparently desperate cases in effecting a cure when all the usual means have failed.

THE DIAGNOSIS OF TYPHOID FEVER.

An interesting experiment in the blood-serum method of diagnosis of typhoid fever has just been instituted by the board of health of the Province of Quebec. In the circular issued by the board it is explained that Pfeiffer and Widal have discovered that the addition to a pure bouillon culture of typhoid bacilli of blood-serum from a person suffering with typhoid fever causes an abolition of the active movements of these bacilli and an agglutination of the individual organisms into large clusters. This effect is not observed when blood serum from a healthy person, or from one suffering with a febrile disease other than typhoid fever, is added to such a culture. In the method originally employed by Pfeiffer a rather complicated technique was necessary to secure pure serum, but this was greatly simplified by Widal, who found that the test could be made equally well by means of a few drops of blood collected in a sterilized glass tube. Even with this advance the method was still not sufficiently simple to permit of its general employment as a reliable diagnostic measure. Dr. Wyatt Johnston, of Montreal, bacteriologist of the board of health, has recently shown, however, that a drop of typhoid blood which has been dried for several days will give this reaction promptly when moistened with water.

This discovery makes the method applicable to a system of public laboratory diagnosis similar to that now practised in many cities in the case of diphtheria, and the board of health has therefore determined to make a test of the method on a large scale. For this purpose it has distributed a number of envelopes containing a folded sheet of sterilized paper. A physician who has a case of suspected typhoid fever is instructed to cleanse thoroughly the tip of the patient's finger or the lobe of his ear, and, after carefully drying, to prick it with a needle sterilized in the flame. The blood so obtained is dropped on the paper and when it is dry the latter is folded and enclosed in an envelope directed to the laboratory of the board. There it is examined and a report is returned to the physician the following day.

The board desires, through this public proving of the test, to obtain data upon a number of points, and it asks those taking advantage of the offer made to them by the board to do all in their power to aid this inquiry. The following are the questions upon which

it is hoped to obtain some light: 1. The proportion of cases in which a correct diagnosis can be made by the serum test, and the relative efficiency of the method of employing dried samples. 2. The earliest period in typhoid fever at which it can be expected to give indications. 3. The length of time for which it persists after convalescence. 4. The existence of any relation between the intensity of reaction with the test and the course of the disease. 5. The study of the nature of the obscure febrile conditions, clinically termed gastric fever, continued fever, abortive typhoid bilious fever, typho-malarial fever, etc., about which our present knowledge is very meagre and unsatisfactory.

The results of this experiment will be looked for with interest, for the advantage of a reliable means of diagnosis of typhoid fever in its early stages can readily be appreciated.

HOT ROOMS AND CATCHING COLD.

WE are so accustomed to the formula that American houses are always overheated, and it has become so much the fashion among medical men to attribute catarrhal troubles to this cause, that it is interesting to learn of an English writer who thinks it is better to be warm than cold in winter. Dr. William H. Pearse, writing in the *Scalpel* for September, says that he ventures to differ from the popular belief, that there is special danger in going from a hot room into the open air, holding, on the contrary, that the heat of the room or house is a great preservative from chill or "catching cold" on going out into the open air. In Russia, in Central Europe, Canada, and the Northern United States, houses are made very warm with a dry heat in the winter, yet men, women, and children go out into a temperature below zero. The stimulation and heightened condition of the circulation and nerves, and ultimate molecules of protoplasm, give a great power of resistance to the outer intense cold, preventing "chill" in the first exposure until exercise with its infinite motions, as it were, takes up and maintains the conditions of resistance. Dr. Pearse says that he has walked at midnight from a highly heated mansion across Boston Common, in his dress coat only, on a calm starry night, the temperature about zero. He suffered no inconvenience and felt sure that the stimulus of the heat of the house gave him power of resistance to the cold.

Dr. Pearse is undoubtedly correct in his observation that one can come from a hot room into the cold outer air and run but little chance of catching cold. The danger is rather in entering a hot room from without, and especially in entering an overheated and unventilated apartment filled with excrementitious products from the lungs and skin of its inmates. A change from a hot to a cold atmosphere can be made suddenly, but that from extreme cold to indoor heat should be made gradually if one would avoid the catarrhal consequences of "catching heat."

A Woman's Bicycle Class in first aid to the injured is an indication of the progression of the wheel.

REVISION OF CODES.

OUR good brethren across the water are at present very much interested in the revision of their codes of ethics, in the hope of adapting them more nearly to the present requirements of medical men. It must be confessed that these documents read exceedingly well, the principles they contain are lofty and pure, the lines of action straight and distinct, and their general purposes laudable and just. The great difficulties, however, are in their practical application. The evil doer is apt to interpret the law to suit his own requirements, and hence the differences of opinion as to where the real boundary between right and wrong should be drawn. This, however, does not apply to the man who acts his best under all circumstances. The gentleman does not need a law of conduct, and the one who is not a gentleman can never be raised to the common ground of honesty, high morality, culture, or fair play. It is the golden rule, after all, when it can be properly applied. Any doubtful question can easily be answered on such a basis. How would you like it yourself? is a very direct question to the man with an elastic conscience and an easy adaptability to tricky situations. Even the ten commandments are nicely balanced on the "Do-unto-other" principle. We know of lots of good men and true who need no other code—men whom we are always glad to meet in council, whom we can always trust alone with our patient, and in whose mouths our professional character is always safe. It is not What code do you follow? but What kind of man are you?

THE WINTER HEALTH RESORTS.

IN the present issue we publish an account of the principal winter health resorts of this country, as a companion article to "Summer Health Resorts," which appeared in these columns several months ago. It has been truthfully said that on this continent there can be found every variety of climate during the year, suitable not only for the most exacting requirements of every class of invalids, but for such as require merely those changes of environment necessary for simple rest and needful recreation. So much is being done to advertise the special advantages of particular localities by parties interested in their development, that it is oftentimes difficult to select such on the basis of simple and well-established merit. The writer of the article in question has endeavored, very successfully, to be absolutely impartial in his statements, and with no other end in view than that of obtaining reliable data has merely presented them for what they may be worth, leaving each reader to choose for himself and adapt them to the individual cases seeking his advice. Climate cure, like every other means to the end, demands careful study and judicious application. The physician should be able to select his climates with as much certainty as his other remedies. To such an end the data have been collected, and it is to be hoped they will serve their purpose, not only for present study but for future reference. The American people are notoriously a nation of travellers during all seasons of the year, and

it behooves the physician to be acquainted with the more frequented regions, their mean temperature, altitude, scenery, and conveniences, in order to advise those who go for pleasure as well as for health. Aside from this, we trust that the accounts given of the varied attractions of the different resorts will afford interesting and profitably suggestive reading to such as may believe in voyages of discovery and may yearn for the new experiences which are their legitimate rewards. The tired doctor, above all, may need, in the midst of his winter's work, just the little trip which may be thus suggested to him, the taking of which may, perchance, still longer delay the inevitable obituary.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending October 24, 1896: Assistant Surgeon M. S. Elliott, ordered to the naval laboratory and department of instruction, New York.

Dr. Milton E. Artman, of Buffalo Creek, Col., died from pulmonary hemorrhage on September 29th. He was a graduate of the College of Physicians and Surgeons in this city, and served as interne in Bellevue Hospital. He practised for three years in Rochester, but, his health failing, he went to Colorado about two years ago.

Medical Practice in Victoria.—The Melbourne correspondent of the *Medical Press* draws a very long face over the state of the medical profession in that colony. He says the doctors are too thick on the ground, and consequently the normal competition has grown into a struggle for existence. The population of the colony hardly reaches a million and a quarter, and the number of qualified practitioners is one thousand and seventeen. The number increases by about sixty yearly, which is out of proportion to the growth of the general population. It appears also that the physicians of the younger generation, or some of them at least, have been encroaching upon the correspondent's clientèle, for he says that the city is flooded with young men who neglect no opportunity of bringing themselves into conspicuous notice; and, more than all that, "the younger members of the profession have not only no reverence for their elders, but, on the contrary, look down upon them as unprogressive fossils, and comport themselves accordingly."

The Body of George Du Maurier, the artist and author, who died recently in London, was cremated, in accordance with his often expressed wish.

Prophets Not without Honor.—When Crown Prince Frederick of Germany was suffering from cancer of the throat, he sent to England for a laryngologist; when the Tsar of Russia was ill, he had his own physician, but sent to Berlin for a consultant; and now Queen Victoria is suffering from failing vision, and has sent to Germany for an oculist, Dr. Pagenstecher, of Wiesbaden, to examine her eyes. The

Medical Times says that there is a pamphlet in circulation in which many of the leading oculists of England are spoken of in disparaging tones, and it is intimated that the Queen was influenced by that to send abroad for advice.

An Epidemic in Merv.—A telegram from Merv, dated October 1st, states that during the past two months a malignant fever has raged among the Turcomans, nearly ten thousand persons having been carried off. Most of those attacked are children. A similar violent outbreak of fever occurred in 1893.

International Congress of Hydrology, Climatology, and Geology.—At the session of this congress, held during the last week of September, at Clermont-Ferrand, France, the following officers were elected:

Hydrology: *President*, Dr. Cazan (Eaux Bonnes); *Foreign Honorary President*, Dr. Jules Felix (Belgium); *Vice-Presidents*, Dr. Ferres Luchon (France), and Dr. Pinella (Spain).

Climatology: *President*, M. Hurion, director of the Puy de Dôme observatory; *Foreign President*, M. Lancaster (Belgium); *Vice-Presidents* (France), MM. Plumandon and Piche; *Vice-Presidents* (foreign), MM. Angel Anguano (Mexico) and Faralli (Italy).

Geology: *President*, Dr. Labat; *Honorary President* (foreign), Dr. M. E. Tietze (Austria-Hungary).

President of the Congress (national), Dr. de Ranse; *Honorary President* (foreign), Dr. Berthenson (Russia); *Vice-Presidents* (national), M. Linder (inspector-general of mines), M. Angot, and Dr. Garrigan; *Vice-Presidents* (foreign), Professor Ludwig (Austria-Hungary), Professor Kuborn (Belgium), and Laurence Rotch, director of the observatory of Blue Hill (United States).

The London School of Medicine for Women has recently received a gift of \$5,000 from a lady of wealth who had been attending some of the lectures.

Diphtheria is prevailing to an unusual degree in London, the mortality from the disease during the first week in October having been greater than that of any week this year.

The Women's Medical Institute in St. Petersburg, recently established, is forbidden by its regulations to receive any students who are not of the Christian faith. A petition signed by the Jews resident in Odessa, praying for the admission of certain women of their belief, has been rejected.

The Water Supply of Denver, according to the *Colorado Medical Journal*, is as bad as that of Chicago. For years, says our contemporary, the citizens of Denver "have been led to believe that they were drinking pure mountain water, piped directly from the snow-capped peaks in the mountains. Such a monstrous lie was never before circulated. Instead of pipes, are open irrigating ditches; instead of mountain water, pond and contaminated river water is the source of supply."

St. Joseph's Hospital, New York.—Dr. Alfons Müller has been appointed visiting physician to St. Joseph's Hospital.

Dr. Carl von Kupffer, professor of anatomy in the University of Munich, has been elected rector of the university for the coming year.

The Jubilee of the Pathological Society of London was celebrated on the evening of October 24th. There was a reception and an address was delivered by the president, Mr. H. T. Butlin.

To Investigate a Consumption Cure.—Drs. Bouchard, Chauveau, and d'Arsonval have been appointed a special committee by the Academy of Science in Paris to report on the alleged cure for consumption practised by Dr. Crotte. His method comprises the use of electricity and antiseptics, the electricity being employed to open the way for the parasiticide.

Typhoid Fever in Madeira.—A correspondent of the *Medical Times* writes that the water in the Island of Madeira is very bad, and that typhoid fever prevails there to a very great extent. Last spring there were four deaths in four weeks among the English visitors, and that the danger still exists is shown by the fact that one of the English resident physicians is just convalescent from an attack. One fatal case, it is stated, was directly traceable to drinking a glass of water.

The Jubilee of Anæsthesia.—The following congratulatory cablegrams were read at the exercises in Boston, on October 16th, in celebration of the semi-centennial of the first operation performed under ether:

"CHRISTIANIA, October 16, 1896.

"TRUSTEES AND STAFF, MASSACHUSETTS GENERAL HOSPITAL, BOSTON: Best congratulations on fiftieth anniversary.

"CÆSAR BOECK."

"MOSCOW, October 16, 1896.

"BOSTON, MASSACHUSETTS GENERAL HOSPITAL. COLLINS WARREN: The Moscow Surgical Society, at a special meeting held in honor of the fiftieth anniversary of the introduction of anæsthetics, celebrates the memory of Morton and Simpson, the great benefactors of mankind. It greets the committee and wishes it every success in its labors on behalf of science, which knows no geographical boundary.

"DIAKON, *President*.

"WARNECK, *Secretary*."

Mr. Thomas Bryant has been appointed surgeon-extraordinary to the Queen, and is thereupon made the subject of the following puff-extraordinary in the *London Star*: "It has been said of the new surgeon-extraordinary that his services are in such request that he wears out six pairs of carriage wheels in a year. He is not one of the showy surgeons, but a business-like, sturdy man of large experience, whose long professional life and freedom from fads have endowed him with much professional skill, and who has filled most places of honor to which surgical distinction leads in his time. Mr. Bryant is above the middle height, broad-shouldered, and erect, with hair shaded with gray, and firm, full lips. He lives in Grosvenor Street, and has a kindly and sympathetic manner."

Dr. A. Jacobi, in an address at the dedication of the Bender laboratory connected with the Albany Medical College, October 27th, referred to matters of hygiene, and dwelt upon the part taken by laboratory workers in bringing hygiene, and the etiology and prevention of disease up to their present high standard. He pointed out the shortsightedness of laws which would restrict vivisection in laboratories devoted to the advancement of science, the prolongation of human life, and the abolition of suffering.

An Anæsthesia Number.—The October issue of *The Practitioner* is devoted to the jubilee of anæsthesia, and contains the following articles: "The Past, Present, and Future of Anæsthesia," by Frederic W. Hewitt; "The Work of Simpson, Snow, Lister, and the Hyderabad Chloroform Commission," by George Rowell; "The Administration of Ether," by F. Woodhouse Braine; "The Principles of Ether Administration," by George H. Bailey; "The Story of the Discovery of Anæsthesia," by Dudley Wilmot Buxton; "Anæsthetics in Operative Surgery," by Frederick Treves; "Anæsthetics from the General Practitioner's Point of View," by Alfred Hartley; "The Need for Better Instruction in the Administration of Anæsthetics," by Marmaduke Sheild; "Hypnotic Anæsthesia," by J. Milne Bramwell; and "The Present State of the Law as to the Administration of Anæsthetics," by R. W. Turner. There are also bibliographical sketches of the "pioneers of anæsthesia," William Thomas Green Morton, Horace Wells, Sir James Young Simpson, John Snow, and Joseph Thomas Clover. The first administration of ether in England to induce anæsthesia, the editor writes, took place on December 19, 1846, at 24 Gower Street, London, the house of Dr. Boot, to whom the news of Morton's discovery was communicated by the late Dr. Bigelow, of Boston. The agent was administered to a Miss Lonsdale by Mr. Robinson, a dentist, who extracted a molar tooth from her lower jaw while she was under its influence. On December 22d Robert Liston amputated a limb under ether in University College Hospital, and so intense was the emotion of the great surgeon on the occasion that when he turned to address the spectators after the operation he could hardly speak. The administrator was Dr. William Squire, who is still living.

Southern Surgical and Gynecological Association.

—The ninth annual meeting of this association will be held in Nashville, Tenn., Tuesday, Wednesday, and Thursday, November 10, 11, and 12, 1896. The Nicholson House has been selected as headquarters for the association. Those who contemplate attending the Pan-American Medical Congress, to be held in the City of Mexico, November 16th–19th, will have time to do so after the meeting of the Southern Surgical and Gynecological Association. A rate of one fare the round trip has been made on account of the congress, stop-over privileges being allowed the holders of tickets. The president is Dr. E. S. Lewis, of New Orleans, La.; and the secretary, Dr. W. E. B. Davis, of Birmingham, Ala.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 15, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

The Relations of Diseases of the Eye to General Diseases.—In connection with this subject three papers were read, the first one being on

The Effects of Extrinsic Poisons on the Eye.—

DR. J. H. CLAIBORNE was the author. The list of agents which when taken into the system produced disturbance of vision was a long one. He would speak of the more frequent ones, and in doing so would acknowledge indebtedness for much of the information to the works of De Schweinitz and Wood. The importance of the subject appeared from the brief summary with which the author concluded his paper: 1. There were certain poisons which, when introduced into the human system, produced characteristic toxic symptoms in the eye. 2. These poisons were divided into two grand divisions: (a) Those which produced organic changes in the optic nerve and retina. (b) Those which produced no organic changes but whose effects on the eyes was only functional. 3. The majority of these poisons were found in the list of medicinal remedies.

Among the agents in the first division which the author dwelt upon were alcohol and tobacco, which occupied respectively first and second place. The habit of taking many small doses of alcohol a day, particularly before meals, was most likely to produce retrobulbar optic neuritis. This was illustrated in bartenders. Idiosyncrasy had something to do with it, for some persons drank all their lives and were not thus affected, while others suffered after limited indulgence. Most cases occurred between forty and fifty years of age, and men were naturally affected oftener than women, because the latter were less addicted to alcohol. This was equally true of tobacco amblyopia. Those who smoked short pipes and strong cigars were more likely to have amblyopia than those who did not. Some claimed to be able to distinguish between alcohol and tobacco amblyopia. The first symptom complained of was indistinctness of vision, and the patients were apt to come for glasses, especially if presbyopic, as they usually were. Perhaps the most distinctive symptom was inability to recognize red and green—central scotoma for these colors. The ophthalmoscope would show optic neuritis, but it was a question whether this form of optic neuritis alone would ever lead to complete blindness. It was well to look to syphilis as a combination, for tobacco, alcohol, and syphilis frequently went together. For his own part he had no faith in the word of chronic smokers and drinkers when questioned as to their venereal history.

Quite a number of cases of amblyopia from carbon bisulphide, used chiefly in the manufacture of vulcanized rubber goods, had been reported. Perhaps chloride of sulphur, associated with it, had something to do with the ocular symptoms. Some other agents named in this class, but less certain in their action, were hashish, cannabis indica, iodoform, arsenic.

Lead was apt to affect sight as well as to produce muscular paralysis. Quinine occasionally caused amaurosis, the dose necessary to do this varying with the idiosyncrasy of the patient. The author's case was the only one on record in which the blindness continued two years. Further, among the agents of the second division, Dr. Holden mentioned the venom of serpents, ergot, absorption of mercury rarely, male-

fern, pomegranate, belladonna, hyoscyamin, duboisine, cocaine, ptomaines from eating spoiled fish, etc. Among agents which produced contraction of the pupils were opium, chloral and its hydrate, eserine, pilocarpine, strychnine, and nicotine.

The poisons which produced variable eye symptoms constituted a long list. Among them were santonin, anilin, naphthalin, bromide of potassium, picric acid, amyl nitrite.

Eye Diseases Seen in Some of the General Infectious Diseases.—DR. CHARLES J. KIPP, of Newark, read the second paper, or as much of it as the time would permit. He said it contained nothing new. Beginning with the eruptive fevers, in measles a catarrhal inflammation of the conjunctiva was regularly present before the appearance of the eruption, and usually went away in the course of a few weeks. In exceptional cases it persisted for months. If ulcers of the cornea should form they might lead to its destruction if maltreated, as in one case which he had seen. Meningeal or cerebral complications might lead to atrophy of the optic nerve and blindness. Rapid and destructive suppuration of the cornea, also gangrene of the lids, acute inflammation of the lacrymal glands, and albuminuric retinitis had been seen in measles.

In scarlet fever inflammation of the conjunctiva was present in many cases during the eruptive stage, but by no means so often as in measles or small-pox. Blindness had often been observed when the scarlet fever was accompanied by renal disease, and optic retinitis with more or less impairment of sight had been observed during convalescence when no signs of renal disease were present. Albuminuric retinitis was more likely to be seen later. Dr. Kipp had seen one case of embolism of the central retinal artery in the left eye on the thirteenth day of the fever, without signs of renal or cardiac disease. One similar case was on record. Pustular inflammation had occasionally occurred in the lacrymal gland, on the cornea, etc.

The affections of the cornea might be said to be the most dangerous of all the lesions seen in small-pox. Circumscribed ulceration and infiltration of the cornea was most commonly seen about the fourteenth day. Dr. Kipp had seen a number of cases, and they were characterized by the slowness of repair, four to six months, or even more, elapsing before the cornea healed. In two there was total destruction of the cornea. Disease of the uveal tract was occasionally met with. The course of iritis was, on the whole, favorable. Pustules on the lids should be opened and treated with some simple ointment. Hyperæmia of the conjunctiva was nearly always present.

With the exception of a mild form of conjunctivitis, affections of the eye were rarely observed in typhoid fever. During and after convalescence weakness of accommodation, transient amaurosis, optic neuritis, ulcers of the cornea, and iritis had occasionally been observed. Optic neuritis might be due to meningitis, which was not infrequently mistaken for typhoid fever. Dr. Kipp also read on diseases of the eye in septicæmia.

The Visual Disturbances Due to Nervous Diseases.—DR. WARD A. HOLDEN treated of this subject in a technical way (see page 626).

A Warning to the Youthful Smoker.—DR. HERMAN KNAPP opened the general discussion. With regard to blindness being permanent in simple optic atrophy, he had seen one case in which the sight in one eye returned in two-thirds degree, the other remaining totally blind, the original cause being, it was said, meningitis during childhood. But he had never seen the optic atrophy of locomotor ataxia improve. If Dr. Kipp meant to say that septic irido-choroiditis

was mostly fatal to sight he could agree with him, but if he stated that it was always fatal to sight he must disagree, for in one instance he had known the sight again to become and remain good. He had never seen total blindness from tobacco or alcohol. Scarcely a case of tobacco amblyopia in his experience had occurred in a person who did not begin the habit before the twentieth year, most of them before the age of thirteen or fourteen. In tobacco and alcohol cases it was the central field which was affected, in quinine amblyopia it was the peripheral field. Those who drank and smoked much could not see so well during the day, but could see better comparatively at dusk. Another symptom was premature presbyopia. They had to use glasses five to ten years earlier than their state of refraction would warrant. Dr. Claiborne had mentioned some poisons with which Dr. Knapp had had no experience, but one he had not mentioned, namely, coal gas. He had seen one case of amblyopia due to inhaling coal gas in a sleeping-room.

DR. JOSEPH COLLINS mentioned a case of tumor of the aqueduct of Sylvius and immense internal hydrocephalus, with pressure on the optic chiasm, which did not cause visual disturbance until a few days before death. He could corroborate Dr. Claiborne's statement that there might be optic neuritis without much disturbance of vision; also as to the effects of tobacco and alcohol. He was unable to comprehend how sight could be recovered in the case of blindness attributed to early meningitis in Dr. Knapp's case, in view of the fact that the neuraxon when once destroyed could never be regenerated. The necessity for a thorough examination of the eyes was shown by the case of a girl who went to an ophthalmologist for failing vision and he treated her for hypermetropic astigmatism. Six months later she was seen by Dr. Collins, who discovered signs of cerebellar disease, and the diagnosis was further confirmed by an examination of the eyes made by Dr. Holden. To-day there was complete blindness from optic atrophy. Dr. Collins invoked a higher centre than the visual centre in the cuneus in explanation of crossed amblyopia. Regarding hemiopic pupillary reflex, he said great care was required to elicit it.

DR. T. M. POOLEY thought that in tobacco and alcohol amblyopia, which was due to a form of chronic inflammation of the optic nerve, there was more marked interference with the clear outlines of the optic disc than in other forms of retro-bulbar neuritis. The important factor in tobacco poisoning was the nicotine. Persons who began using the weed in adult life had comparative immunity from complications of the eye. Pipe smokers and those who used strong tobacco were oftenest affected. He had seen a number of cases of quinine amaurosis, and must disagree with the statement that it was usually complete. In the cases which he had seen the central vision had remained good. The contraction of the field of vision never, so far as he knew, became free. He was sceptical as to arsenic. He had seen complete paralysis of accommodation from wearing belladonna plaster and also from ordinary doses of hyoscyamus too often repeated. He had seen the morphine habit produce marked diminution of the amplitude of accommodation after it had been left off, and in two cases it had caused nystagmus, which afterward disappeared. In fact, affection of the extrinsic muscles of the eyes was present in a number of cases of toxic amblyopia. All cases of septic irido-choroiditis seen by him followed the course stated by Dr. Kipp and ended with total blindness. Dr. Pooley had seen a case of complete restoration of the field of vision which had been disturbed by syphilitic gumma.

DR. WILLIAM LESZYNSKY said he was present when Dr. Seguin demonstrated his case of Wernicke pupil-

lary reflex to the satisfaction of the ophthalmologists of the hospital. He was sorry Dr. Holden did not refer to the fact that examination of the visual field was not of a great deal of value without a complete examination of the eye. In Dr. Knapp's case of coal-gas poisoning, it might be explained by small hemorrhages about the nerve nuclei, which were absorbed before they did much damage. Dr. Leszynsky had seen a case of peripheral neuritis from arsenical poisoning, in which there was also optic neuritis.

DR. CLAIBORNE said he must have been misunderstood on one or two points. He had not said there was total atrophy of the optic nerve from quinine. Regarding Wernicke's symptom, he thought it was of value when it could be elicited, but its absence was not significant.

SECTION ON SURGERY.

Stated Meeting, October 12, 1896.

B. F. CURTIS, M.D., CHAIRMAN.

THE evening was devoted to the presentation of cases.

Extirpation of Tongue for Epithelioma.—DR. A. L. FISK presented a man thirty-three years of age, who had come to the hospital with epithelioma of the posterior portion of the tongue on the right side, which had started in February of this year. He extirpated the entire tongue and the enlarged glands of the right side in the neck. The interesting point was the unusual rapidity of healing, the man being able to sit up on the third day; and at present, two weeks after the operation, was able to speak so as to make himself understood.

The Radical Operation for Carcinoma of the Breast.—DR. R. A. SANDS presented a woman on whom he had performed the radical amputation of the breast for carcinoma. Some of the arm portion of the pectoralis was left. Dr. Sands called attention to the fact that he purposely modified the incision; instead of carrying it into the middle of the axilla, carrying it upon the arm. This gave a better functional result than in Halsted's cases, the patient being able to carry the arm up to the back of the head in dressing the hair; there were less trouble from the scar, and less likelihood of œdema of the arm.

Metastatic Abscess from a Latent Appendicitis.—The chairman, DR. CURTIS, presented an Italian boy, who, he said, gave a rather curious history. He had come to his clinic, suffering with a swelling of the heel. Under wet dressing the swelling subsided somewhat, but after four or five days he returned, with a painful swelling in the arm, evidently an inflammatory swelling in the region of the biceps. The abscess, for such it proved to be, was incised and considerable pus was evacuated. It had no connection with bone, was entirely in the muscle, and he remarked to the staff that it must be metastatic, although the origin was not apparent. The second night after the operation the boy complained of some pain in the abdomen, but had not done so before. Placing his hand over the appendix, Dr. Curtis found a considerable tumor, and on operating evacuated an abscess between the cæcum and omentum. Of course, the peritoneal cavity had to be entered, which necessitated large packing of the wound. The boy also had a rather severe bronchitis, also of metastatic origin, and was generally septic, but made a good recovery.

Resection of Knee for Tuberculous Disease.—DR. CURTIS presented a boy who for some years, or since the sixth year, had had tuberculous disease of the knee, which had resulted in ankylosis at 90°. He was brought to Dr. Curtis for amputation, but it was decided to try resection, removing as little bone as possible. Everything was cut, except vessels and nerves,

down to bone; a few foci of disease were gouged out, the leg was straightened, and it looked at present as though there would be complete healing. The shortening was about an inch; and a sufficient amount of the epiphyseal cartilage was left, he thought, to permit of further growth of the limb.

Amputation of Hip for Sarcoma.—Dr. Curtis presented a girl, aged six years, who had had swelling of the left thigh since infancy. Finally a distinct tumor developed on the thigh just below the pelvis, becoming as large as the child's head, and presenting an ulcerated papillomatous surface anteriorly. A fragment was excised and was pronounced myxosarcoma by the pathologist. It had evidently been a myxoma which had undergone sarcomatous degeneration. The limb was amputated. On account of the tumor on the anterior part of the thigh it was impossible to get an anterior flap; consequently a long posterior flap was made, and it was in this fact that the interest of the case lay. In another instance he had been compelled to resort to a long posterior flap for the same reason, the tumor lying so far to the front of the thigh. The wound of amputation being distant from the anus and genitals, there was less danger of infection than when an anterior flap was obtained. There was little tendency to hemorrhage, but what there was he controlled by the Macewen method, an assistant pressing upon the abdominal aorta through a folded towel.

General Fecal Peritonitis Following Perforative Appendicitis.—Dr. HOWARD LILIENTHAL presented a young woman, whom he had first seen on March 26th, after two days' illness. The first day she had had pains in the abdomen, and the second day violent chills and high fever. Evidently there was appendicitis; slight thickening existed on the right side. An incision was made in the right iliac region; pus was encountered on opening the peritoneum; the perforated appendix was in a mass of adhesions. It was removed, and a small incision was made in the median line, to learn whether the entire cavity was infected. There was peritonitis of a most intense type, and a large amount of feces present in the peritoneal cavity. He washed out the cavity as thoroughly as he could, through a catheter inserted into the small median incision, and injected some of Dr. Gibier's streptococcus antitoxin, feeling that it could do no harm, since the patient would die any way. Greatly to his surprise, she was better next day, and continued to improve. About the tenth day she had a chill and fever, and a few days later he felt a resistance in the left side, which he cut down upon and evacuated an abscess, which communicated along the posterior wall of the pelvis and behind the uterus with the opening originally made on the right side. From that time on recovery was uneventful but slow. The sinus closed and the patient went home; but at her first menstruation after the operation the sinus reopened, and had shown a disposition to close and reopen since. Fluid injected into one opening passed out of the other. He thought of injecting a fifty-per-cent. zinc-chloride solution, with the hope that it would cause it to heal permanently.

Rebellious Tuberculous Disease of the Skin Treated with Nosophen.—Dr. Lilienthal presented a young man, who had first appeared at the Mt. Sinai Hospital nine years ago, when he had a sinus of the forearm and a cicatrix of the upper arm. The surgeon at the hospital opened the sinus in the forearm, and found a small focus of disease in the ulna. From that time until the present, nine years, the boy had sinuses in the arm, apparently always limited to the soft parts, except on one occasion, when the surgeon found a small focus of disease in the olecranon. The operations were numerous; the arm was covered with scars,

the elbow was stiff, and the arm was wasted and practically useless. The condition was looked upon as tuberculous. Finally, all of the wounds healed except one, which was very rebellious. In his experiments he put on nosophen in powder, and at once the aspect of the wound changed entirely, and after the second dressing was quite healed. He did not wish to suggest that nosophen would have healed the original disease nor a sinus which was not drained.

Discussion on the cases being called for, Dr. CURTIS remarked that in his opinion the operation performed by Dr. Fisk in his case of cancer of the tongue, a combination of Whitehead's and Kocher's, was the only proper one.

Dr. F. TOREK thought Dr. Sands had not performed Halsted's operation on the breast, for, as he understood it, Halsted left no part of the pectoral muscles. Dr. Torek had performed the operation, after the manner described by Willy Meyer, five times, and preferred it to all others.

Dr. FISK had operated several times by carrying the incision up somewhat on the arm instead of into the axilla, but had obtained the idea from Dr. Mixer and another surgeon in Boston. It had the advantages referred to by Dr. Sands—no œdema, good skin approximation, useful arm. Of four patients operated upon by him, there had been no local recurrence in any, but in two death took place from cancer of internal organs within about a year.

Dr. GALLANT had employed the curved incision on the arm in about six cases, and said it was a safer one than the other, because of less danger to vein and nerve.

Dr. CURTIS thought the extent of the operation for carcinoma of the breast should depend upon the case. Halsted's operation was not necessary for small movable tumors not adherent to the pectorals. Not enough time had elapsed to pass final judgment upon the curative value of Halsted's operation. His (Halsted's) first statistics were not large, and were published too soon after the operation to exclude possible recurrence.

Dr. SANDS remarked that he had just read Halsted's description of his operation, and could positively assert that sometimes a part of the pectoral muscles at their insertion was left.

Dr. GALLANT inquired whether it was safe to allow pregnancy to go on in a woman who not long before conception had had the breast removed for cancer.

Dr. SAMUEL LLOYD had had no experience with carcinoma bearing on this question, but in a case of removal of the breast for mastitis the woman subsequently had one or two abscesses about the axilla during lactation following pregnancy and childbirth.

Dr. R. T. MORRIS said, with regard to gauze packing in appendicitis cases, that it was employed through fear of infection of the general peritoneal cavity. It having seemed to him that surgeons were thus getting a good many weak abdominal walls, he had resorted to rather a smaller drainage tract and walled off the area with aristol or something similar, which would produce a lymph coagulum about the drainage tract. The result was satisfactory. Another method which could be employed as a safeguard against hernia consisted in attaching the cæcum, or that portion of it from which the appendix had been removed, to the margin of the abdominal wound. The cæcum acted as a plug, preventing hernia. He had used this method in six cases.

Dr. KAMMERER would leave a free opening and use plenty of gauze in appendicitis with abscess and threatening general peritonitis.

Dr. F. TILDEN BROWN thought there might be some danger of hernia of the cæcum or inversion thereof, when stitched to the abdominal wound, as described by Dr. Morris.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 27, 1896.

JOHN SLADE ELY, M.D., PRESIDENT.

Dilated Stomach Simulating Ascites.—DR. C. N. DOWD presented a greatly enlarged stomach, taken from a patient who had the usual signs of ascites, with flatness on percussion in the dependent portion of the abdomen, no matter what position the patient was in, and tympanitic resonance above. There was also a small nodule in the right hypochondrium. The patient was doing badly, and an exploratory incision was made to determine whether she would be benefited by any operative procedure. This enormous stomach was found to occupy practically the entire abdominal cavity, extending into the pelvis below and pushing out the abdominal walls on each side. There were several quarts of fluid swashing about in it, and this, with the gas which was also there, gave the signs of ascites. It was impossible to pass a stomach tube. The patient made a good recovery from the ether, but died at a later time of inanition. The pyloric thickening was cancerous.

Scope of the Work of the New York City Board of Health.—DR. HERMANN M. BIGGS said that he had been connected with the health department since 1887, at the time of the first of the recent cholera outbreaks in this city. Dr. W. M. Smith, the health officer of the port, had requested him to make a bacteriological examination to establish the diagnosis of cholera. Dr. Prudden was associated with him in this work. This was the second time that such an examination had ever been made for the purpose of diagnosing cholera. Shortly afterward, at the request of Health Commissioner Bryant, they had been made bacteriologists to the health board. The disinfecting-station was then established. In the fall, at his suggestion, a memorial was presented to the health board, regarding the restriction of pulmonary tuberculosis; but so much opposition was made by the medical profession that nothing was done, except in an educational way. At that time, only one prominent medical practitioner supported the view that pulmonary tuberculosis was a communicable disease, and that the health board should take steps looking toward its restriction. In 1892, when a number of cases of cholera actually gained entrance to this harbor, it became possible to get money for the establishment of a bacteriological department. A resolution was introduced by Dr. Bryant, and passed December 18, 1892, establishing the division of pathology, bacteriology, and disinfection. In 1893 a system of house disinfection and disinfection at Sixteenth Street were put in force, and means for the transportation of articles was secured. An outbreak of typhus fever soon put the new system to a severe test. In January, 1893, the speaker said, he presented a communication suggesting the appointment of a bacteriological diagnostician for diphtheria and naming Dr. W. H. Park as a suitable person for the position. He was appointed in April, 1893, and the work in the bacteriological diagnosis of diphtheria was begun. In 1893 and 1894 the temporary corps was kept on duty. In the spring of 1894 his investigations in Berlin into the question of the value of diphtheria antitoxin had so impressed him with the value of the new treatment that on his return he urged the board to enter upon this work.

A special appropriation of \$3,500 was made in January, 1895, and the permanent force of the laboratory was then considerably increased, it reaching in the year a total of thirty-one. In another communication he had recommended that some steps be taken toward the control of pulmonary tuberculosis. Arrangements were early made for the free distribution

of diphtheria antitoxin. Experiments had also been carried on regarding the tetanus antitoxin, the testing of the virulence of bacilli found in throats which were affected apparently by simple angina, etc. Dr. Huddleston had recently carried on experiments to determine the best methods of producing vaccine virus. Last summer Dr. Alexander Lambert studied this subject in the large cities of Europe, and as a result of all this it was decided to adopt the fluid virus. More than thirty thousand diphtheria cultures had been examined during the past year; about two thousand examinations of sputa for tubercle bacilli had been made by Dr. Fitzpatrick; about five hundred vials of antitoxin had been produced weekly. The discovery of diphtheria antitoxin fortunately furnished a plea for securing money from the board of estimate and apportionment which could be used for the establishment of a research laboratory. None of the largest cities in this country, he said, was at the present time without a bacteriological laboratory for use in connection with the work of health boards. The money collected from the sales of antitoxin here had been sufficient to assist very materially in the scope of the work.

Mixed Infection and Virulence of Diphtheria Bacilli.—DR. W. H. PARK said that he had been deeply interested in the question of mixed infection, because of the important bearing of this subject on the antitoxin treatment of diphtheria. He presented temperature charts of three children affected with laryngeal diphtheria. In the first case, between February 11th and 19th, the temperature had ranged between 105° and 105.5° F. The glands had become swollen four days before death, and the pneumonia which had been present had become more marked. The autopsy showed broncho-pneumonia, and lesions of the kidneys and other organs. The cultures from the lungs showed numerous streptococci, as well as Loeffler bacilli. The cultures from the neck were nearly pure growths of streptococci. Cultures from the blood of the various organs showed pure growths of streptococci. When these streptococci were injected into a rabbit, they were found to be of moderate virulence. His experience had been that after the streptococci were passed through a few rabbits they increased somewhat in virulence, but then the virulence remained stationary.

The second case was that of a child of one year, with laryngeal diphtheria and high temperature. It was given antitoxin. Twenty-four hours later it was intubated, but after three and one-half hours the tube was removed. Thirty-six hours after admission the temperature was 106° F., and remained high until death. The child remained a large part of the time in a position of opisthotonos. The lung showed a late stage of broncho-pneumonia. Cultures from the lungs and other organs gave streptococci.

The third child had been sick only two days, but the chest was full of râles. There was no membrane in the throat; some diphtheria bacilli were found in the throat. The temperature at the end of forty-eight hours reached 107° F., and the child died. The autopsy showed both lungs consolidated. Cultures from the lungs and from the blood showed the pneumococcus, and a few colonies of diphtheria bacilli were found in the cultures from the lungs.

Cultures from the blood of those dying early in diphtheria, without high temperature, were usually sterile; when there was a high temperature, septicæmia was generally found. When the lungs showed lesions, diphtheria bacilli were always present in the consolidated areas. Streptococci were also found. The diphtheria bacilli were found in the blood only twice in fourteen cases. It had been suggested by Dr. H. M. Biggs that the work done some time ago regarding the virulence of the diphtheria bacilli be again

tested. In cases in which the clinical diagnosis was follicular tonsillitis or pseudo-diphtheria, the virulence of the cultures was tested and notes were made regarding the number of diphtheria bacilli, and whether or not they were characteristic. In four months 71 such cases had been tested, and from 50 of these bacilli were obtained in pure culture and inoculated into guinea-pigs. In 38 of the 50, the bacilli were characteristic and abundant; in 37 they were virulent; in 1, non-virulent. In 2 the bacilli were atypical. Out of 48 characteristic cultures, the bacilli were virulent in 46 and non-virulent in 2. In 2 cultures of the pseudo-type they were virulent. Of those tested, in 26 the diagnosis was not diphtheria; and of these 22 were virulent and 4 non-virulent. In 24 doubtful cases the bacilli were virulent in 22, and in 2 not virulent—in other words, in twelve per cent. of the 50 cases they were non-virulent. In 2 of these the bacilli would be called atypical.

DR. L. WALDSTEIN asked Dr. Park if he had noted any relation between the size of the individual links and the lengths of the chains and the virulence of the bacilli; also whether in making cultures of the streptococci the virulence was affected by the alkalinity or acidity of the medium.

DR. PARK replied that he had examined swabs from slight pus cases, and in these the chains had been very long. In some of the cultures from the severer cases the chains had been rather short. He had made no exact observations as to the effect of the alkalinity of the medium on the virulence of the bacilli.

Tetanus Antitoxin.—DR. ALEXANDER LAMBERT said that he had been trying for three years to get a culture of tetanus bacilli which would retain sufficient virulence to allow him to investigate the tetanus antitoxin. Finally he had obtained a culture one cubic centimetre of which would kill a guinea-pig in five or six days. It then occurred to him that, as clinically tetanus was usually a mixed infection, it might be well to try mixed cultures. He had, therefore, mixed the tetanus bacillus with the bacillus *roseaceum metalloides*. The result was that a guinea-pig inoculated with this mixture promptly died in tetanic spasms. Following out this line of investigation, he was soon able to get a toxin 0.001 c.c. of which would kill a guinea-pig in two and one-half days. He was now able to obtain from the horse the tetanus antitoxin, one cubic centimetre of which would kill three million three hundred and fifty thousand grams of guinea-pig. Apparently, two and one-half to three times the equivalent of antitoxin was necessary to protect the animal from a fatal dose of toxin. Antitoxin already obtained was of therapeutic strength, and he believed it would soon be placed by the health board upon the same commercial basis as diphtheria antitoxin.

DR. GEORGE P. BIGGS said that he had found that the antitoxin animals were capable after a time of taking enormous quantities of the antitoxin. The doses taken now by some of the animals under treatment the longest were five hundred cubic centimetres at a time. It had been found that new horses could within four to six weeks be made to yield an antitoxin of high strength, whereas formerly it was thought that three months were required. The expense of production was thereby much lessened and a higher grade of antitoxin obtained. Very few of the horses this year had died under the treatment with toxins. He had made autopsies on many of the patients dying at the Willard Parker Hospital, but no new lesions had been found in the cases treated by antitoxin.

THE PRESIDENT asked if any lesion had been found in the horses which had died, which would explain the death or their susceptibility to the toxins.

DR. BIGGS said that autopsies had been made, but

nothing had been found to explain the varying sensitiveness of different animals.

Vaccine.—DR. J. H. HUDDLESTON said that the virus was collected from heifers two to four years old. Clinical tests could alone furnish a guide as to the quality of the virus. Experiments were made to determine in what part of the vesicle the living germ was present, using for this purpose four young children and vaccinating them in from three to five places. The vaccinations were successful in all of these children, and it was found that the base gave the best results and the serum the poorest, although it was the latter that had been usually employed on quills and ivory slips. Other comparative tests showed that the younger the animal the better the results, and the more nearly typical the eruption. In practice, heifers two to three months old were found to be best, all things considered. It had been found that a small area covered with well-developed vesicles yielded as much as a larger area, because on the latter the vesicles were not usually so numerous. The area selected was usually the posterior portion of the abdomen, and a small extent on the inner surface of each thigh. The maximum quantity of lymph was obtained just before the vesicle became a pustule—in other words, usually four or five days after vaccination; but there was a considerable individual variation in the animals. If several vaccinations were made on the calf at intervals of a day, the later vaccinations, as in the case of a child, would be found to mature much more rapidly than the first ones. Continued experiments had shown that the liquid virus gave a higher percentage of successful vaccinations in the proportion of seventy-one successful vesicles by the dried virus to one hundred by the latter. The best method of preservation had not yet been determined. Experiments had been made of mixing it with lanolin, with glycerin, and with chloroform water, and glycerin and water. The lanolin seemed to be the best preservative of the vaccine, but the glycerin had more power to limit the number of bacteria in the vaccine. The receptacles for the virus consisted of small stoppered glass vials. The virus was so thick that it was with great difficulty that it could be drawn up into capillary tubes. The heifers were examined by a veterinarian, and, if found healthy, were kept for two or three days before vaccination. There was no advantage in previously disinfecting the skin with sublimate solution, for it must become infected again before the time for removing the virus. When the vesicles had properly developed, the parts were thoroughly cleansed and the pulp was taken and passed through a rolling machine, and at the same time mixed with glycerin. The average product from each of fifty recent calves was 16.5 c.c. By using a small spear-shaped lancet and moistening the point with the fluid vaccine, one quick puncture was sufficient to complete the vaccination. The vaccination made in such a way yielded a small, typical vesicle, with a small areola, and caused the patient scarcely any discomfort. There seemed to be considerable evidence to show that a single inoculation was not as complete a protection against small-pox as it had been supposed to be. An inspection of a number of these scars showed them to be so minute that they might be after a time easily overlooked.

The Examination of Tuberculous Sputum.—DR. CHARLES B. FITZPATRICK said that the method of staining that he had employed was that described by Gunther. In this, Ehrlich's anilin-water-fuchsin solution was used for the coloring agent, and a three-per-cent. solution of hydrochloric acid in alcohol as the decolorizing agent. The bacilli by this method were stained a very distinct red. Examinations made in eight cases of influenza during the past winter failed to show the presence of any specific bacillus. In many instances

the examinations of the sputum showed a mixed infection—a few tubercle bacilli with, perhaps, a streptococcus infection. On the disappearance of the mixed infection, it was often reported by the attending physician that the patient showed marked general improvement. The addition of twenty-four parts of English salt to a one-half-per-cent. solution of carbolic acid acted with the same efficiency as a preservative as did a five-per-cent. solution of carbolic acid, and it did not coagulate the sputum into balls.

THE PRESIDENT said that for several years he had entirely abandoned the use of strong acid solution. He would take about eight ounces of alcohol, and drop into it a few drops of sulphuric acid. This formed an excellent decolorizing agent, although perhaps somewhat slower in its action than the stronger solutions. Nuttall had found that many of the tubercle bacilli were decolorized by strong acid, and proposed the use of this weak-acid decolorizing solution.

DR. FITZPATRICK said that with a simple mixture of alcohol and water one could remove enough of the primary stain to admit of the application of the secondary stain to the bacilli.

DR. WALDSTEIN said that in the decolorization of smears it was not important to have the acid dissolved in water; but in staining sections the solution should be an aqueous one, in order to avoid the shrivelling of the sections.

Isolation of Diphtheria Antitoxin.—DR. MILLER said that so far he had been unable to fully corroborate the interesting experiments of Brieger on the isolation of the antitoxin. The essential point was the separation of the antitoxin as a zinc compound. It seemed to be especially difficult to completely separate it from the albumin.

The society then went into executive session.

Clinical Department.

A CASE OF RUPTURE OF THE UTERUS.

By JOSEF SAXL, M.D.,

NEW YORK.

ONE night last week I was summoned in haste to attend a woman in labor. Her husband told me on the way to the house that she was thirty-two years of age, of Bohemian nationality, and that this was her sixth confinement. She has always been in perfect health. For all previous confinements as well as in this one she was attended by a midwife.

She was in labor for a few hours, and then suddenly the pains ceased and she fainted away with a piercing cry.

On arrival I found the woman semi-conscious, pale, and covered with clammy sweat. There was complete absence of radial pulse, the heart was very weak and rapid, the respiration was shallow and rapid, and the woman vomited twice. The abdomen was distended and doughy to the feel. The fetal head was presenting upon the perineum. I injected strychnine, gr. $\frac{1}{60}$, and digitalin gr. $\frac{1}{100}$, hypodermically, raised the foot of the bed, and proceeded to deliver with forceps. The child was dead. I removed the placenta and examined the uterus, and found a tear through the cervix on the left side, extending up to the body of the uterus. After that I administered ergot and compressed the womb from above, and directed the midwife to give her an enema of salt water and whiskey. The patient revived somewhat and regained consciousness, but complained of terrific pain in the abdomen. I gave her a dose of morphine and atropine hypodermically, and she seemed to do well for about half an hour, after which she fainted again, and although stimulants were given

freely she expired about fifteen minutes later. No autopsy was performed. The midwife denied having given ergot.

A RELAPSING FEVER.

By H. G. MURRAY, M.D.,

BALTIMORE, MD.

THE following case seems to me worth reporting. I was called on August 14th to see the patient, a strong, robust farmer, who was suffering, as he said, from intense fever. The temperature was 104° F.; pulse, 90. He complained of great pain in the back and limbs. The spleen was slightly enlarged. The next day jaundice developed, but was not severe. There were no other symptoms of any account. On August 21st the patient was well, and on the 22d he was riding a bicycle. On August 28th he was again attacked, the fever reaching 105° F. on the first day. The muscular pains were not severe. Jaundice was not present. In a week the temperature began to decline, and soon reached normal. He is at present very weak and much depressed. A blood examination was not made, and, of course, the case is not complete; but no doubt will exist as to a case with such a history being one of relapsing fever.

The treatment recommended was useless. Quinine in powerful doses had no effect. Diet, sponging, and stimulants were used.

TWO CASES OF TAPEWORM.

By FRANK OVERTON, A.M., M.D.,

PATCHOGUE, N. Y.

IN the spring and summer of 1894, Mr. W——, a nurse in a city hospital, passed links of tapeworm at intervals. For his relief the mixture of malefern, pomegranate root, pumpkin seed, and croton oil, popularly known as the "early-bird mixture," was prescribed, without special attention being given to previous dieting. About an hour and a half after he had taken it his bowels began to move; there were cramps, and he felt extremely nauseated. Some of the worm was passed through the anus, when an attack of vomiting came on, in which the patient felt a large lump coming up, which gave him a severe sensation of choking so that he felt faint. By violent retching he finally expelled the lump, which proved to be a mass of tapeworm. He examined it for a moment and saw that it tapered to a small thread and then he went away, intending to examine it carefully later, but an attendant emptied it down the closet. But little of the worm was passed by the anus. For six weeks, until he left the hospital, there was no recurrence of the trouble.

Vomiting of the *ascaris lumbricoides* is comparatively frequent; but persistent search and inquiry has failed to reveal another case in which a tapeworm was vomited.

In September, 1895, a young woman presented herself in great distress of mind, bringing a few joints of tapeworm which she had just passed. The "early-bird mixture" was prescribed after brisk catharsis had been established with Rochelle salt. In about two hours a large mass of tapeworm was passed. Examination showed that there were two tapering strings of tapeworm, each becoming as fine as a thread; but only one head was found.

About six weeks afterward the patient again began to pass links of tapeworm, and the same treatment brought away a single tapeworm, about ten feet in length, which tapered to a fine thread; but no head could be found.

In six or seven weeks she again passed links, and treatment again brought a long tapering string of tape-worm, but without a head. As before, links began to be passed inside of two months. She then consulted an eclectic physician, who administered three drachms of malefern in two ounces of castor oil. Although he failed to find the head, there has been no recurrence of the trouble.

This case is interesting because it demonstrates the extremely rapid growth of the worm. For three successive times its head produced enough links in six weeks so they were passed from the bowel. So if the head is not found, and no links are passed for two months, the trouble is almost certainly cured.

OCCUPATION NEUROSIS OR IRONER'S CRAMP.

By L. PIERCE CLARK, M.D.,

ASSISTANT PHYSICIAN AT CRAIG COLONY, SONYEA, N. Y.

I DESIRE to place on record a case of ironer's cramp, as I am not aware of its having been reported before by writers on neurology. There seems to be no reason why it should not be a common affection, but I have never seen or heard of a similar case. It appears that ironer's cramp partakes also of the nature of a pressure paralysis, as described by Gowers. Occupation and professional neuroses, as Gowers,¹ Dana,² and Strümpell³ term them, are very common affections in this work-a-day world, and there is no reason why the same should not be common among ironers. Probably the firm grasp of but two or three fingers upon the flatiron has greater etiological significance than the pressure resulting from the weight of the shoulder and arm. Therefore, all things being equal, the stronger and the more vigorous the worker, the greater the liability to the disease. This affection of ironer's cramp and its kindred affections ought to be classed under the more comprehensive and preferable heading of occupation neuroses or spasm, and many cases of pressure neuritis would properly come under this head also. We generally find the neuralgic and spasmodic symptoms closely associated in the same case, as the one here reported shows. There is some inflammation with almost all occupation neuroses, either in the early part of the disease or later on, especially after long-continued application of the cause. The following case, which has but recently come under my observation, is reported:

W. S.—, thirty-one years of age, laundress. For three months she was employed at laundry work, and during this time she was engaged in the sole occupation of ironing. After two weeks of this kind of work, the two middle fingers of the right hand became "numb," and at night the pain was quite severe, running from the wrist to the elbow. The sharpest pain was noticed just at the elbow, on the anterior surface of the forearm. She also noticed that within the next four or five days the muscles of the right arm became quite weak, and that the numb and painful sensation made itself felt almost nightly. Occasionally this was present when she was unemployed for a few hours. After ironing for some time, these two fingers cramped and became "stiff," and she was unable to bend them easily. Upon examination, paræsthesia was found to be present in the forearm, wrist, and palmar surface of the hand. About half the time two points appeared as one, when applied simultaneously. Dynamographic examination showed the right hand pressure to be sixty-eight pounds; left hand, seventy-eight pounds. Dur-

ing the next three days the affection grew steadily worse, and in consequence she made several trials in using her left hand instead of the right in doing her work. As this practice did not prove satisfactory, her occupation was changed. The pain in a great measure ceased, numbness and prickling sensations were no longer troublesome, but the loss of muscular power still persisted.

The treatment of an occupation neurosis is unsatisfactory: First, because of the tendency of the affection to recur after having been once firmly established; secondly, because the physician is usually obliged to make concessions to the causation. It is necessary to exercise twice as much ingenuity in the treatment of an occupation neurosis in the very poor, because the patient cannot cease from daily labor. This case was no exception to the rule. Deep massage was first tried. It was applied from the centre of the palm to the elbow. The greater freedom from pain and the "cramped feeling" was obtained when massage was applied two hours after the daily work. If the muscles were painful before going to work in the morning, they were massaged again before work was begun, and at all spare moments during the day systematic muscular exercise of the affected hand was maintained.

Finally, this treatment failed of its desired effect, and douches and tonics were supplemented. These gave freedom from "pain and cramp" for a few days, when they, too, failed, and laundry work was ordered discontinued. A month's treatment has improved the use of her hand, although full muscular power has not yet returned.

HERPETIC NERVE DISTURBANCE.

By W. M. WELLER, M.D.,

ITHACA, MICH.

IN the MEDICAL RECORD of September 26, 1896, I notice an article entitled "Counter-irritation in the Treatment of Herpes." I do not question the value of blisters in treating the nerve disturbance accompanying herpes, but give them an important, if not, indeed, first place as a remedy; yet they sometimes fail to give relief.

I have a case of herpes zoster under treatment now, in which I have not only failed in getting the happy results which Dr. Wilkins describes, but have failed to give any permanent relief whatever, although the area affected has been pretty well covered by repeated blisters, beginning early in the attack and continuing to the present time.

My patient is an old lady, sixty-seven years of age, and in rather feeble health. Severe pains commenced four weeks ago in the right side, and were followed in a few days by an eruption of isolated patches of vesicles, extending from the spine across the subscapular and mammary regions to the median line in front. The pain has continued with unremitting severity up to the present time, September 29, 1896, aggravated by movements and relieved only by hypodermic injections of morphine.

Another case, which was a great source of perplexity and discouragement to me, happened in my early professional struggles. This patient, too, was an old lady, and the case lasted for many weeks.

On the other hand, I have seen cases like those described, in which a blister seemed to cut short the pain as if by magic.

The point I wish to make is this: that while the majority of cases of herpetic nerve disturbance are amenable to treatment in a time ranging from a few days to two or three weeks, cases occurring in the aged, and in which there is a well-marked neuritis, may possibly continue so long as to be a source of discouragement to both patient and physician.

CONGENITAL TRANSPOSITION OF THE VISCERA.

By F. C. STUDLEY, M.D.,
MILWAUKEE, WIS.

THE following case of congenital complete transposition of the thoracic and abdominal viscera may, perhaps, be interesting to the readers of the *MEDICAL RECORD*. In this patient the apex beat of the heart is in the right thorax, between the fifth and sixth ribs, directly in the nipple line. Left of the sternum I could not detect any dulness whatever on percussion. The liver, which is somewhat enlarged, is entirely in the left hypochondriac and epigastric regions; while the stomach, from cardia to pylorus, and the spleen as well, are placed to the right of the median line. The patient, a German, thirty-seven years of age, aside from occasional attacks of indigestion with cardiac palpitation, does not complain of any indisposition whatever; nor, so far as one can understand, is his condition at all inconsistent with long life and perfect health.

DOUBLE OVARIOTOMY, FOLLOWED BY PREGNANCY; AND DOUBLE OVARIOTOMY DURING PREGNANCY, FOLLOWED BY THE BIRTH OF TWINS AT TERM.¹

By R. STANSBURY SUTTON, M.D., LL.D.,
PITTSBURG, PA.

ON October 18, 1892, Mrs. J. R. P.—, aged twenty-eight years, was admitted to my private sanatorium. She was greatly emaciated and feeble. Pulse, 40. Her abdomen was very large. Diagnosis, ovarian cystomata.

She was married in 1885, at twenty-one years of age. One year later, in 1886, her only child was born at term. Prior to the birth of this child, her attending physician diagnosed an ovarian tumor lying to the right of the uterus. Six years and seven months intervened between the date of this discovery and her admittance to the hospital.

On October 20, 1892, two days after her admission, I opened her abdomen and removed from the right side a twenty-five-pound multilocular ovarian cyst, the pedicle of which I severed with a Paquelin cautery, the ligature on the stump lying close to the horn of the uterus. From the left side I removed a multilocular cyst weighing six pounds. The cautery failing to get hot, I severed the pedicle with a pair of scissors; the ligature on this pedicle lay close to the horn of the uterus. The cavity was sponged dry, and the patient elevated to the Trendelenburg posture. The wound was long, the abdominal wall exceedingly thin, and the pelvic contents were fully exposed. The uterus was somewhat larger than normal, the pedicle stumps were short, and the ligatures lay close to the uterine cornua. The uterus was retroverted; the fundus was brought forward to the lower angle of the wound; a patch of its peritoneal covering was abraded with the edge of a knife; it was then fixed at the lower angle of the abdominal wound with two buried silkworm-gut sutures. The wound was closed. The operation occupied twenty-five minutes. The tumor from the right side contained a large amount of colloid material, and this was characteristic of the one on the left side.

To repeat: This operation was done on October 20, 1892. On June 10, 1894, the subject gave birth to a male child weighing ten and one-half pounds. Again, on February 25, 1896, she was delivered of a male child weighing eight pounds.

Some ovarian tissue must have been left in one of the pedicles, and the tube must have remained patu-

¹ Read by title at the International Gynecological Congress, Geneva, Switzerland, August 31 to September 6, 1896.

lous, through which the ovum found its way into the uterus.

Prior to the operation the patient had remained sterile for about six years after the birth of her first child. In this instance we have the remarkable paradox that double ovariectomy terminated the sterility. My opinion is, that in this case an aberrant patch of ovarian tissue existed at a point close to the uterus and adjacent to the tube, that the section of both with the scissors brought the cut surfaces of the patch of ovarian tissue and tube into juxtaposition, that the lumen of the tube was not destroyed, and that ova passed from the patch of ovarian tissue into the uterus.

This case has a remarkable bearing on the question of surgical conservatism in dealing with the ovaries. If, in this instance, no ovarian tissue had been left, two fine children would not have been born. This case and the numerous conservative operations by operators in all lands urge the necessity and prove the wisdom of saving even a small particle of ovarian tissue wherever it is possible, and when there exists no contraindication for such action.

The case has also suggested to my mind the possibility of ovarian grafting, and the wisdom of doing our cases in pairs—that is, two cases at the same time, in order that we may find in two cases sufficient healthy ovarian tissue to supply both patients, by leaving some healthy ovarian tissue in one and transferring some by grafting to the other patient, if necessary.

The second case referred to in the title of this report now follows: On February 13, 1893, Mrs. D.—, aged thirty-four, widow for ten years, mother of one child, thirteen years old, was sent to me for operation. At her menstrual periods she had cataleptic seizures and frequent attacks of severe pain in the ovarian regions. She was incapacitated for work, and all remedies had failed to relieve her. She stated that she had menstruated two weeks prior to this date. Digital examination revealed a linear stricture at the juncture of the upper and middle third of the vagina, which arrested the finger. The finger was now transferred to the rectum, and by the aid of the superimposed hand I made the following diagnosis: Stricture at the upper third of the vagina, lacerated cervix, subinvolution of the uterus, chronic salpingitis and ovaritis.

On the 18th, five days later, I made a very short incision in the median line, and through it removed the ovaries and tubes. I noted the supposed subinvolution of the uterus, and closed the wound. The patient recovered promptly, and left the hospital.

About ten months after her discharge from the hospital her attending physician informed me that in nine months less forty-one days after the operation, he had attended her in confinement. She gave birth to twins, healthy children.

This case and others in our literature prove the tolerance of the pregnant uterus to surgical operations on its appendages. It has also proven that we are not safe in placing too much dependence on statements made to us by female patients.

The suggested merits of these cases, I trust, may prove a sufficient apology for presenting them to this learned body of representative gynecologists.

Instruments.—A heaping tablespoonful of washing-soda to a quart of water is the proper proportion for the solution in which instruments should be boiled for sterilization. Do not boil non-metallic sutures in this liquid, for it will very greatly weaken them. Do not boil an aluminium instrument in this liquid, for it will be corroded and completely ruined. — *International Journal of Surgery*.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE FIRST HUXLEY LECTURE—PROVINCIAL MEDICAL SCHOOLS—SIR J. LITTLEJOHN AT LEEDS—MR. HUTCHINSON AT MANCHESTER—MR. VICTOR HORSLEY AT LIVERPOOL—THE CARTER-HORSLEY CONTROVERSY—THE COMMITTEE ON WATER SUPPLY—DEATHS OF MR. MORRANT BAKER AND DR. LANGDON DOWN—MEDICAL COUNCIL CANDIDATES.

LONDON, October 9, 1896.

THE first "Huxley lecture" was delivered on Monday by Prof. Michael Foster, at Charing Cross Hospital. This lecture has been founded to commemorate the late Professor Huxley, whose medical education was obtained at Charing Cross. Dr. Foster proposed that this first lecture should be a sort of preface to those of the future, as his successors would probably single out some new advance in science and expound its bearings on medicine and surgery. He therefore took account of the state of science when Huxley took his seat as a student in the school, compared with its present condition. But he could not give an account of the progress made in those fifty years, and would, therefore, only dwell on two or three points. These were the observations of the brothers Weber on the inhibitory action of the vagus, Bernard's discoveries as to the effects of section of the sympathetic leading to our knowledge of vasomotor action, the formation of glycogen, and Waller's observations on nerve nutrition. The lecturer concluded with a notice of Huxley's influence on physiology, and asserted that the hopeful position of English physiology to-day is in large measure due to that influence.

The provincial schools of medicine have of late shown a vigor that does them credit. They have always celebrated October 1st with the time-honored introductory, and often invited lecturers from a distance to occupy the chief place on the occasion. The value of these schools has now and then been called in question, and their defence was taken up at the opening of the session at Sheffield by Sir H. Littlejohn, who had been invited to come from Edinburgh to deliver the lecture. Taking up the subject of provincial schools, he maintained that they had certain advantages over such great teaching centres as London, Edinburgh, and Dublin. He pointed out that in smaller schools there could be more personal superintendence on the part of teachers, so that the deficiencies of students were ascertained and a healthy stimulus given. This, which is a revival of pupilage in a better form, could not be the same in large schools, and the close companionship of teacher and taught could not fail to strengthen good resolutions and beget that *esprit de corps* which is the essence of professional life. Besides this, the great provincial hospitals afforded ample scope for clinical work, and in this respect contrasted favorably with the wards of metropolitan hospitals, crowded with the students of the great schools. In the provincial schools students could now complete their education with practical bedside tuition in all departments, including attendance in lunatic asylums, in hospitals for children, for infectious diseases, and for diseases of the eye, all of which has now become compulsory and which can scarcely be practicable in the largest schools.

Mr. Victor Horsley went to Leeds to deliver the introductory lecture at the Yorkshire College. He called attention to the superlative value of chemistry in the study of physiology and pathology, and expatiated on the advantages and disadvantages of guilds, mediæval

and modern. This led up to the subject of combination for medical defence, which was treated with considerable vigor. In fact, Mr. Horsley gave a parting shot anent the controversy with Mr. Brudenell Carter, respecting the Medical Council, on which I have already written and which is now over. Mr. Carter, in his last letter, again twits his antagonist with looseness in the use of English words; says he cannot "understand the force either of the adverb or the adjective" in the phrase "practically commits literary forgery," and asks whether non-literary forgery would be one "not yet written down"? There is a paragraph, too, about the phrase "misrepresenting acts of Parliament," which Mr. Carter says is an offence he had no idea could be committed, though he can imagine "the possibility of misrepresenting the language of the acts, or their intention, or their effect." After this, he rather superciliously suggests that this may be what Mr. Horsley means, and "his obscurity may only be due to his not knowing how to express himself." This trifling is amusing enough, but convinces no one. It is no more an argument than telling Mr. Horsley he is so much the younger. Mr. Carter closes by saying: "The farrago of rubbish and falsehood, the meanness and malignancy of which I have, I think, sufficiently exposed, is connected together by coarse personalities and vulgar abuse, such as are no longer tolerated in any decent society. I do not think it would be consistent either with my own dignity or with my professional position to continue a controversy which my opponent conducts in such a manner." The editor has said the correspondence must cease, and regrets the "bitterly personal nature" of many of the letters, and wisely adds that "neither the cause of medical reform nor the elucidation of the medical arts is furthered by accusations of mendacity and other crimes."

Mr. Hutchinson went to Manchester and discoursed on "Medical Education" to the students of Owens College. He set before them a high ideal, advising a training in a wide knowledge of all that concerns our terrestrial environments. Not to discourage students too much, he mentioned some things they might, after learning them properly, forget, as not likely to be called upon to practise. None, he thought, should neglect to spend a few months in Paris and Vienna before settling down, and should learn the languages in those months, as he would afterward want to read them. As to recreation, he assured them that whoever enters with proper zest into the study of climate, topography, botany, geology, and zoology would never be at a loss for motives to go into the fresh air and get exercise, and such might very well leave cricket, football, and golf to men of less resource and less responsible pursuits. He would also relieve them from such things as games of cards, and possibly also from the gratification of music. Altogether an arduous curriculum, as he acknowledged, but then he said it was only temporary, and its reward lasting through life.

The report of the select committee on the bills of the London water companies shows that the question of supply ought not to be delayed. The committee pronounces the existing state of things to be a most unsatisfactory compromise between public control and commercial enterprise. It results in waste of large sums in promoting and opposing various bills, thus adding to the burden of consumers. It is difficult and almost impossible to decide the extent of monopoly that should be granted to enable the companies to procure ample supplies without adding unfairly to the capital, and therefore to the compensation whenever they are bought up. It is a fact, I believe, that, though the companies have made and are making enormous sums out of their monopolies, the consumers pay more for

their water than it costs in a fourth-rate continental city.

During the dry summer I had to report that a considerable district was suffering from want of water, to the great danger of the public health; and this because the company, running short, did not choose until very late to buy the overflow of another company. Yet that company has collected its dues just as if it had fulfilled its contract. In that case, I think it would be only just to forfeit the monopoly. In every case in which such a company fails to carry out its contract, the least compensation to the public should be the forfeiture of the current quarter's dues.

Mr. Marrant Baker died on October 3d, after a long illness. He resigned the surgeoncy of St. Bartholomew's Hospital several years ago, on account of ill health. He had filled other offices, and had been on the council of the College of Surgeons, and also examiner in surgery at the London University. He contributed valuable papers to St. Bartholomew's Hospital Reports, to the societies, and to the medical journals.

Dr. Langdon Down died on Wednesday, aged sixty-seven. His career was associated with the London Hospital, of which he had become consulting physician after passing through the various positions open to him. Soon after graduating at the London University, he was appointed resident physician to the Earlswood Asylum, and this appointment he was allowed to retain several years after he became assistant physician to the London. This asylum (for idiots) directed his attention to the education and training of the feeble in mind, on which he published a monograph in 1876, and this was followed in 1887 with his "Mental Affections of Childhood and Youth." Meantime, he contributed numerous papers on allied subjects to the societies and journals. At the same time he carried on his work at the London Hospital until, on the expiration of his term, he was elected to the consulting staff. His residence at Hampton Wick was also an establishment for the feeble in mind and the scene of many hospitalities to his professional brethren.

The Society of Members have endorsed the nomination of Mr. Rivington by the Association of Fellows of the College of Surgeons. He has accordingly issued an address, accepting the joint invitation to contest the election, and, having been a leading reformer for many years, will doubtless receive much support.

OUR PARIS LETTER.

(From our Special Correspondent.)

PARISIAN MEDICAL AND SURGICAL MEASURES DURING THE CZAR'S RECENT VISIT—THE BABY GRAND-DUCHESS OUT FOR AN AIRING—PUERICULTURE AND PROTECTION—OYSTERS PROPAGATE CHOLERA AND TYPHOID FEVER—PROFESSIONAL SECRECY—DOCTORS' LETTERS CANNOT BE PRODUCED IN COURT.

PARIS, October 15, 1896.

So important an event as the visit of the Czar and Czarina of all the Russias to Paris could not but make its influence felt upon the medical department, as well as upon the profession at large. Many physicians preferred, in fact, to prolong their vacations rather than be subjected to the crowds and many difficulties of attending to their practice. When we add that it is estimated five millions of people were in Paris during the stay of their imperial majesties in the capital, some idea of the serious impediment to free circulation and traffic may be formed. In other words, the entire population of Paris was doubled, or very nearly so indeed, during the fêtes which are just over.

The danger to life and limb was correspondingly

great; there were numerous medical and surgical accidents, such as asphyxiations, syncopes, falls, run-overs, etc.; also several deaths therefrom, notwithstanding the excellent police and sanitary organizations. The latter took the form of ambulances, stationed in different parts of the city along and near the routes that the emperor and empress would take when going to any function or visiting any public building. These ambulances were changed every day during the three days' visit of Nicholas II., and the prefect of police, M. Lepine, had posters put up in the eighty different quarters of Paris before the arrival of the nation's guests, telling explicitly where these ambulances were to be found each day. Cards, or "*coup files*," were also issued to physicians, enabling them to pass the lines of police and soldiers.

It was not uninteresting to see the baby Grand Duchess Olga, the only child of the emperor and empress, being taken out for an airing in the arms of her nurse, dashing down the Avenue l'Alma, the carriage surrounded by cavalry. This brings us to the subject of puericulture and protection, upon which Dr. Ledé has just written a very valuable essay. The conclusions he reaches are these: In order to assure equal protection to child and nurse, the age of the milk of a woman that is to act in the capacity of wetnurse should be limited to five months. The nurses should be strictly supervised, and situations given them only after they have received medical certificates. Children should receive only natural milk (mother's or wetnurse's milk) until they have cut at least four incisors. After the appearance of these teeth, the addition of a small quantity of animal milk, cow's milk sterilized, may be tolerated, to which a pap of flour may be added during the period of second dentition. Only after the appearance of the canines ought we to attempt to wean children, or begin feeding them with eggs and soups until completely weaned; and they should always be closely watched by the physician and weighed frequently.

Speaking of food hygienically, the oyster is likely to fall into disfavor with the general public, which is beginning to realize the serious risk it runs of contracting not only typhoid fever but sometimes cholera, as was demonstrated by the epidemic of Grimsby, in 1893. In 1889 Giaxa made a series of bacteriological experiments, with reference to the action of sea water and oysters on pathogenic microbes. He found that the multiplication of the cholera bacillus in sea water depended upon the number of other microbes present. The opinions regarding the presence of the bacillus of Eberth and its harmful power were not thoroughly established until Professor Chantemesse took up the question and cited facts proving the reality of the propagation of typhoid fever by oysters. A merchant in a small town in the province of Hérault, not long since, received a consignment of oysters coming from Certe. Fourteen persons of the town (where there had not been a single case of typhoid fever for a year) contracted the disease after eating of these fresh raw oysters; two of them died of malignant typhoid fever. It was impossible to deny the relation of cause to effect in this instance, so well studied and authenticated. The point to elucidate was whether other oysters, coming from no matter where, were capable of producing the same deleterious results. In order to determine this absolutely, Professor Chantemesse bought at the Paris markets Marennes oysters, English and Ostende oysters, oysters from Portugal, and other countries. A bacteriological examination disclosed to him the presence of numerous germs, and especially that of the coli bacillus. Some of the best and most healthy oysters were placed in sea water purposely contaminated with the dejections of typhoid cases and the bacillus of Eberth; after remaining twenty-four hours in

the water, they were taken out and preserved closed twenty-four hours longer. At the expiration of that time they were still fresh and contained numerous coli bacilli and typhoid bacilli living. There is, therefore, a manifest danger as regards the contamination of oyster beds or parks for fattening and preserving oysters, by rivers, brooks, and streams carrying in their currents morbid germs of different sorts, as they empty into the ponds, coves, inlets, or bays where oyster cultivation is usually carried on. Unfortunately, it is next to impossible to guard against this danger effectively. But there is a ray of hope for the epicure—a good cook can produce a preparation of the luscious bivalve quite as palatable as the raw material, while he destroys in the fiery furnace the death-dealing microbes.

The case of Dr. Playfair, of London, who was recently condemned for revealing professional secrets, has been a good lesson to all who do not hold sufficiently sacred the confidences obtained in the exercise of their profession. Let us now hear the French on this point. The court of appeals of Douai decided quite recently that in no case can a tribunal authorize the production in court of letters written by a physician and having reference to the treatment and care given a patient, even though the production of said letters be authorized by the physician himself.

It would seem from the foregoing that the permission of the recipient of such missives is not even to be considered. Neither is anything said with reference to their production in court when both writer and receiver agree to it. But as this is strictly a medico-legal question, we prefer to leave it in abeyance. It is enough to know that in France the violation of professional secrecy is a criminal offence, punishable by fine and imprisonment, and that the English law is in the same tenor.

THE TREATMENT OF ACUTE ABSCESES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A wrong statement is made in the article appearing under the above title in this week's MEDICAL RECORD, which must not, in my opinion, be left uncorrected. Dr. Peet says in his paper on the treatment of acute abscesses:

"The acetate of aluminium is made up as follows:

R Pulv. alum. 5 v.
Pulv. plumbi acet. 5 xxv.
Aque distil. q.s. ad O iv.
M.

"There is a precipitate when this solution is made up and the bottle should be shaken before its contents are used."

This would give one the idea that the precipitate is the acetate of aluminium, or at least some ingredient with medicinal properties. As a matter of fact, the precipitate is the inert sulphate of lead, and should never be used when acetate of aluminium is wanted, but should always be filtered away; or, still better, the perfectly clear solution of aluminium acetate is decanted after allowing the heavy sulphate of lead to settle down to the bottom of the vessel. The chemical reaction occurring in making this preparation is as follows:

As the solution of aluminium acetate is, on account of its harmlessness, generally used profusely in open wounds, granulating surfaces, extensive burns, etc., the presence of the sulphate of lead may prove a positive source of danger, namely: the absorption of lead

may cause lead poisoning. That this possible source of danger is taken into consideration by others besides myself is shown by the fact that in all pharmaceutical books in which a formula for the preparation of soluble aluminium acetate or solution is given, the directions are added that it be not made in warm weather or that it be allowed to stand a few hours on ice before being filtered, so as to allow the lead sulphate to precipitate out as completely as possible (the latter being to a very slight extent soluble in warm water). In conclusion I will say that the solution of aluminium acetate has been used for decades as an antiseptic dressing and is the well-known "solutio Burrowi," of the European physicians. The formula, though, differs materially from that given by Dr. Peet, the latter containing an unnecessarily large proportion of lead acetate and too small a proportion of alum.

WILLIAM J. ROBINSON, PH.G., M.D.

NEW YORK, October 10, 1896.

Surgical Suggestions.

Indications for Removal of Surgical Dressings.

—1. The removal of stitches. 2. The removal of drainage tubes. 3. Saturation of dressings by an abundant discharge. 4. Soiling of dressings by faces, urine, or vomited matter. 5. The disturbance of the dressing by a restless patient. 6. Pain if it is due to pressure, and especially if of a pulsating character. 7. The occurrence of secondary hemorrhage. 8. Fever if it points to some trouble in the wound.—ROTH.

Malignant Diseases of Larynx.—Dr. Delavan (*New York Medical Journal*, September 5, 1896) advances the following propositions: 1. Every malignant growth of the larynx of intrinsic origin which can be dealt with should be treated by an operation, in the absence of a decided indication to the contrary, and the operation should be performed with the least possible delay. 2. Every tumor of the larynx suspected to be malignant, of intrinsic origin, of limited extent, and apparently freely removable, justifies an exploratory thyrotomy in a suitable patient, in the absence of infiltration of the surrounding structures and of affection of the lymphatic glands.

Treatment of Crural Hernia by an Inguinal Operation.—This operation is performed in six stages, viz.: 1. Opening of the inguinal canal. 2. Exposure of the superior orifice of the crural canal and isolation of the neck of the crural sac. 3. Extension of the crural hernia into the inguinal wound. 4. Opening of the crural sac and removal of the same, together with any omentum it may contain. 5. Closure of the crural ring by sticking Poupart's ligament to the pectineal fascia. 6. Closure of the inguinal wound by sutures.—*Revue de Chirurgie*, March, 1896.

Pus Tubes.—Dr. Thomas A. Ashby (*American Journal of Surgery and Gynecology*, August, 1896) says: "I have become more and more convinced from a large experience with pus tubes that the best results will follow in those cases in which the uterus is removed with the pus sacs. The rule I adopt is this: When the pus tube or tubes can be enucleated and removed without rupture or without leaving an infected area behind, to confine the operation to a simple removal of the pus sac. When the tube is closely attached to the uterus and cannot be easily separated from it, or when the uterus has been infected, either by the constant discharge of pus through the uterine cavity, or by softening or localized deposits of pus in its walls, it is far safer to remove the entire organ or to amputate at the junction of the body with the neck.

Spastic Paralysis.—Dr. Bullard (*Boston Medical and Surgical Journal*, September 3, 1896) summarizes as follows: Operative procedures—tenotomy and tenomyotomy—are of much value in cerebral spastic paralysis when their aim and scope are fully understood. They correct the deformity permanently, and they place the limb in a favorable condition for treatment by other means; they are not themselves curative. Muscular tissue alone should not be divided. When possible the tendons should be cut. When this is not possible either muscle and tendon, or muscle and aponeurosis.

Operative Gynecology and Insanity.—Dr. A. H. McFarland, in the *Cincinnati Lancet-Clinic*, says that: 1. Gynecological operations are more likely than any other surgical procedure to distract the mind. 2. Hereditary antecedents of the patient should always be determined. 3. In insane patients operations should be performed only when the physical condition endangers life or renders it insupportable. 4. Patients, precedent to the operation, should be in a calm frame of mind; hence, moral treatment of the patient previous to operating is the best prophylaxis. 5. Inherited and acquired insane constitution is the fundamental factor in most cases of insanity. This conclusion does not, however, justify us in ignoring physical diseases immediately preceding or associated with insanity. 6. Healthy genital organs do not give rise to reflex symptoms; consequently caution should be exercised in operating for the relief of insanity. 7. Operations may be satisfactory in properly selected cases.

Fistula in Ano.—Dr. S. G. Gant gives the following twelve cautions that should be observed in operating for fistula in ano: 1. Always operate under rigid aseptic conditions. 2. Be certain that all sinuses and diverticula have been divided. 3. See that the director is not forced out of the main tract into the neighboring tissues. 4. Divide the sphincter at a right angle, and not obliquely. 5. Ligature or twist all spurting vessels. 6. Guard against injuring the peritoneum when the sinus is high up. 7. Guard against cutting the vagina, prostate, or urethra when the sinus is in the anterior wall of the rectum. 8. Do not operate on patients suffering from acute phthisis or Bright's disease. 9. Give patients the benefit of the sun as much as possible. 10. Do not pack the dressings tightly after the first twenty-four hours, but lay the gauze loosely in the bottom of the tract. 11. Warn your patient of the possibility of incontinence following the operation. 12. Be guarded in your prognosis.—*Langsdale Lancet*.

Tuberculous Abscesses.—Dr. Gage, in the *Boston Medical and Surgical Journal*, September 10, 1896, draws the following conclusions: (1) An abscess occurring in connection with tuberculous disease of the bones or joints is always secondary in importance, as well as in development, to the primary disease. Its treatment must not, therefore, in any way interfere with the treatment of the original lesion. (2) When the abscess is accompanied by any evidences of constitutional impairment, or interferes in any way by its location with the use of proper mechanical treatment, it should be immediately opened. When there is no interference with general health or with mechanical treatment, the abscess, if it presents a pure tuberculous infection, may be left until it is nearly ready to open spontaneously. If it presents a mixed infection, it is to be opened at once. (3) In all cases abscesses are to be opened as soon as they approach the surface, to avoid unnecessarily extensive burrowing. (4) Of the

methods commonly used in opening these abscesses, aspiration with irrigation, free incision with curetting, all seem to give inferior results to those obtained by simple incision in the most dependent portion, with the least possible interference with the walls of the abscess.

Hip-Joint Disease.—In young children the very beginnings of hip-joint disease are announced by muscular twitchings during sleep; added to this, the subject is irritable, the secretions are disturbed, the appetite is fictitious, the muscles are flabby and shrunken away on the affected side, the countenance is pale, and the signs of illness are very apparent. Soon follows a little limp in the gait, attended with pains in the knee or ankle-joint—not often in the hip. These pains are at first very slight, and may escape attention unless the medical attendant is very alert. A rise of temperature will be sometimes noticed in the evening, and it may be continuous; toward the last of this stage more or less spasm of the muscles will have supervened.—*Medical Arena*.

Absolute Alcohol as a Disinfectant for Instruments.—Dr. Robert L. Randolph publishes, in the *Johns Hopkins Hospital Bulletin*, September-October, 1896, a bacteriological study of Squibb's absolute alcohol (98½ to 99½ per cent.) as a disinfectant for cutting instruments used in eye operations. The fact that cataract operations require a keener knife than other operations in surgery, and that heat is therefore objectionable, because it dulls the edge, led the writer to test the value of alcohol, which Reinicke says is the quickest disinfectant that can be relied upon for disinfecting the hands. Scrubbing them in alcohol of ninety per cent. strength for five minutes, he thinks, in taking up the fat takes up the bacteria from the hands, so that they can be washed away. The writer has found no experiments recorded as bearing upon the efficacy of alcohol as a disinfectant for instruments, and in so far his tests represent the only work of the kind that has been done. Inoculation of fifty tubes with fifty eye instruments, taken at random from the experimenter's case and from those in hospital use after being cleansed in the usual way, resulted in sixteen tubes remaining sterile. We will not enter into the experimenter's test methods, but in his own words: "It is evident that the alcohol in the first and second series was adequate for disinfecting purposes, but it is equally true that alcohol is totally inadequate for disinfecting instruments which have been infected with the staphylococcus albus in pure culture, and this might contraindicate our relying upon absolute alcohol for disinfecting instruments which had been used in an operation when the pyogenic organisms are present in great numbers—as, for instance, in panophthalmitis." The conclusions he draws are: 1st. That of a given number of eye instruments, by far the majority are infected by exposure to the air. 2d. That absolute alcohol would seem a valuable disinfectant for instruments infected under the conditions which ordinarily surround us in everyday life. This conclusion seems warranted by the results obtained in the first and second series of experiments. Attention may be called to the fact, too, that in the second series the nails were all without a doubt infected, and it might be said that they had been exposed to conditions which, to say the least, were extraordinarily favorable for infection; so that this series, I think, is strongly suggestive that alcohol possesses disinfectant properties of no little value. 3d. That the septic character of instruments infected with a pure culture of staphylococcus albus is not altered by exposure for twenty minutes to the action of absolute alcohol.

Reviews and Notices.

ANATOMY, DESCRIPTIVE AND SURGICAL. By HENRY GRAY, F.R.S., F.R.C.S., Lecturer on Anatomy at St. George's Hospital Medical School. A New Edition, thoroughly Revised by American Authorities from the Thirteenth English Edition, Edited by T. PICKERING PICK, F.R.C.S. With 772 illustrations, many of which are new. Philadelphia: Lea Brothers & Co. 1896.

THIS new edition of Gray's Anatomy is thoroughly revised and brought up to date. There are many new illustrations, though the old ones which we have cause to regard, through long association, with some affection are in great part retained. With these constant and careful revisions, Gray's will long remain pre-eminent among the text-books of anatomy.

A TEXT-BOOK FOR TRAINING-SCHOOLS FOR NURSES. Including Physiology and Hygiene and the Principles and Practice of Nursing. By P. M. WISE, M.D., Medical Superintendent, St. Lawrence State Hospital; Editor of the State Hospitals Bulletin; Professor of Psychiatry, University of Vermont. With an Introduction by Dr. EDWARD COWLES, Physician-in-Chief and Superintendent of the McLean Hospital, Boston, Mass. In two volumes. New York: G. P. Putnam's Sons. 1896.

THE first volume of this useful work is devoted to a brief study of anatomy and physiology and to the elements of nursing, such as bedmaking, observation of symptoms, and clinical records. In the second the principles and practice of nursing are taught in a thoroughly practical and interesting manner, considerable space being devoted to the nursing of the insane in hospital and in the household. The two volumes together constitute an excellent book of instruction for nurses, and one which they may profitably study as a supplement to the lectures and bedside teaching in the training-school.

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS. From Models in the Museum of the Saint Louis Hospital, Paris. With explanatory woodcuts and text by BESNIER, FOURNIER, TENNESON, HALLOPEAU, DECASTEL, FEULARD, and JACQUET. Part IV. Edited and Annotated by J. J. PRINGLE, M.D., F.R.C.P. London: The Rebmman Publishing Company, Limited. Philadelphia: W. B. Saunders. 1896.

PLATES XIII. to XVI. in regular series represent in this part mycosis fungoides (two plates), psoriasis, and tubercular leprosy of the face. The first of the illustrations of Alibert's disease was made in 1889 from one of Besnier's cases. It is a typical case of what Alibert called in 1812 *Piau fungoide*. The second photolithochrome shows a single ulcerating tumor in the axillary region—illustrative of the form in which tumors appear from the first. Accompanying this instructive article are six woodcuts showing various stages of this affection. The text is furnished by the careful pen of Henri Feulard, while Ernest Besnier has written the interesting description which goes with the first plate.

Feulard also contributes the article on psoriasis, for which the illustration is taken from a model of one of Fournier's cases. It is of the ordinary type.

The lesions upon a separate figure of the penis would need the *etiquette* to make one sure of the disease.

Tuberculated leprosy is well represented and the disease is well treated of by Besnier. A woodcut shows the same patient nine years later, when the face has been freed from active lesions by internal and external treatment. A high order of lithographic work and of literary accompaniment are combined to make this production valuable.

RHEUMATISM, ITS NATURE, ITS PATHOLOGY, AND ITS SUCCESSFUL TREATMENT. By T. J. MACLAGAN, M.D., Physician-in-Ordinary to their Royal Highnesses Prince and Princess Christian of Schleswig-Holstein. Second Edition. London: Adam and Charles Black. 1896. New York: The Macmillan Company.

It is twenty years, the author tells us, since he wrote the opening sentences of the preface to his first edition. We do not remember having reviewed the first edition, so cannot dismiss the present attempt with the usual few lines pointing out the changes and improvements made in the rewriting.

To us and to most readers it is a new work. Those who read the first are, many of them, dead, but others will remember the author's introduction of salicin as a remedy for rheumatism, in 1876. Prior to this rheumatic fever was, as the author says, the despair of physicians, who were practically helpless in cutting short the attack. In the opening chapter the forms of rheumatism are described and compared with each other, and with conditions which occasion similar symptoms. Then follows a review of the lactic-acid theory, the neurotic theory, the action of malaria, etc.

The writer considers the lactic-acid theory ingenious and beautiful, and by no means devoid of foundation, but one which cannot be accepted without careful consideration. It is impossible, he says, that the curative effect of salicylic acid can be due to any neutralizing action on lactic acid.

The many and varied forms of treatment which have prevailed at different times are discussed, perhaps at greater length than the fallacious theories upon which they are based would seem at times to warrant. A good-sized chapter is devoted to the mode of action of the salicyl compounds.

Chapters on rheumatic hyperpyrexia, the relation of rheumatism to chorea, and anomalous forms of rheumatism, which close the work, furnish interesting reading. The paper and printing are excellent.

THE HUMANE SOCIETY OF THE COMMONWEALTH OF MASSACHUSETTS. Report 1895 and 1896. Boston. 1896.

THIS volume contains an interesting report by Drs. J. COLLINS WARREN and GEORGE B. SHATTUCK of an investigation into the methods of resuscitating the apparently drowned. It contains also much valuable information concerning the society and its work.

JACKSON'S READY-REFERENCE HANDBOOK OF SKIN DISEASES. The Ready-Reference Handbook of Diseases of the Skin. By GEORGE THOMAS JACKSON, M.D., Professor of Dermatology, Woman's Medical College of the New York Infirmary and in the University of Vermont, Chief of Clinic and Instructor in Dermatology, College of Physicians and Surgeons, New York. New (second) edition. In one 12mo volume of 589 pages, with 69 illustrations and a colored plate. Cloth, \$2.75. Philadelphia: Lea Brothers & Co. 1896.

IN bringing out a second edition of this work considerable improvement has been made both by the author and by the publisher. The volume presents a better appearance, and the text and illustrations have been added to, both in quantity and quality.

The same yellow-jacket-like frontispiece confronts one as heretofore. While the pathological portion of the picture may be true to nature, the outline drawing of the individual's anatomy can scarcely be so considered. One is always prepared to admire in art, though never having seen it in nature, a blue Italian sky or a lilac atmosphere of the Pacific Coast, although believing the painting overdrawn. It is difficult to admire this picture from the artistic side, or to believe that the coloring is not exaggerated. However, the case is an interesting one.

While the alphabetic arrangement of skin diseases is not to be compared to a scientific classification, were one possible, it does away with the possibility of controversy and criticism, and makes reference to particular subjects easy.

To the list of the first edition have been added some seventeen additional diseases, beginning with acromegaly and ending with porokeratosis, and the number of extra illustrations exceeds the new chapters.

The text in many parts has been rewritten and added to, enhancing the value of an already useful work conscientiously prepared.

Intercostal Neuralgia, double-sided and very violent, persisting for months, was completely and definitely cured by Dr. Goldberg after three injections of ichthyol. The solution employed contained thirty centigrams in one hundred grams of water. A syringe-ful each day was injected. The pain lasted two or three hours after each injection, but was not too severe to keep the patient away from the theatre.—*Gaz. hebdomadaire de la Russie Médecine*, No. 2, 1896.

Therapeutic Hints.

Pseudo-Jusquiamine, one of the three alkaloids discovered by Merck in the *Duboisia myoporoides*, acts as a mydriatic, decreases salivary secretion, and when injected subcutaneously, even in large doses, diminishes the number of pulsations without paralysis of the vagus. It has no value in hystero-epilepsy, and is not toxic even in large doses.—BUONAROTTI.

Headaches.—Dr. M. Galliard directs attention to a form of headache which is differentiated from migraine and syphilitic cephalalgia by its continuity, the absence of nausea and vertigo, and its cessation at night. It is nearly always limited to the forehead, occasionally to the vertex, to the occiput, or to the temples. It generally survives any coincident disorder of the *primæ viæ*, and is distinct from the persistent headache of neurasthenia, which it resembles in its resistance to ordinary remedies. Dr. Galliard recommends a grain and a half of calomel in the morning before breakfast for six consecutive days. On the third or fourth day diarrhœa with colicky pains may set in. The gums should be carefully watched. If the headache should persist, a similar six days' course should be given after a few weeks.

Alcohol as a Disinfectant in Obstetric Practice.

—Drs. Ahlfeld and Vahle (*Deutsche medicinische Wochenschrift*, 1896, No. 6) describe some experiments made to ascertain the value of alcohol as a practical disinfectant in obstetric practice. The results obtained by disinfecting the hands with alcohol have been ascribed to the solvent properties of alcohol upon fatty tissues, thus allowing bichloride of mercury and other antiseptics to come into immediate contact with the bacteria. Some assert that alcohol does not destroy bacteria, but coagulates the epithelia of the skin, and in this way hardens them without preventing the passage of germs. It has been found that alcohol does destroy germs, but acts more efficiently upon micro-organisms containing water or those found in tissues containing water. Dr. Ahlfeld finds that alcohol does not act simply by dissolving fatty substances, because ether, which is a better solvent of fat, is not very efficient as an antiseptic. Experiments prove that alcohol exerts a direct influence in destroying virulent streptococci. Alcohol exerts but feeble influence upon dried tissues containing bacteria and upon bacteria from which the water has been removed. An experiment was made with amniotic membrane when wet and when dry, which illustrated in a striking manner the action of alcohol on a moist membrane. Experiments upon the hands of attendants and nurses demonstrated the value of alcohol as a disinfectant.

Disinfectants in Obstetrics.—Dr. Jewett (*American Gynecological and Obstetric Journal*) submits the following interesting conclusions to an article on this subject: There is no clinical proof that puerperal infection can occur from normal vaginal secretions. All childbed infection in women previously healthy is by contact. Prophylactic vaginal disinfection as a routine measure is unnecessary, and even in skilled hands is probably injurious. Its general adoption in private practice could scarcely fail to be mischievous. In healthy puerperæ, delivered aseptically, post-partum douching is also contraindicated. These rules must hold good in the simpler cases of manual or instrumental interference in which the uterus is not invaded. A purulent vaginal secretion exposes the woman to puerperal infection. In the presence of such discharges at the beginning of labor, the vagina should be rendered as nearly sterile as possible. Concentrated antiseptic solutions should not be used, and the process should

be conducted with the least possible mechanical injury to the mucous surfaces. In case of highly infectious secretions, the preliminary disinfection should be followed by douching at intervals of two or three hours during the labor. Sterilized glycerin, or other suitable material, may be used to restore the proper lubrication of the birth canal. The safest and most efficient means for correcting vicious secretions is a mild antiseptic douche, repeated once or oftener daily for several days during the last weeks of pregnancy. It is the duty of the obstetrician to know before labor the amount and character of the vaginal discharge. Clinically, the amount of the discharge, its gross appearance, and that of the mucous and adjacent cutaneous surfaces usually furnishes a sufficient guide to the treatment. Probable unclean contact within twenty-four or forty-eight hours is an indication for prophylactic disinfection.

Measles.—Chronic bronchitis, broncho-pneumonia long in resolution, and, though less often, empyema, are familiar sequelæ, as well as chronic tuberculosis, especially of the lungs and bronchial glands. Measles indeed seem to prepare the ground for the tuberculous process in a large proportion of children who die from tuberculosis in its various forms, whether acute or chronic; and there are very frequent instances of previously healthy children in whom wasting and chronic disorder, both in the pulmonary and alimentary tracts, and not necessarily tuberculous, seem to arise directly out of severe attacks of measles.—H. BRYAN DONKIN, *The Diseases of Childhood*, p. 186.

Eczema of the Breast and Nipple.—The treatment of eczema of the breast and nipple is with soothing lotions, dusting powders, and cooling salves. When fissures occur, every effort should be made to avoid weaning a child dependent upon its mother's milk; and in such event pencillings of the crack with weak solutions of the nitrate of silver or with compound tincture of benzoin may be used. The Lassar paste, made stiff enough with talc to resist simple contacts sufficient to remove a softer unguent, is an admirable application to these surfaces. All lotions and salves require removal with a weak alkaline and glycerin wash before the child is put to the breast. The use of the rubber nipples and shields sold in the shops is not wholly satisfactory. In treating eczema of this region it is of value to spread strips of soft muslin with the unguent or pomade ordered, and to retain the dressing in contact with the inflamed surface by the aid of cheese-cloth bandages.—JAMES NEVINS HYDE, M.D., *Twentieth Century Practice*, vol. v., p. 226.

Neurasthenic Headache.—

R Ammonii carbonatis..... ʒ iij.
Tinct. moschi..... ʒ vi.
Spts. lavandulæ..... i.
Elix. ammonii valerianatis..... ʒ viij.
M. S. Two teaspoonfuls in water at a dose.

—HAMILTON.

Paralysis Agitans.—

R Strychninæ sulphat..... gr. i.
Acid. arseniosi..... gr. i.
Ext. belladonnæ..... gr. v.
Quininæ sulphat..... ʒ ij.
Pil. ferri carbonat..... ʒ ij.
Ext. taraxaci..... ʒ i.
M. et ft. pil. No. 90. S. One pill three times a day.

—S. W. GROSS.

Obstinate Vomiting of Pregnancy was cured by the application of electricity, but it was discovered that the battery was not in working order at the time the electrodes were applied, so that it was purely by suggestion that the result was accomplished.—DOLÉ-RIS, *Lyon Médicale*, May 17, 1896.

Lobelia may be given in nauseating doses to facilitate reduction of strangulated hernia.—ADOLPHUS, *The Medical Brief*, October, 1896.

Dyspeptic patients with constipation and enlarged liver often do better on bicarbonate of sodium, ten grains to a pint of hot water, slowly sipped three times daily, than on any other form of treatment.

Loeffler's Solution.—

R Alcohol 60 parts.
Toluol. 37 "
Liq. ferri perchloridi. 4 "
Swab the affected parts with this every two or four hours.

Malarial Chills.—

R Liquor potassii arsenitis,
Tinct. iodi āā ℥. ss.
S. Ten drops in water or milk three times a day.
—*New York Polyclinic*.

Antiseptic Wash for the Mouth.—

R Thymol. gr. iv.
Benzoic acid gr. xlv.
Tincture of eucalyptus ℥ ss.
Essence of peppermint ℥ i.
Chloroform ℥ xv.
Alcohol ℥ iij.
M. Twenty drops of this solution, in a glass of water, may be used at a time.
—*Presse Médicale*.

Ulcerated Sore Throat.—

R Chloral hydrate. gr. xx.
Water. ℥ iij.
Syrup. ℥ i.
S. Teaspoonful every hour or two for pain and to induce sleep.
—BRODNAX, *Medical Council*.

Preventive Treatment of Gout.—We may almost always prevent the painful attacks in chronic gout and dissolve the deposits of biurates in the joints by combining the use of lycetol with proper regime. This drug has the uric-acid solvent properties of piperazin joined to the diuretic action of tartaric acid.—HENLEY, *Denver Medical Times*, January, 1896.

Hot Baths in broncho-pneumonia of children are advocated by Dr. Lemoine (*Gaz. Méd. de Liège*, May 7, 1896). Fifty-six cases have been thus treated. They were all severe and all recovered. If there are no extensive pulmonary lesions in the beginning, a tepid bath is given and repeated every three hours until defervescence. If lesions are extensive and the fever is high, twice daily for two or three days a mustard bath is given, and in the intervals a simple bath every three hours. In five adult cases of very severe congestion in the grippe, the bath succeeded completely after all other medication had failed.

Asthma.—There have been numerous classifications of the disease, but it appears to me that they can all be included under three heads, according to the apparent provoking cause, viz.: (1) Irritation of the terminal filaments of the vagus nerve, either in the respiratory passages, particularly the nasal, or in the digestive tract, the stomach probably chiefly; (2) irritation of the main trunk of the nerve itself; (3) irritation of its origin in the brain. Of these three causes, the first two are decidedly the most common, and are frequently combined, as is illustrated by some of the cases I have recorded. The last, or purely nervous form, in which the paroxysm occurs independently of any local irritation, is probably rare, and, I am inclined to believe, will be found to be more uncommon the more thoroughly we are able to investigate the conditions in each of our patients under which an attack occurs.—DR. SAUNDERS, *Canadian Practitioner*, March, 1896.

Oil of Cloves is added to small doses of ipecac to correct the nauseating properties.

Threatened Abortion.—Inject by the rectum twenty-five or thirty drops of tincture of asafœtida in two or three soup-spoonfuls of water.—WARMANN.

Antineuralgic Powder.—

R Powdered guarana. 0.75 cgm.
Sulphate of quinine 0.20 "
Bicarbonate of sodium. 0.75 "
Salicylate of sodium 0.75 "
For one dose to be taken in several cachets.

—*Le Scalpel*.

Intestinal Hemorrhage in Typhoid.—

R Benzonaphthol. 5 gm.
Salicylate of bismuth. 10 gm.
Extract of opium 0.10 cgm.
Syr. of rhatany. 30 gm.
Syr. of orange flower. 30 gm.
Mucilage 120 gm.
Soup-spoonful every half-hour.

—*Le Scalpel*.

Aqueous Extract of Cannabis Indica is said by Lees (*British Medical Journal*, I., 300, 1895) not to possess the almost toxic influence of the alcoholic preparation. It does not influence the secretion of the bronchial glands, and hence is at times preferable to opium. In phthisis it is said to calm the attacks of cough, and is a valuable soporific in diseases of infancy. The adult dose is from two to four grams, while children may be given one or two centigrams for each month of their age. The following formula is given:

R Ex. cannabis indicæ aq. 10 gm.
Aq. aurantii flor. 50 gm.
Saccharin (soluble) 0.2 dgm.
Dessert-spoonful once or twice daily.

Extract of Myrtle.—This preparation, made from the dried fruit of the *vaccinium myrtillus*, has been employed by Winternitz in certain cutaneous affections (*Blätter für klin. Hydroth.*, No. 4, 1895), such as seborrhœal, mycosic, and squamous eczemas, with prompt and favorable results. Other observers have extended its beneficial influence to the treatment of burns. A thick layer is painted upon the skin and covered with a thin layer of absorbent cotton, and the whole is retained by a gauze bandage. Upon the face after the extract is applied rice powder is sprinkled. When the cotton adheres it should be removed once a day or less frequently, after moistening with a one-per-cent. chloride-of-sodium solution.

Constipation in Women.—A very frequent cause of disease in women is constipation. It is remarkable how careless many women are in this respect. It devolves upon the mother to educate the daughter that it is necessary to health that the bowels should move at least once in twenty-four hours. Not only do they have from constipation a poisoning of the system from absorption of the liquid and gaseous contents of the bowels, the ptomaines or poisons developed in them from fermentation producing depressing effects on the nervous system, with derangement of the stomach and assimilative organs, as shown in pale faces, debility, neuralgia, headache, etc.; but we get, in addition, from impaction of the feces in the rectum, uterine displacement, with its consequent disturbances in the pelvic circulation and with its general reflex neuroses. Gynecologists know well that the left ovary is more often diseased than the right one. The left ovarian vein has no valve, and a slight pressure upon it prevents it emptying. Doubtless the pressure of a loaded rectum in this event is a prolific cause of ovarian disease, especially on the left side.—DR. HOLMS, *Southern Medical Journal*.

New Instruments.

TWO NEW NEEDLE HOLDERS.

By GEORGE HASLAM, M.D.,

FREMONT, NEB.

SOME time ago Messrs. Tiemann & Co. made for me a needle holder which has proved very satisfactory for suturing or catching on a needle and thread a bleeding point in any deep cavity.

The blades of the instrument are five inches long, making the whole instrument nine and one-half inches in length; at the same time the blades are only one-fourth of an inch in cross-section.

As seen in Fig. 1, the chief advantages offered in

FIG. 1.

FIG. 2.

this instrument are an almost unobstructed view of the site of operation; an instrument which will with equal facility hold a Hagedorn or an ordinary needle; lastly, the ease with which a needle is caught, for there is no necessity of passing one jaw under the needle, as with most instruments.

Fig. 2 represents a smaller instrument, fitted with the well-known automatic catch, and designed for more superficial work. Both instruments have proved very useful in my hands, and they are readily cleaned.

An Imaginary Invalid, who lived in a large square of London, was ordered by his doctor to take a turn round the square every morning before breakfast. One day the doctor found him very nervous and dejected. "Ah, doctor," he said, "I am certainly much worse. I have been able to walk round the square until to-day, but this morning I was so tired that when I had walked half-way I had to return home again."—*The Scalpel*.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 24, 1896:

	Cases.	Deaths.
Tuberculosis.....	185	101
Typhoid fever.....	33	9
Scarlet fever.....	72	5
Cerebro-spinal meningitis.....	4	1
Measles.....	43	2
Diphtheria.....	163	16
Smallpox.....	0	0

The Russian Government has issued instructions to all its consuls to give the necessary *visé* to the passports of all physicians, whether Jew or Christian, who may wish to attend the Moscow congress.

Insomnia is a common complaint of Arctic explorers who winter in the polar regions, but with the return of the sun the ability to sleep the usual number of hours is regained.

Medical Women in the Elizabethan Period.—During the sixteenth century two women were licensed to practise, one surgery and the other medicine, in Norwich.

The Cost of a Medical Education in Germany is estimated to be about \$700 a year for four years. This includes only the necessary expenses for tuition fees, books, and board, and allows nothing for beer and tobacco.

An Inspector of Medical Schools.—It has been proposed that an official be appointed to inspect all the medical schools of the country, in order to make certain that they do what they promise in their catalogues to do in the way of imparting an education.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

A TEXT-BOOK OF DISEASES OF THE NOSE AND THROAT. By Francke Huntington Bosworth, M.D. 8vo, \$14 pages. Illustrated. William Wood and Company, New York. Price: muslin, \$5.50; leather, \$6.50.

A PRACTICAL TREATISE ON MEDICAL DIAGNOSIS FOR STUDENTS AND PHYSICIANS. 8vo, 938 pages. Illustrated. Lea Brothers & Co., Philadelphia, Pa.

TRANSACTIONS OF THE MICHIGAN STATE MEDICAL SOCIETY for the year 1896. 8vo, 834 pages.

TRANSACTIONS OF THE MEDICAL SOCIETY OF WISCONSIN for the year 1896. 8vo, 593 pages.

DISEASES OF THE EYE. By G. E. de Schweinitz, M.D. Second Edition. 8vo, 679 pages. Illustrated. W. B. Saunders, Philadelphia, Pa. Price: cloth, \$4.00; sheep or half morocco, \$5.00.

A TEXT-BOOK OF SPECIAL PATHOLOGICAL ANATOMY. By Ernst Ziegler. Translated and edited from the eighth German edition. By Donald MacAlister, M.D., and Henry W. Cattell, M.D. 8vo, 575 + xxxii, pages. Illustrated. The Macmillan Company, New York.

MODERN GREEK MASTERY: A SHORT ROAD TO ANCIENT GREEK. By Thomas L. Stedman, M.D. 12mo, 380 pages. Harper & Brothers, New York.

Winter Health Resorts.

By A. F. McKAY, M.D.,

CHICAGO, ILL.

FROM meteorological tables, geographical and other data, a general opinion can be derived as to the nature of the climate of a section, and whether it is favorable or unfavorable to health. It will generally be found, however, that there are strictly local conditions which may seriously affect the salubrity of a particular resort or hotel, as too much shade, bad drainage, poor water, malaria, etc., which should enter into consideration in determining whether a given locality is or is not the best place to send a special case, which can be ascertained only by a personal examination by disinterested parties. We would, therefore, call attention to the responsibility assumed by a physician in sending a patient a long distance from home, merely with a vague idea of the benefit to be derived from a change, without a precise knowledge of the place or conditions which the patient will find at his destination.

Climate is so dependent upon purely local conditions, pertaining often to only a limited area of territory, that it is impossible for any work based solely upon "official" data, taken at fixed points, to convey anything more than a generalization. These conditions can only be ascertained by a careful study of the localities claiming the patronage of the health seeker, and the physician who prescribes climatic change for his patient on generalizations will benefit just about as large a proportion of them as he would if he filled his prescription for all patients from one bottle. The ideal health resort must have a natural basis upon which to build, conditions of soil which render it easily drained, ample supply of water free from contamination and not too strongly impregnated with minerals to be suitable for drinking-purposes. Owing to the attempt so often made to combine the functions of health and pleasure resorts, places which have the elements of the former in large degree are often rendered useless as such from the preponderance of the latter. In studying winter resorts we will save space and avoid repetition by making a classification of climates into four classes, based upon variations of altitude, temperature, rainfall, and humidity.

Class 1.—A low, damp, warm climate will include all below fifteen hundred feet in altitude, with a mean annual temperature of 55° F. or above, an annual rainfall of thirty-five inches or more, and a relative humidity of seventy-five per cent. or more.

Class 2.—A medium, damp, warm climate will include all having an altitude between fifteen hundred and three thousand feet, a mean annual temperature of 50° F. or higher, an annual rainfall of twenty-five inches or more, and a relative humidity of seventy per cent. or more.

Class 3.—A medium high, dry climate is one between three thousand and forty-five hundred feet in altitude, with an annual mean temperature of 45° F. or higher—governed by latitude—a rainfall of twenty or more inches, and a relative humidity of sixty-five per cent. or more.

Class 4.—A high, dry climate is one above forty-five hundred feet in altitude, with mean temperature from 40° to 50° F., an annual rainfall of less than twenty inches, and a relative humidity of below sixty per cent.

While in a low, damp, warm climate pulmonary affections are less prevalent as indigenous disease than in a low, damp, cold climate, yet it is not so favorable for recovery as the higher and drier climates. Kidney disease, in general, is most favorably affected

in the medium high, dry climate, where evaporation from the skin is active if not subject to too sudden changes. Digestive diseases are less frequent and less severe in the low, damp, warm climate than in almost any other, although affections of the liver are more frequent, this type of disease being more prevalent in all warm, damp climates. The warm, damp climate is the most favorable for nervous diseases, especially if complicated by disturbances of the circulation. Acute inflammatory diseases are more prevalent and more severe in the high, dry climates than in the low levels and where there is more moisture. Rheumatism is generally improved by the high, dry climates more than the low, damp ones, except when complicated by cardiac affections, when a low altitude and dry climate should be selected. While this classification is but crude and fragmentary, yet it may aid the physician somewhat in the selection of a resort for various classes of invalids.

In the consideration of winter resorts the aim will be not so much to cover all the possibly available resorts of the South as it will be to mention a few resorts available for all classes of invalids, not only classes with regard to the diseases for which it may be desirable to find a resort, but with regard to the circumstances and conditions of the health seeker.

Beginning with Washington, on the border line between summer and winter resorts, we will consider a limited number in Virginia, North Carolina, South Carolina, Georgia, Florida, Alabama, Tennessee, Mississippi, Louisiana, Arkansas, Kansas, Colorado, New Mexico, Texas, Arizona, and California.

WASHINGTON, D. C.

In an article of this kind no detailed description of Washington as a city need be attempted, further than to state that it furnishes more attractive entertainments as a winter resort than perhaps any other city in the union. The winter climate is an uncertain one, as experienced by the writer during nine years' residence. Some winters, in fact most of them, average delightful weather; yet there are many disagreeable days and occasionally a winter of severity, when cold weather and a frozen river remind the Northern visitor very forcibly of the weather he left behind him. Washington is practically at sea level, the Potomac being a tidal river to a point some miles above the city. The mean annual temperature is 55° F.; mean precipitation, forty-three inches; per cent. of cloudiness for winter, fifty-eight; and relative humidity, seventy-two per cent., bringing the city under Class 1. Washington is not a desirable winter resort for pulmonary invalids.

VIRGINIA

Can hardly be considered a winter resort, except, perhaps, along the coast region, on the ocean and great bays which indent its shores, where fine fishing and hunting afford ample sport for the pleasure seeker, while the invalid will find almost too many winter days, and is likely to move on farther south. Richmond, Norfolk, Virginia Beach, Newport News, Old Point Comfort, Char'ottesvile, Lynchburg, and Danville, all are places where breaks in the journey to the Southern resort may be made and many entertaining features be enjoyed; but none except those on the coast offer any special attraction as resorts.

NORTH CAROLINA

Furnishes quite a variety of resorts, varying in altitude from sea level to a number of thousands of feet above. The State is divided into three distinct

divisions, known as the "eastern section," the "middle and Piedmont section," and the "mountain section." These divisions are a consequence of the general topography of the State, which may be described as a vast declivity, sloping from the summit of Smoky Mountain, at an altitude of seven thousand feet, to the level of the Atlantic Ocean, which forms the eastern boundary of the State. The length of this slope is about five hundred miles, and it is made up of three immense terraces. The first is the "eastern section," constituting a vast plain extending from the coast inland for a distance of about one hundred and twenty-five miles. The surface of this plain rises by easy gradations at the rate of a little more than a foot to the mile. The second or "middle section," comprising nearly half the area of the State, varies from three hundred to one thousand feet above the sea level. The third terrace, or "mountain section," is the highest elevation in the United States east of the Rocky Mountains, averaging about three thousand feet above the sea. With a situation nearly midway of the nation, north and south, and with the varieties of altitudes, North Carolina furnishes all the gradations of climate found at sea level between the Gulf of Mexico and the Gulf of St. Lawrence, and a variety of products, from the palmetto and *Magnolia grandiflora* to the white pine and hemlock, and from the sugar cane and rice to Canadian oats and buckwheat. One of the first of its resorts reached by rail from the north is

Raleigh, situated midway of this general slope and on the second terrace, enjoying the average of the general temperature of the State. The city is situated upon a granite foundation, which crops out on its southern limit, furnishing abundant material for the finest buildings. The site slopes gently in every direction, affording perfect natural drainage. The clear water streams rising from the granite mountain renders the problem of an abundant and pure water supply one of easy solution. Raleigh is called the "City of Oaks," some of the most magnificent specimens of this monarch of the forest gracing the streets and parks. The elevation of Raleigh above sea level is three hundred and fifty feet. The mean annual temperature is 60.1° F. The mean temperature for January for a period of twenty-one years is 41.2° F. The mean of the lowest temperatures for January is 32.1° F., and, as January is the coldest month, these figures give an idea of the coldest weather likely to be experienced. The average yearly rainfall in 47.67 inches. The average for January is 3.38 inches, and for February 3.67 inches, this being a light average for the two months most likely to be needed as a resort for Northern invalids. Raleigh, being the capital of the State, naturally abounds in social and educational advantages for the home-seeking invalid to whom its medium climate may be adapted. There are good hotel accommodations, and quite a resort business has been attracted. Raleigh comes under Class 1.

Salisbury.—Passing westward and upward from Raleigh, we come to Salisbury, at an altitude of seven hundred and sixty feet. It is one of the best of the small cities of the State, and in climatic features is very similar to Raleigh, the slight rise of a little over four hundred feet not being sufficient to make any marked difference in temperature.

Hickory.—At an altitude of eleven hundred and seventy-five feet and among the foothills of the "mountain section" is Hickory, which, with a fine hotel and beautiful country surroundings, offers many attractions for the invalid.

Hendersonville.—Next to Asheville in size and advantages of hotel and modern city improvements, Hendersonville is the best resort in the mountain section of North Carolina. Its altitude is twenty-two

hundred feet, only two hundred and forty feet below that of Asheville, and, as far as climate is concerned, essentially in the same class.

Charlotte is historically interesting, from the fact that it was here that the Mecklenburg declaration of independence was adopted. It is also the centre of the North Carolina gold fields, has well-paved streets, and is, perhaps, as typical a city of the "new South" as can be found. Tourists *en route* to or from Florida will find Charlotte an excellent place to break the journey, as most excellent hotel accommodations are obtainable. The altitude of Charlotte is eight hundred and eight feet; mean annual temperature, 60° F.; mean annual rainfall, fifty-three inches; mean relative humidity, sixty-seven per cent., bringing the city under Class 1.

Asheville.—Until quite recently Asheville has been known principally as a summer resort, but since the erection of several large and very fine hotels especially adapted to the winter business the place has steadily grown in favor as a winter resort and is one of the most popular in the South. Asheville is situated in the "mountain section" or high terrace of the State, at an altitude of twenty-three hundred and forty feet, protected on all sides by spurs of the Appalachian chain of mountains, which constitute the "feature" of this section. Asheville has attracted some of the wealthiest men of America, who are spending millions of dollars in beautifying and embellishing a country for which nature has done much. The city has spent other millions in furnishing every convenience known to modern city building. Six mountain streams, draining as many valleys, afford perfect drainage for Asheville, while springs of the purest water gush forth in endless number from the hillsides in every direction, thus furnishing an abundance of that very essential element of the ideal health resort. The mean annual temperature at Asheville is 59° F.: mean for winter, 45° F. Total annual rainfall, 42.6 inches, of which 9.5 inches fall during the winter; relative humidity, 70.1 per cent. Asheville is within Class 2 in every particular, and may be considered an eligible resort for consumptives as well as many other invalids.

Tyrone is a little hamlet of about three hundred inhabitants, nestled among the hills at the foot of the Tyrone range of mountains, forty-three miles southwest of Asheville. Its population is almost exclusively of Northern and Western people, and it affords a desirable resort for the home-seeking invalid of moderate means. The altitude of Tyrone is fifteen hundred feet above sea level. Mean temperature for January, 41.29° F.; February, 41.3° F.; March, 52.8° F.—bringing Tyrone on the dividing line between Classes 1 and 2.

SOUTH CAROLINA.

In topography South Carolina very much resembles the eastern and middle sections of North Carolina, but it lacks the mountain section, the highest elevation in the State not exceeding one thousand feet and falling gradually from the northwest to the southeast. The eastern or coast section has but one place of any importance as a resort, viz.,

Charleston.—The climate of Charleston differs but little from that of many favored localities of southern Europe. The mean annual temperature is 67° F., and the mean annual rainfall sixty inches. The relative humidity is seventy-eight per cent. Charleston comes under Class 1, and is hardly to be considered a desirable climate for consumptives, but more favorable for nervous diseases, especially those with cardiac complications. Charleston offers many attractions for the tourist, as the city has many interesting features along commercial and historical lines.

Columbia.—The men who laid out the city of Co-

Columbia over one hundred years ago were far-sighted, liberal-minded men, for the streets are one hundred feet wide, with avenues of one hundred and fifty feet in width, and the site, elevated on a picturesque hilltop overlooking valleys for scores of miles, is one rarely excelled. It affords excellent natural drainage, and there are no stagnant pools or marshes in the vicinity. Columbia has one of the finest water powers in the South. Many of the streets have magnificent rows of elms that shade the walks, and also rows through the middle of wide avenues, giving the city the appearance of a large park. The mean annual temperature at Columbia is 63° F.; and of winter, 47.5° F. The total rainfall is forty-seven inches, the average for the winter months being a little less than four inches. The altitude is four hundred feet.

Aiken has for many years been a prominent resort for consumptives. It is situated in the pine woods, which fact gives it some advantages over places with similar climate but without the woods. The mean annual temperature is about 64° F., with a mean for winter of about 50° F. The mean relative humidity is about sixty-three per cent., the rainfall forty-nine inches, and the altitude two hundred and fifty feet, the town being situated on a ridge overlooking the low country around.

GEORGIA.

In general topography Georgia differs but little from South Carolina, except that in the extreme north-western portion the country is given the characteristics of western North Carolina by the southern extremity of the Appalachian mountains. The highest altitudes in the State are less than two thousand feet, sloping gradually down to the ocean on the east and toward the Gulf on the south. Beginning with the higher resorts, the most prominent from its importance as a metropolis is

Atlanta, the name of which has been so indelibly written on the historical and commercial pages of this nation's history. It is not within the scope of this article to enter into detail with regard to the great industrial and commercial interests of Atlanta, except so far as it may be a matter of interest to the invalid or tourist to know that there will be found every modern convenience and comfort of the most metropolitan cities of the North, together with a climate which admits of the enjoyment of these advantages almost uninterruptedly a great portion of the winter. Atlanta is at an altitude of eleven hundred and thirty-one feet, has a mean annual temperature of 62° F., annual rainfall of fifty-seven inches, and relative humidity of sixty-nine per cent., coming within Class 1, except as to humidity, in which respect it is below that class.

Lithia Springs.—Within forty minutes' ride of Atlanta are the Bowden Lithia Springs, where the temperature rarely goes above 85° or 90° F. in summer, or below 40° F. in winter. The altitude is twelve hundred feet. The place has a semi-sanatorium with artesian water, besides the springs, which contain over four grains of lithium bicarbonate to the gallon.

Mount Airy is one of the highest resorts in northern Georgia, seventeen hundred feet above sea level, and has quite a reputation as a winter resort for consumptives and asthmatics, is free from malarial influences, and is worthy of consideration.

Marietta, but a few miles distant from Atlanta, is quite a popular winter resort, and has some reputation as a resort for consumptives, though why more favorable than other points similarly situated is not apparent.

Rome is a flourishing city of over fifteen hundred inhabitants, situated in the northwestern corner of the State sixty-five miles north of Atlanta. Rome is situated among the foothills of the southern Appalachian

mountains, at an elevation of nine hundred feet, and has a picturesque as well as healthful location.

Augusta is situated on the Savannah River, two hundred and fifty miles from its mouth and two hundred feet above the sea. The city extends along the river bank for a distance of about four miles, giving it a pleasing picturesqueness. The streets are very broad, are bordered with fine trees, and are exceptionally well kept, many being paved with asphalt. Just outside the city, about two miles, is Summerville, built upon the sand hills, a natural sanatorium. Summerville is on the same chain of hills as Aiken, S. C., sixteen miles distant. The mean annual temperature at Augusta is 65° F.; rainfall, fifty inches; and relative humidity, sixty five per cent.

Savannah is pre-eminently a beautiful city, and it is to the fortunate early arrangement of the town that it owes much of its beauty. No other American city has such wealth of foliage, united with all the conveniences of a great commercial city. Its parks and squares are adorned with statues, fountains, and gigantic oaks and magnolias, and among these are roses which bloom luxuriantly in open air all winter. Savannah is eighty-seven feet above sea level, has an annual mean temperature of 67° F., annual precipitation of fifty-three inches, and relative humidity of seventy per cent. Points of interest near Savannah are Bonaventure, a cemetery noted for its unique foliage; and Thunderbolt, where oyster roasts and fish dinners are great attractions. The Isle of Hope is another popular resort, where the best of fishing is found. All of these are reached by electric cars.

Brunswick has grown in ten years from a straggling village to a thriving city of ten thousand souls. Situated upon a peninsula almost completely surrounded by salt water, and with a complete system of sewerage, the town is exceptionally healthful. One of the pleasant features of Brunswick is its chain of a dozen sea islands, with long stretches of magnificent beach, which are rapidly gaining prominence as a winter resort. These islands abound in game, such as wild boar, deer, and quail. From the standpoint of either business, pleasure, or health, Brunswick should not be overlooked by the tourist or home seeker. Brunswick is supplied with artesian water from wells four hundred feet deep. The mean temperature for six months, from October to March, is 59° F. The mean for January is 47° F., while that of August is 82° F.

Thomasville.—Among the pines of southern Georgia is Thomasville, which for some years has been gaining in popularity as a winter resort for invalids, especially those of a tuberculous type. Thomasville is three hundred and fifty feet above sea level, and with a rolling topography has good natural drainage and freedom from malarial influences. Realizing the value of invalid patronage, Thomasville has provided liberally in the way of hotel and boarding-house accommodations. The mean annual temperature is 68° F.; the mean for December being 52.70° F.; January, 52.15° F.; and February, 56.60° F.

FLORIDA.

The general reputation of Florida as a winter resort is so well established that little need be said in the way of an introduction. That many invalids who have been sent to Florida might have done much better somewhere else is not so much an evidence of the defects of Florida as a health resort as of the ignorance of its true sphere on the part of those who sent them there. For consumptives for whom there is a chance of recovery in Florida there are better localities, while for those for whom palliation only remains there is perhaps no place more favorable; while for the nervous, wornout invalid, with func-

tional or organic heart complications, there are few if any more favorable places than Florida.

Fernandina, situated just within the border, in the extreme northeastern corner of the State, offers many attractions to the tourist. A seaport on the Atlantic, with a fine harbor and all the "modern improvements," there is no lack of attractions. The climate is practically the same as that of Jacksonville, thirty-six miles distant.

Jacksonville.—The largest city of the State is Jacksonville, which, with its thirty thousand of population, stretches back from the banks of the St. Johns River. Being the gateway through which the throngs of winter visitors pass to the many resorts of the State, the city has a metropolitan air. The accommodations for the tourist and invalid are extensive and of every class, from the very highest to those which can meet the requirements of a limited purse. The mean annual temperature is 69° F.; mean precipitation, fifty-three inches; and relative humidity, seventy-four per cent. Average cloudiness for winter is forty-seven per cent. of possible sunshine.

St. Augustine.—As one proceeds southward along the coast, St. Augustine is the next resort of note. St. Augustine has many attractions of antiquity as well as modern improvements, and is one of the most interesting places in Florida. Being situated on the Atlantic, its climate is more essentially an ocean climate than is that of the resorts situated inland or on the Gulf coast. Other resorts along the coast line, with climatic conditions varying but little except to escape all frost, as one goes farther south, are Ormond, Titusville, Rockledge, and Lakeworth, the latter being the most southerly point accessible by rail on the Florida peninsula. Almost directly across the peninsula on the Gulf coast is

Punta Gorda, which means full point or fat point. Though the town is not yet full-grown, it is taking shape and beauty, and affords excellent hotel facilities for the winter tourist, who finds sport and recreation in the waters of the bay. Punta Gorda was below the frost line in the disastrous winter of 1894-95, which so materially altered the meteorological records of the State of Florida.

Fort Myers was an army post for many years, but now is assuming all the airs and ambitions of a health resort. The streets are shelled, and shaded by tropical trees. The Punta Raesa River affords the finest sport in tarpon fishing to be had in Florida waters, over a hundred a day of these gamy monsters having been landed by the fishermen.

Tampa is to the west coast of Florida what Jacksonville is to the east, *i.e.*, the gateway from the Gulf of Mexico. Tampa has rapidly grown to an important commercial centre, and is becoming a rival of Jacksonville for the patronage of the winter tourists, having hotels equal to those of any of the resorts of the Atlantic side of the State. While it is not the purpose of this article to mention hotels in particular, it is perhaps excusable for us to say that the Tampa Bay Hotel has no superior anywhere from the standpoint of sanitary perfection. The mean winter temperature of Tampa is 72° F.

St. Petersburg.—From Tampa can be seen St. Petersburg, a growing village six miles away, located on the southern extremity of the peninsula which lies between Tampa Bay and the Gulf. This is a delightful resort for the invalid in winter, and is especially appropriate for those who do not care for the more expensive attractions of the larger hotels.

Bartow.—Thus far we have considered only the coast resorts of the State. Almost directly east of Tampa, near the centre of the State, east and west, is Bartow, a town of twenty-five hundred people, with many interesting features.

Lakeland, as suggested by its name, is in the centre of the lake region. The lakes of Florida all have a common level and are on the highest land of the State. Lakeland has pure air, pure water, and an excellent hotel.

Orlando.—The largest interior town in the State, situated among the lakes and with excellent hotel facilities, Orlando offers good features to those who prefer an inland resort. For many classes of invalids the inland resorts are more favorable during January, February, and March; but by April the weather gets warm and the ocean resorts are more comfortable for those who do not care to return North so early.

Gainesville is the centre of an "all-around" region, and is the meeting-point of the up-country and low-country products. Corn, oats, and Jersey cows flourish, and, although tropical fruits catch a frost occasionally, it is a good region for the home-seeking invalid.

Pensacola.—Western Florida has been less prominent as a health-resort region than the peninsular section, but Pensacola is entitled to a place among the eligible resorts, and is by all odds the leading resort of western Florida. Its principal attraction is its bay and the entertainment that can be derived from fishing and sailing thereon. Many winter tourists already appreciate the attractions of Pensacola, and its old forts, its navy yard, and its facilities for driving, boating, fishing, and hunting will attract increasing numbers. The mean annual temperature is 64° F.; rainfall, sixty-nine inches; relative humidity, seventy-six per cent.

ALABAMA.

There are no marked features of special interest to the tourist or invalid in Alabama. The topography is without much variation, except in the extreme northern portion of the State, where the terminal spurs of the Appalachian Mountains render the country rough and rugged, the highest points lying about two thousand feet above the sea, and gradually sloping from that to its level or nearly so at the southern line.

Huntsville.—Situated in the northwestern portion of the State, at an altitude of seven hundred feet, with the mountain spurs surrounding it to a height of several hundred feet, Huntsville offers many attractions as an early winter and early spring resort. In fact, the entire winter is mild and pleasant, though not entirely devoid of winter features, such as an occasional snow and frost. Huntsville has good hotel accommodations and as good water as can be found anywhere. The mean annual temperature is 62° F.; annual rainfall, fifty-eight inches; relative humidity, seventy per cent. There are a number of fine mineral springs in the vicinity of Huntsville.

Citronella, in southern Alabama, in the pine belt, has more than a local reputation as a consumptive resort. It is not much of a place, but has a good sanatorium and enjoys a large patronage.

Mobile.—Mobile Bay and its attractions offer inducements for the tourist, though the city has not made any effort to attract invalids. While Mobile is a seaport city, it is quite elevated, affording good drainage, and, with the breeze from the Gulf to temper the heat of summer and the cold of winter, it has a mild and equable climate. The annual mean temperature is 67° F.; rainfall, sixty-six inches; and relative humidity, seventy-four per cent.

TENNESSEE.

While Tennessee is not far enough removed from the snow and ice of the Northern States to be considered a typical winter resort, the region has a good winter climate and is especially well adapted to the

purposes of a "half-way" stopping-off place for early winter and late spring for invalids who must leave the North early and return late. It is a high, dry, and healthful State, free from malaria, as a rule, and offering many advantages for the home-seeking invalid.

Nashville is five hundred feet above sea level, in the beautiful and fertile Cumberland valley. The city is one of the best built and best paved in the country, and offers many advantages for either the invalid, tourist, or home seeker. The mean temperature is 60° F.; rainfall, fifty-two inches; and relative humidity, seventy per cent.

Chattanooga.—In the southwest corner of the State and in the heart of the mountain region of Tennessee lies Chattanooga, which, with its Lookout Mountain, comprises one of the most attractive resorts of the South. It is far enough south to have the advantages of a mild climate without the debilitating effects of malaria, which are to be guarded against in the lower Southern resorts. The traveller expects to find such combinations of mountain and plain in the edge of the Rockies and other great mountain chains, but it is doubtful if any other such combination is to be found so accessible to all the great centres of the country. Lookout Mountain has one of the finest resort hotels of the South. Chattanooga is seven hundred and eighty-three feet above sea level, while Lookout Mountain is twenty-three hundred feet. The mean annual temperature of Chattanooga is 61° F.; annual rainfall, sixty inches; and relative humidity, seventy per cent.

Knoxville is nearly in the centre of the east Tennessee valley, in full view of the highest peaks of the Appalachian Mountains, and surrounded by hard-wood forests and valuable mineral deposits. Knoxville has forty-five thousand population and excellent hotel accommodations, is nine hundred and eighty feet above the sea, has a mean annual temperature of 57° F., rainfall of fifty-three inches, and relative humidity of seventy-two per cent.

Memphis.—In the extreme southwestern corner of the State, on a bluff rising one hundred feet above the Mississippi, is Memphis, not noted as a health resort, yet having many features which will commend it to the winter tourist and certain classes of invalids, viz., those of a nervous type. The city is built on a series of low hills, affording excellent drainage, which has been supplemented with an excellent sewer system. It has an ample supply of pure artesian water, and has in ten years reduced one of the highest mortality rates to the rank of one of the lowest. With good hotels and a number of excellent sanatoriums, Memphis offers much to the invalid other than pulmonary. The mean annual temperature is 61° F.; rainfall, fifty-five inches; and relative humidity, seventy per cent.

MISSISSIPPI.

With the exception of a few resorts upon the Gulf coast, Mississippi has but two or three places worthy of mention.

Holly Springs, in the northern portion of the State, is a pretty and well-drained town of moderate size, but with better than the average hotel accommodations.

Jackson is the State capital, and as such has many advantages not enjoyed by other cities of the State. The topography is rolling, affording good drainage, besides which the city has many other attractive features.

Vicksburg.—Since the great siege of Vicksburg by Grant, its name has been a familiar one to every intelligent American. Probably few of this generation are aware that the city is situated upon a high bluff, rising very abruptly from the river to a height of several hundred feet, which fact gives it a unique place among

the cities of the Mississippi Valley. There are excellent hotel accommodations, and aside from its historical interest the city has a place among winter resorts.

Bay St. Louis is located on the Bay St. Louis, an arm of the Gulf of Mexico, and for some years has been growing in popularity both as a winter and as a summer resort. Being only fifty miles from New Orleans, it is a popular resort for the people of that city in summer, and for the invalid or tourist from the North in winter. While the hotel accommodations are fair, there is room for a very much better resort hotel. There are numerous boarding-houses.

Pass Christian.—Like Bay St. Louis, this town is situated upon a long peninsula. Along the entire water front is a shell-paved avenue, lying under the shade of magnificent live oaks and magnolias, which, with its surrounding forests of pine, cover the place with a perennial verdure. Roses and violets bloom all winter, and it is always a land of flowers. The mean annual temperature is 60° F. Pass Christian has one of the best hotels on the Gulf coast.

Biloxi possesses all the advantages of climate and attractions characteristic of the Mississippi Gulf coast, and is a popular resort for Southern people, with a growing popularity for the Northern tourist as a winter resort. The town has several hotels, which were built for summer-resort purposes, but have been reconstructed to meet the demands of the Northern visitors in winter. None of the Mississippi resorts are provided with as fine hotels as are the prominent Florida resorts, but from all other standpoints they are fully the equals of Florida.

LOUISIANA.

Louisiana has a few points where with better hotel accommodations a large class of invalids would find congenial climatic conditions, but in this respect not much is to be said.

New Orleans, with its unique cosmopolitan characteristics, with its cemeteries, old markets, old civilization, and good hotels, will afford a desirable and interesting point for a time, and should by all means be included in the itinerary of the tourist who proposes to "do" the Southern resorts. The mean annual temperature is 69° F.; rainfall, sixty-five inches; relative humidity, seventy-one per cent.

Hammond.—Fifty miles north of New Orleans, at an elevation of fifty feet above sea level, is Hammond, situated in the long-leaf pine region which stretches across the southern portion of the State. The soil at Hammond is sandy, well drained, and very productive. Hammond has a good hotel, pure and abundant artesian water, and in all respects is a most favorable place for the classes of invalids who must keep to a low altitude. Bright's disease is almost unknown among the inhabitants, and the locality has proven very beneficial in many cases, the pure water and mild climate with the "piney" air seeming to be a good combination.

La Fayette.—Westward from New Orleans about one hundred and fifty miles is La Fayette, a town of some five thousand population, and the only place between New Orleans and the Texas line that has any appreciable elevation above the sea level. La Fayette is situated upon a sandy soil, fifty-two feet above the sea, and for a few miles the topography is rolling and broken, offering excellent drainage. There is comparative freedom from the malarial influences which are more or less prevalent in the towns of the lowlands. La Fayette has very good hotel accommodations, but it must be remembered that very few places in the territory southwest of the Mississippi have first-class hotels, according to the Northern standard.

Lake Charles is located in southern Louisiana, at

the eastern end of the long-leaf pine region of western Louisiana and eastern Texas. It lies beside a small lake, is a well-built town, made up principally of Northern people, and affords excellent opportunities for the home-seeking invalid or for the tourist not too fastidious as to accommodations, although they are not below the average.

KANSAS.

Many consumptives have passed through one of the most favorable regions in the country for the climatic treatment of their disease to regions better known but no more favorable than southern and southwestern Kansas. The latter, especially, is a region which comes so near the point of aridity as to be uncertain for agricultural purposes except under irrigation, but one which combines with a medium altitude a very large percentage of sunshine, absence of severe weather, and entire freedom from malarial influences—conditions which have proven curative to hundreds of pulmonary invalids.

Wichita.—The city of Wichita is in central southern Kansas, not far from the southern line of the State. It is a city which outgrew itself, but has many metropolitan features which render it available as a health resort. Good hotels, abundant supply of good water, good drainage, and freedom from malaria are there. Mean annual temperature is 54° F.; rainfall, twenty-nine inches; relative humidity, 68.4 per cent., with two hundred and eighty-eight fair days in the year. The altitude is thirteen hundred and sixty-six feet.

Hutchinson is a substantial city of ten thousand people, the centre of the Kansas salt industry. It is on the Arkansas River, and has much to commend it as a winter resort for the pulmonary invalid, especially those with nervous or cardiac complications. The altitude is fifteen hundred and forty feet above the sea level. The general meteorological data are about the same as those of Wichita.

Garden City is a small place at present, but its boom left it good buildings, water works, and sewerage not often acquired by the small town away out on the plains. Its climate is especially adapted to the needs of the pulmonary invalid. It lies at an altitude of three thousand feet, the mean annual temperature is 53° F.; rainfall, 20.8 inches; and it averages sixty-three per cent. of sunshine.

ARKANSAS.

The eastern half of Arkansas is composed largely of swamp land, and has perhaps as unsavory a reputation as regards healthfulness as any portion of the United States. But the western or Ozark Mountain region is as exceptionally healthful as is the swamp region unhealthy, and the time is coming when this mountain region will become a favorite sanatorium, both on account of its healthfulness and of its accessibility.

Hot Springs.—The Arkansas Hot Springs are too well known to need more than a mention. Everything that money can add in the way of embellishment is being furnished to make the more available the many natural attractions. Situated among the southern foothills of the Ozark Mountains, the place is surrounded with the spurs of the mountains, giving it a topography both pleasing and healthful. The place is well supplied with hotels and bathhouses, which will sustain any standard of comparison. The altitude is six hundred and ten feet; mean annual temperature, 61° F.; mean for winter, 51.77° F.; annual precipitation, 72.26 inches.

Eureka Springs.—The altitude of Eureka Springs, which is twenty-one hundred feet, together with its

general meteorological and sanitary conditions, entitles it to consideration as a medium-altitude resort for pulmonary cases. While the precipitation is rather high, the exceptional facilities for drainage render the soil very dry, as shown by a relative humidity of 59.4 per cent. This is considerably below that of most of the popular low or medium altitude resorts. Annual mean temperature is 58.93° F.; mean for winter, 42.08° F.; rainfall, 32.79 inches; clear and fair days, two hundred and ninety-nine. Eureka Springs has excellent hotel and boarding accommodations.

Little Rock.—While not posing as a health resort, Little Rock offers good hotel facilities, good society, and a winter climate permitting much life out of doors. The city stands upon rolling ground, affording excellent natural drainage, and has all modern city improvements. Little Rock is three hundred and seventy-one feet above sea level, has a mean temperature of 63° F., annual rainfall of fifty-six inches, and a relative humidity of seventy-two per cent.

TEXAS.

To attempt to describe Texas, with all its altitudes, climates, and conditions, would require more space than is allotted to this article, for it includes almost every variety to be experienced in the entire country, from sea level with sixty inches of rainfall and roses in winter in the southwestern portion, to seven thousand feet elevation, fifteen inches of rainfall, and the winter of the temperate zone in the northwestern portion. Between these extremes are all gradations. The high altitudes of the northwest are cold and rigorous in winter, while the high altitudes of the south are mild and free from snow or ice.

Fort Worth.—Entering the State by the principal northern route, Fort Worth is the first city likely to be considered as an eligible health resort. The city is somewhat rolling in topography, has excellent hotel accommodations, and though in some seasons it experiences considerable winter, yet the average for that season is mild and pleasant.

Waco.—Following the central valley of the State southward, Waco, with its hot artesian wells rivalling those of Arkansas in valuable therapeutic effect, lies in the direct pathway of the tourist. Waco has one of the finest natatoriums with sanatorium combined to be found anywhere in the South. Waco has fair hotels, but they are the least of her resort attractions.

Austin.—The capital city has many natural advantages as a winter resort, though no especial effort has been made to attract tourists. Lake McDonald, formed by the great dam across the Colorado River, constitutes an attractive feature not to be found elsewhere in the State. Austin has one excellent hotel and a number of good ones. The mean annual temperature is 68° F.; that of January, 50° F.; February, 54° F.; March, 58° F. The annual precipitation is thirty-three inches, and the relative humidity sixty-eight per cent.

San Antonio.—There is probably no city in Texas or elsewhere in the Southwest so well known as a winter resort as San Antonio. Situated just on the edge of the arid region of southwest Texas, it partakes somewhat of the characteristics of the country north and east, which has ample rainfall for agricultural purposes, and of that of the south and west, where irrigation must be depended upon. The result of this location is a considerable rainfall in average years, yet a dry climate from the rapid absorption of the moisture by the atmosphere of the arid region just beyond. While San Antonio has not a tourist hotel proper, yet it has excellent hotel facilities and very numerous and good boarding-houses. The city is of varied topog-

raphy, well drained naturally, and has now a complete sewer system and an excellent water supply. Malarial influences are scarcely ever experienced. The altitude of San Antonio is six hundred feet; mean annual temperature, 68° F.; annual rainfall, 31.88 inches; relative humidity, sixty-eight per cent. With proper precaution in dress against an occasional "norther," San Antonio is a very desirable resort for the pulmonary invalid who has still a chance of recovery.

Kerrville is seventy miles north of San Antonio, at an altitude of seventeen hundred feet, and offers about the same general climatic conditions as that city, except as to altitude.

Boerne is forty miles from San Antonio and fourteen hundred feet above sea level. It has quite a reputation as a resort for consumptives, many of the San Antonio physicians sending their patients there for a change of scene and air.

Llano.—One hundred miles northwest of Austin, at an altitude of eleven hundred feet, is Llano, situated upon a granite formation, which insures the best of sanitary conditions. This place is worthy of consideration in looking up the Texas resorts.

Corpus Christi.—One hundred and sixty miles southeast of San Antonio, on the Gulf of Mexico, is Corpus Christi, a town of about six thousand inhabitants, with good society and considerable reputation as a winter resort. The region about Corpus Christi affords the best of winter fishing and hunting, and offers unlimited entertainment for the tourist or invalid. The climate of Corpus Christi and the Live Oak Peninsula adjacent is the driest coast region on the Gulf, and for mildness and dryness in winter can be compared only to the climate of San Diego, Cal. The hotel accommodations are not better than those of the ordinary type, and would not suit fastidious invalids.

Galveston has many attractions, the principal one being the magnificent beach, where bathing is frequently indulged in all winter. Roses, orange blossoms, and strawberries are abundant all through the ordinary winter. Galveston has a fine tourist hotel, and is a progressive modern city. The mean temperature is 70° F.; rainfall, fifty-three inches; and relative humidity, seventy-seven per cent. Galveston is not a favorable resort for pulmonary invalids, but is best adapted to those suffering from neurasthenia and the general run of nervous diseases.

Houston is one of the best cities of Texas, though as a health resort perhaps not so desirable as some others. Yet there are good hotels, and many would find it a pleasant and in every way desirable place to spend a season.

Sour Lake is a small place about forty miles out of Houston, toward the east, noted locally for its medicinal qualities in the treatment of rheumatism. While somewhat crude in its accommodations, many well-to-do patrons go there for treatment.

El Paso.—Next to San Antonio, El Paso is the best-patronized winter resort in Texas. The climate of El Paso is essentially that of New Mexico, as it is but a few miles from the southern border of that Territory. The city is substantially built upon a gently sloping site, and is naturally well drained. The city water supply is pure so far as regards contamination, but is not of the best quality for drinking, the best water for that purpose being procured from springs adjacent to the city. While the hotel accommodations are ordinary, there are many good private boarding-houses and a most excellent sanatorium, Hotel Dieu, where invalids can obtain the very best of care. The altitude at El Paso is thirty-seven hundred and sixty feet; mean annual temperature, 64° F.; rainfall, eleven inches; and relative humidity, forty-seven per cent.

NEW MEXICO.

New Mexico has for some years been gaining in favor with the medical profession as a winter resort for the pulmonary invalid. The portions of the Territory best adapted as winter resorts have thus far received the least attention, owing, very likely, to the less desirable accommodations than are obtainable at the northern resorts. With the development of irrigation so that available tracts of land can be brought under cultivation, more attention will be given to points in the southern part.

Las Vegas.—Entering the Territory from the north, the first place of any note is Las Vegas, near where is located the most pretentious resort hotel in the Territory. Las Vegas Hot Springs, six miles distant, have also gained quite a reputation for their medicinal qualities. These are two distinct towns, though rapidly growing together, and the distinction of race is also becoming less pronounced as the towns approach each other. Las Vegas is at an elevation of sixty-five hundred feet, has an annual temperature of 49° F., rainfall of fifteen inches, and relative humidity of forty-five per cent. Las Vegas has a winter, but the snow which occasionally falls lasts but a little while, the dry soil rapidly drinking it up.

Santa Fé.—Rising to an altitude of seven thousand and sixty-four feet at Santa Fé, the invalid will find the atmosphere a little light if he has come rapidly from the low altitudes of the north and east. But at this high altitude and in the very heart of the continent, he also finds the oldest civilization in the land. Santa Fé abounds in interesting features and offers many attractions to the tourist. The hotels are unique and interesting. Many invalids find the winters a little cooler than is agreeable, but there is no doubt that if persistent the invalid will do as well here as at the more southerly resorts. The mean temperature is 48° F.; rainfall, fourteen inches; and relative humidity, forty-five per cent.

Albuquerque is lower down the valley of the Rio Grande, at an altitude of five thousand feet. The winter is less severe here than in Santa Fé, but some snow and frosty weather will be encountered. Albuquerque has more of the characteristics of the modern city than any other place in the Territory; very fair hotels and boarding-houses afford accommodations.

Las Cruces.—Between Albuquerque and Las Cruces there are a number of towns of some importance, but they have but meagre accommodations. As they develop, Socorro and Rincon will become good towns. Las Cruces is in the centre of the Mesilla Valley, about forty miles north of El Paso. Las Cruces is one of the oldest settlements in the Territory. As a winter resort for the tuberculous invalid, its climate is unsurpassed. It is a land of almost constant sunshine, with very little rain, where the invalid can be out of doors from autumn until spring. The altitude of Las Cruces is thirty-eight hundred feet; annual mean temperature, 59° F.; annual rainfall, seven inches.

Deming.—About one hundred miles west of El Paso is Deming, at an altitude of forty-six hundred feet, and with general conditions very favorable to the tuberculous invalid, especially in the matter of pure water.

Silver City.—North of Deming some sixty miles, among the foothills, at an altitude of six thousand feet, is Silver City, one of the best of New Mexico's health resorts, as far as climate is concerned. With an altitude the same as that of Colorado Springs and Las Vegas, it is much milder in winter than either. Very fair hotel accommodations are obtainable.

SOUTHERN ARIZONA.

Southern Arizona comprises but little except mountains and desert, but for the pulmonary invalid offers

superb climatic conditions, and where water can be obtained for irrigation the pursuits of horticulture and agriculture are profitable.

Tucson has the characteristics of a medium altitude, twenty-four hundred feet, and, with fairly good hotels and good social advantages, is the best point for those who require more altitude than Phoenix affords.

Phoenix has, perhaps, the better climate for those cases a little farther advanced or for those complicated with nervous or cardiac symptoms. The altitude is eleven hundred and fifty feet; rainfall, eleven inches; mean temperature, 67.2° F.; relative humidity, forty per cent. This city has less wind—an average of less than three miles per hour—than any other resort known to the writer, and the winter climate is superb. Phoenix has exceptionally good hotels and other accommodations desired by the invalid.

Yuma.—At an altitude of one hundred and forty feet, situated on the Colorado River about one hundred miles from the Gulf of California, Yuma offers a mild and genial climate in winter; but, with the exception of the railroad hotel, which is very good, the accommodations are limited.

CALIFORNIA.

The first place to be noticed as a winter resort after crossing the Colorado River into California, is

Indio.—The place is situated on the northern border of the old bed of the Gulf of California, in what is known as the Colorado desert. This is the only place where the invalid can get the benefits of compressed air permanently, as it is forty feet below the level of the sea. Some most remarkable recoveries have been accredited to the very peculiar climate of Indio. Patients have been carried there on stretchers, pronounced to be in the last stage of consumption, and after a few months have gone back to business. It is an almost rainless region, but with a very productive soil where under irrigation. The place consists of a hotel and a few cottages for invalids.

Beaumont is situated on the edge of the desert also, but at an altitude of twenty-five hundred feet, being almost on the summit of the ridge between the Colorado desert and the Pacific slope. Beaumont has good hotels and excellent climatic conditions for the tuberculous invalid.

Riverside has an altitude of one thousand feet, is a town of several thousand population, and affords a desirable winter home, though not especially as a health resort.

Los Angeles is the typical climatic centre of southern California. It is the distributing point for invalids as well as merchandise. For all-the-year-round purposes, Los Angeles, with its immediate vicinity, which includes Pasadena, Mt. Lowe, Santa Monica, Long Beach, San Pedro, and Santa Catalina Island, comprises the finest combination of high and low altitudes, coast and inland resorts, to be found in this or any other country. At no other place can the invalid go from blooming roses and sea-bathing in January to snow-clad mountains and a moderate winter climate at five thousand feet elevation, in three and one-half hours by electric car. Los Angeles is well provided with everything to be found or desired in a first-class resort except a really first-class hotel. She has many good hotels, but not what tourists call a real first-class one. The altitude of Los Angeles is two hundred and seventy feet, topography very favorable for good drainage, and water supply good. The mean annual temperature is 62° F.; rainfall, seventeen inches; and relative humidity, sixty-nine per cent.

TWO MEXICAN HEALTH RESORTS.

From an unpublished article entitled "From Laredo to the City of Mexico, thence West to Morelia and Patzcuaro, over the Mexican National Railroad and Its Branches," by Dr. R. H. L. Bibb, chief surgeon of the road, who resided and practised for many years in Saltillo, and who is thoroughly familiar with health resorts in Mexico, the MEDICAL RECORD is permitted to copy the following description of Monterey and Saltillo.

"Stepping out of the sleeper," says Dr. Bibb, "one is confronted with one of the gentlest, balmiest breezes, one of the brightest, bluest skies, and one of the grandest, most picturesque outlooks that ever delighted the soul of man. In front and all around stands Monterey, sometimes written Monterrey, the 'Mountain King,' the capital of Nuevo Leon, at the foot of the Sierra Madre Mountains, one hundred and seventy miles away from the Texas frontier, and at an elevation of seventeen hundred feet, like a mighty sentinel guarding ingress into Mexico from the northeast. Northward from the gently sloping declivity on which the city is built the verdure of the plain beneath seems to mingle with the azure of the sky above. To the east the aerial head of the Saddle Mountain juts high aloft, the Garcia and the Mitre Mountains on the southwest, while the grand old 'Mother of Saws' to the south, with her jaggy summits looking upward into the vaulted canopy, majestically presides over the lovely panorama below.

"Monterey is a rich progressive city of sixty thousand inhabitants, who are rapidly absorbing American ideas and customs from hundreds of permanent American residents of the city, and from thousands of American tourists and invalids seeking health and a *dolce-far-niente* life in the Aztec republic, who annually find rest, repose, and restoration in the genial suns and balmy breezes of this great health resort.

"There are four American physicians in Monterey, an excellent German drug store, an Episcopal, a Baptist, a Methodist, a Presbyterian, and numerous Catholic churches and schools: five good American hotels: beautiful alamedas, plazas, drives, and promenades: delightful fruits and vegetables: excellent, tender juicy meats, game, and fish, and a supply of water from crystal spring and rippling mountain streams which is abundant, wholesome, pure, and sweet.

"From meteorological observations taken at the Civil College at Monterey for a series of years, the following figures are taken, viz.:

WINTER TEMPERATURE.

Maximum	73.2° F.
Minimum	46.2° F.
Average	57.1 F.

SUMMER TEMPERATURE.

Maximum.....	102.3° F.
Minimum.....	46.2° F.
Average	86.0° F.

BAROMETER.

Maximum	29.24 in.
Minimum	27.96 in.
Average.....	28.10 in.
Average relative humidity	66.3
Average yearly rainfall.....	38.22 in.
Avery yearly amount of clouds	4.5
Average yearly rainy days.....	50
Prevailing winds, northeast.	

"Four miles north of Monterey, to be reached by a tramway, are the renowned Topo Chico Hot Springs, the Baden-Baden of America, the virtues of whose waters, if Indian legends be worthy of belief, was known to the ancient Montezumas years before the Spanish conquest.

"Topo Chico waters—very similar to those of the Arkansas Hot Springs—with a temperature of 106° F. at the spring, 102° F. in the bathtub, and an output

of sixty-eight thousand gallons per hour, contain, according to the Mexican Pharmacopœia:

Hydro-sulphurous acid.....	0.010 per gallon.
Sodium chloride.....	0.296 "
Calcium chloride.....	0.040 "
Magnesium chloride.....	0.076 "
Calcium bicarbonate.....	0.100 "
Calcium sulphate.....	0.419 "
Aluminium silicate.....	0.165 "
Calcium silicate.....	0.350 "

"One may drink to repletion, for days and weeks, of these waters, and aside from the very copious perspiration which always follows, feel neither nausea nor other inconvenience; but when a mixture of the same ingredients in the same proportions is made and heated to a temperature of 106° F., a disgustingly nauseating compound results, thus proving that elements put together in nature's own laboratory, heated in her crucibles, and distilled in an alembic of her own choosing possess properties not imparted to them when compounded by the chemist, however expert or learned he may be.

"The waters of Topo Chico, when properly used, as the writer can attest after many years of experience with them, are of signal efficacy in the treatment of gout, rheumatism, syphilis, Bright's disease, hepatic and gastric troubles, uterine, nasal, and vesical catarrh, chronic malaria, and many forms of skin diseases.

"An excellent hotel—close to the capacious bath-house—constructed of black marble which is found in large quantities and of the best building qualities in the mountains north of Topo Chico Springs, furnishes a comfortable home for the many invalids and visitors to this northern Bethesda.

"Saltillo—a little jump—'Highlands of Many Waters,' 'the City of Roses,' the place where Hidalgo, the author of Mexican independence, on his way to the United States in quest of aid for the struggle for liberty he had inaugurated, was betrayed and captured; now the capital of the rich and prosperous state of Coahuila, on the Mexican National Railroad, two hundred and thirty-seven miles from the Rio Grande, with a population of twenty thousand people, is located fifty-five hundred feet above the sea, at the foot of the Buena Vista tablelands, five miles north of the memorable battlefield of Buena Vista, on a chalky, limestone plateau that gradually dips northward with a grade of six to eight feet per hundred, in a basin in the Sierra Madre Mountains, in latitude 55° 25' 15" N. and in longitude 100° 29' 33" west from Greenwich.

"The city, especially noted for the evenness of its temperature and its excellent water supply, has two good American hotels, American physicians and drug stores, a Baptist, a Methodist, a Presbyterian, and six Catholic churches, with their schools and other institutions of learning. Its water supply, slightly impregnated with lime, furnished by a bold and limpid stream which bursts forth from the mountain side high above the city, and far away from all contamination, is cool, refreshing, and inexhaustible. Its fruits and its flowers, its meats and its vegetables, its fish and its game, equal in savor, in wholesomeness, in variety, and in profusion those of any other town of equal size in America. Here it is that the fragrance of the rose mingles with the violet's sweet incense from January to December, and it is here where one's table may be supplied with the luscious strawberry from one's own garden the year round.

"Meteorological observations, carefully taken at Saltillo for the past ten years, show for that period:

Average barometrical reading.....	24.86 in.
Maximum.....	25.34 in.
Minimum.....	24.43 in.
Average relative humidity.....	59
Maximum.....	99
Minimum.....	11
Prevailing winds.....	North.
Average velocity of wind.....	3.93 miles.
Maximum velocity of wind.....	41.50 miles.
Clouds, average amount.....	4.3
Rainy days, average.....	66.10
Average rainfall.....	22.67 in.
Total rainfall.....	226.75 in.

"These observations also show that the average temperature at Saltillo in January, the coldest month of the year, for the past ten years has been 52° F., and that the average July temperature, the warmest, has been 72° F.

"Near Saltillo are several warm springs of high repute among the natives for the cure of skin diseases, gout, rheumatism, scrofula, malaria, and syphilis. The waters are strongly impregnated with sulphur, iodine, bromine, and arsenic.

"Taking these geographical, topographical, sociological, and meteorological facts into consideration, it will be easily seen that Saltillo, hidden away in its mountain fastnesses, with towering peaks and enchanting scenery on every side, high above the yellow-fever line and away from other epidemic influences, offers not only a safe and a pleasant refuge for the many overworked and worn, and the numberless victims to lung, throat, and bronchial troubles, fleeing from summer's heat and winter's cold, but also ideal facilities for a modern sanatorium—facilities not surpassed, hardly, if at all, equalled, on the American continent."

Diphtheria.—Dr. Ustler says: "Where a bacteriological examination cannot be made, the practitioner must regard as suspicious all forms of throat affection in children, and carry out measures of isolation and disinfection."

Bloody Stools.—Dr. Ullman (*Buffalo Medical Journal*, September, 1896) names the following disease processes which we should bear in mind: (1) Toxic inflammations and strong drastic cathartics. (2) Traumatism. (3) New growths, as carcinomata and polypi. (4) Circulatory diseases: (a) embolism of the superior mesenteric artery, a condition coming on in disease of the heart and general atheroma. It occurs in the feeble and the aged and is accompanied by all the symptoms of peritonitis, great pain, tense, rapid pulse, meteorism, and the passage of blood; (b) general venous hyperæmia; (c) congestion of the portal system; (d) small aneurisms of intestinal vessels; (e) venous varicosities, especially in the small intestine; (f) amyloid degeneration of the vessel walls. (5) Diseases of the blood: (a) pernicious anæmia and leukæmia; (b) grave intermittent fever; (c) hæmoglobinuria. (6) Diseases of the stomach: (a) carcinoma; (b) ulcerus ventriculi; (c) acute gastritis. (7) Diseases of the intestine: (a) acute enteritis; (b) amœbic dysentery; (c) ulcerations from typhoid fever; (d) carcinoma; (e) duodenal ulceration; (f) incarcerated hernia; (g) ankylostomum duodenale; (h) fissure and hemorrhoids. (8) Constitutional diseases: (a) scorbutus; (b) purpura hæmorrhagica; (c) phthisis; (d) diabetes mellitus. (9) Infectious diseases: (a) typhoid fever; (b) yellow fever.

Police Surgeons in Liverpool are paid \$350 a year and furnish their own medicines. The average number of men under the care of each surgeon is two hundred and eighty, and, deducting the cost of the drugs supplied, the surgeon receives about one dollar per annum per man.

Average temperature.....	62.6° F.
Maximum.....	96.5° F.
Minimum.....	32.8° F.

ON THE TREATMENT OF SOME FORMS OF ALBUMINURIA BY RENIPUNCTURE.¹

By REGINALD HARRISON, F.R.C.S.,

LONDON.

I PURPOSE offering you a few remarks bearing on the treatment of some forms of albuminuria by renipuncture as a contribution to the inaugural proceedings of our session that opens this evening.

Early this year, in connection with some observations I published² on kidney tension relative to albuminuria, I narrated the particulars of three cases in which albuminuria of some standing completely and, I believe, permanently disappeared after the digital exploration and puncture or division of the kidney capsule was practised. I will briefly refer again to these cases, together with some others to which my attention has since been called, as bearing upon the point to which I desire to direct your attention on this occasion.

It is, however, only right to state that my cases were all instances in which the kidney was explored and punctured, or incised, not with the intention of treating an albuminuria, but with the object of discovering some other coexisting morbid condition, which, though previously suspected, was not on exploration found to exist. I regret that only scanty notes were kept at the time of these and some other cases to which I might have referred, arising from the fact that, in the absence of what was more directly sought for, the existing conditions were insufficiently appreciated, while the good results accruing appeared at the time either unexplainable, or were referred to local states, such as the accidental fixation of a movable kidney, the division of a disordered nerve, or the moral effects of an operation. It was not until several instances had come under my notice in this way that I began to suspect that a different explanation, for the total disappearance of one symptom of disease at least, might with some degree of reason be offered. My cases are briefly as follows:

CASE I.—In 1878 I cut down on the kidney from the loin in a youth aged eighteen years, expecting to find a suppuration either within or around the organ. The patient was suspected to have had scarlet fever three weeks before this was done and had since suffered from intense lumbar pain. He had had a slight rash, some desquamation, a sore throat, and albuminous urine with casts. I undertook the operation with some hesitation and limited my incision so as just to enable me to put my finger on the kidney. It felt so tense that I extended my incision and opened it with confidence, expecting to find matter. This was not the case, and I closed the proceeding with the feeling that I had made an error in diagnosis. There was a full discharge of blood and urine from the wound for some days. The latter was lightly plugged with lint and in the course of ten days or so healed soundly. After the incision was made, the excretion of urine

became far more abundant, and the albumin gradually and completely disappeared.

CASE II.—In 1887 I operated upon a man, aged fifty years, who by nature of his occupation spent a large part of his time underground. Occasionally he suffered from hæmaturia in conjunction with colicky pains about the groins, and I came to the conclusion that he was suffering from renal calculus. As, however, the symptoms were neither urgent nor confined to one kidney, the consideration of operation was postponed. In the course of a few months after I first saw him, and while he was continuing his work underground, the urine became largely and constantly albuminous and there was some pain, referred to the right loin. I took him into the Royal Infirmary at Liverpool, where I was then residing, and explored the right kidney. The organ was found to be enlarged and tense. An incision of an inch in length was made through the cortex, and the pelvis was explored with the finger, but after careful examination no stone could be found. There was a considerable discharge of blood and urine, which continued for a fortnight or so, a drainage tube being retained in the wound; on the withdrawal of the latter healing followed, and the urine became quite normal. I heard some time afterward that the patient remained in excellent health and was able to resume his ordinary occupation.

CASE III.—The third case is one that came under my observation in 1893. It was that of a woman, aged forty-four years, who had suffered from slight hæmaturia at times for a year previously; occasionally the urine was albuminous. Shortly after I saw her she had a severe attack of influenza, which was followed by an aggravation of her renal symptoms. She complained of pain on pressure over the left kidney, and the albumin not only increased in quantity but was constantly present in the urine. As she believed she had passed a small calculus some months previously, I thought it a proper case for exploration, and this was accordingly made. The late Mr. Durham saw the patient in consultation with me. The left kidney was found to be swollen and very tense. It was opened and explored with the finger, but no calculus could be discovered. There was a free drain of urine with some blood, which continued for about a fortnight, when the wound closed. The patient is now quite well and the urine normal.

Looking at the three cases I have briefly related, I believe that the first was scarlatinal nephritis, the second nephritis from exposure to cold and damp, and the last subacute nephritis following most probably upon influenza. Among other features each case was characterized by the presence of albumin in the urine, which I am inclined to attribute to previous inflammation or its immediate effects.

Since these cases were published, Newman, of Glasgow, has recorded two others in which albuminuria ceased after the performance of an operation for fixation of the kidney. The cases are thus epitomized:¹

CASE A.—Right movable kidney, causing torsion of the ureter and leading to hydronephrosis, albuminuria, and tube casts in the urine. With the onset of the paroxysms of pain, hydronephrosis was sometimes

¹ Being the presidential address delivered before the Medical Society of London, October 12, 1896.

² *Lancet*, January 4, 1896.

¹ *Clinical Society of London, Lancet*, January 18, 1896.

present; sometimes it was absent or not observable, but was attended by high specific gravity of the urine and albuminuria, and tube casts always appeared in the urine at the same time as the pain. Since the operation no albumin or tube casts had been found.

CASE B.—Left movable kidney causing torsion of renal blood-vessels, albuminuria, tube casts, severe pain, and suppression of urine. There was no hydronephrosis, and operation was succeeded by recovery. The kidney was only freely movable, but no increase in size could at any time be made out.

Commenting on these cases Dr. Newman observes: "In the cases of occasional hydronephrosis the presence of albumin and tube casts was more difficult to explain. Why did the transient passive hyperæmia lead to the presence of tube casts, the occurrence of which physicians were in the habit of regarding as of grave import and an indication of inflammatory trouble?"

Both of these cases appear to me to have an important bearing both upon the pathology and treatment of albuminuria.

I am indebted to Dr. Hoeber, of Homburg, for the following particulars. He writes: "I have seen a case very similar to those you describe, about two months ago. A man of about thirty-six years of age, very strong and otherwise perfectly healthy, got, after an attack of influenza which did not appear very severe, most intense pain in the right lumbar region associated with slight albuminuria. As the pain lasted over a fortnight and yielded to no kind of treatment, I sent the patient to a surgeon, with the diagnosis of probable renal suppuration, particularly as there was slight feverishness. The incision brought a considerable discharge of blood but no pus. The patient became rather anæmic, but lost the feverishness and albuminuria at once, and has had no return since."

From a careful consideration of these cases I do not think it is possible to avoid arriving at the conclusion that the disappearance of albumin from the urine was directly connected with the surgical treatment to which in each instance one of the kidneys was submitted. That the organs were in a state of tension, in one class of cases as the result of inflammatory hyperæmia, while in the other from mechanical vascular obstruction, seems also to be a conclusion which is equally irresistible. Referring to the hyperæmia which exists in the initial stages of nephritis, Sir T. Grainger Stewart¹ observes: "Albuminuria is very often due to changes of an inflammatory character in the tubules and in the stroma of the organ, and in a very large proportion of the cases in which it occurs in practice it is dependent on this cause." That the changes which subsequently ensue as a consequence of nephritis, however commencing, by the substitution of a lower for a higher excretory tissue, as we see in the cirrhotic forms of Bright's disease, is due to the damage the organs received in the early and active stage of inflammation or congestion, seems by no means improbable. Sir Thomas Watson observed in his lectures: "The stress or congestion which befalls the kidney in cases of febrile anasarca may set on foot a morbid process that long works silently and unobserved, but at last declares its operation by symptoms."

Nor is there wanting demonstrable evidence as to the high state of tension which is sometimes present in the kidney. I have frequently called attention to this at the time of operation for exploration of one of these organs. In one instance the degree would resemble that of a ripe or almost bursting plum, while in another the kidney was comparatively flaccid and unresisting on pressure with the finger. Yet these differences were not always at the time explainable.

¹ "Lectures on Albuminuria," 1833.

That the relief of renal tension by direct surgical interference has been proved to be practical and is under certain conditions indicated, is also supported by the cases I have cited. Surgeons have long since learned to recognize the disastrous and far-reaching effects of tension as it occurs in the human body, whether arising from inflammation or otherwise, and do not hesitate to negate any evil effects it may give rise to by means which render this very unlikely to happen.

Possibly my surgical experience has led me to exaggerate the disastrous effects of tension on the tissues of the body, though for the most part it has been gained in regions which may be said to be less highly organized and delicate than the excreting apparatus of the kidney. It certainly seems somewhat remarkable at the present day that so many different views exist, or have been put forward, explanatory of the process by which albumin exudes so as to form a variable part of the urinary excretion. These various theories I shall not attempt to discuss in detail or to reconcile.

I may briefly remind you of two illustrations which seem to be analogous with the subject I am now discussing, both relative to the disastrous effects tension is capable of effecting in a part, and the relief that can be afforded on the pressure being removed by artificial means.

In the eye we have an example of a very highly developed and sensitive organ. Here one of the most disastrous effects of intra-ocular tension is seen in that condition to which the term "glaucoma" is applied. The recognition of the true pathology of this affection and the adoption of mechanical treatment by iridectomy or an allied operation, for the removal of tension and the prevention of the degenerative changes thus initiated, as first practised by Von Graefe, at once resulted in the saving of a large number of eyes which previous to this discovery would undoubtedly have been lost.

In the testicle when it becomes inflamed we have, not unfrequently, transient as well as permanent evidence of the damage that inflammation and tension are capable of bringing about in an organ which, relative to its secreting and investing structures, bears a resemblance to the kidney. It will be in the recollection of many that the late Mr. Henry Smith was the first to draw attention to certain advantages that followed puncture or limited incision through the capsule of the testicle in acute forms of orchitis. It was alleged, and I believe with a considerable amount of truth, that not only was the pain or tension in this way immediately relieved but that permanent damage to the secretory structure of the testis was averted. In fact sterility, so far as the organ involved was concerned, was by this means rendered unlikely to occur.

It may not be out of place here to remind you of the structural arrangements of the kidney relative to the influence that tension is likely to exercise upon it. It may be said to be a highly organized gland surrounded by a thin fibrous capsule and divided up into compartments or sections by barriers of a similar nature. It is capable of distention to almost any degree by a gradual force acting from within, as, for instance, the retrograde pressure proceeding from strictures which oppose the escape of its excretion, but from the nature of its structural constituents is incapable of adapting itself to sudden emergencies of this kind, as those usually arising in connection with the early stages of acute nephritis.

Assuming, however, that the means I have thus suggested for dealing with intrarenal tension, under circumstances to which I will presently refer, are applicable, it may be urged that as the kidney, as normally disposed, is a double organ, both glands must be directly submitted to the proceeding proposed,

inasmuch as in the ordinary forms of nephritis both kidneys are usually similarly involved. This, however, does not necessarily follow, as the sympathies existing between the two organs are such as to cause impressions exercised upon one to be reflected on the other. Relief afforded to one kidney, as my cases illustrate, usually assists the other, while, when the excretory power on one side is suspended or arrested, the opposite organ speedily takes up the whole of this work.

I might further illustrate this point in a variety of ways. The following case, however, seems to me to directly bear upon it. It was that of a man, aged thirty, whom I saw early in 1889, ten days after he had received an injury to his loins by falling down the hold of a ship and alighting on a case of goods. The right loin was ecchymosed and from the presence of a little blood in the urine, which continued for some days after the injury, it was concluded that either one or both kidneys had been severely contused. The daily amount of secretion was considerably diminished, and the day I saw him it had amounted to only sixteen ounces in the twenty-four hours. There was pain on pressure over the right loin, which remained swollen, discolored, and tender to the touch, and the temperature had risen and was variable. I thought it probable that perirenal suppuration had occurred. I therefore exposed the right kidney from the loin, and removed some extravasated blood in the course of the incision. The kidney was found very tense and congested. I believed that suppuration had taken place within it, and therefore a small exploring trocar was inserted in two or three places but without discovering pus. Further, at one point where it was very tense I made an incision into the cortex, but only blood and serum escaped. Considering that we had thus got rid of some of the products of the injury which were on the verge of suppuration, the wound was lightly packed with antiseptic lint and left open; there was a free discharge of blood and some urine for some days after, and all the symptoms which rendered the incision desirable were at once relieved and the patient made a good and complete recovery. It was interesting to notice that the excretion of urine was more than doubled in the twenty-four hours following the operation, and the daily amount now remained normal throughout. Here the tendency toward suppression of urine was evidently connected with the intense congestion resulting from the injury in which probably both organs were involved, a condition of the circulation which was at once removed by the treatment described.

We do not, I think, sufficiently recognize the high degree of vascular and tubular infarction that attends some grades of nephritis. Some years ago I saw a girl, aged seven years, who was suffering from scarlet fever of a malignant type. Almost complete suppression of urine was the leading feature in the case, and death took place in four days from the commencement of the illness. At the necropsy the kidneys were found to be so highly congested that I was not surprised at their being unable to excrete. I remember the passing impression arising in my mind that an incision into them appeared to be the only means that might have been effectual in restoring their function. In a recent paper on "Scarlatinal Nephritis and its Varieties," Dr. Meadows Turner¹ remarks: "Out of the five thousand one hundred and nine cases, fifty-five died with nephritis, either alone or complicated with other lesions. This number includes those who presented some symptoms during life, as well as some others in whom post mortem extensive disorganization of the kidney was found, though during life there were no sufficient symptoms for diagnosing such a complication."

¹ Guy's Hospital Reports, 1894.

I will now endeavor to indicate the kind of cases of nephritis in which it may seem desirable to adopt the practice I have illustrated. In resorting to such measures we cannot entirely, as I have already stated, lose sight of the fact in connection with the subject of albuminuria that its treatment, as it at present stands, cannot be regarded as entirely satisfactory or progressive. Commenting upon this point, Sir Grainger Stewart, one of our most modern writers on the subject, and with whom I had the advantage of conversing a short time ago in reference to the point that is now before us, observes: "Sir William Roberts and Professor Rosenstein have come to the same general conclusion as Dr. Saundby as regards the inefficacy of drugs in diminishing albuminuria, and I have satisfied myself by a long series of careful observations that we have no right to credit any drug with the power of directly diminishing the discharge of albumin."

The grounds upon which it may be desirable to give relief by surgical means directly applied to the kidney may be illustrated by some of those cases of nephritis which are seen as consequent on scarlet fever, though it seems to me that its application is not necessarily limited to these. In the larger proportion of cases of scarlatinal nephritis the kidney complication is only of a temporary character and the disappearance of albumin from the urine is both gradual and complete. Under such circumstances surgical interference could not be regarded as warrantable. On the other hand, there is a considerable number of cases met with in which this is not so. These may be ranged into two groups. The first includes those instances in which the kidney complication is, from the onset, of the gravest nature and death is imminent with more or less suppression of urine, as in the case I have previously referred to in which after death the kidneys were found in a condition of most intense vascular engorgement. In these cases a fatal issue usually ensues most rapidly, the duration of life being largely determined by the degree of suppression that is arrived at.

The second group of cases includes those in which after a limited time the tendency, so far as the renal symptoms are principally concerned, is not in the direction of recovery. The amount of albumin does not decrease, tube casts as well as other evidences of disorganization are found in the urine, and the latter in quantity is below that which may be regarded as an average. Though a physical examination of these organs, either from the loin or by abdominal manipulation, may fail to give any indication as to their condition, tenderness on pressure is often complained of. It is from among the cases represented in these two groups that instances will be found in which I believe the measures advocated may sometimes be advantageously practised. It is in these instances that death either rapidly occurs, or is brought about no less surely in the course of time by the more chronic forms of nephritis in conjunction with the cardiac complications which so frequently arise in connection with them.

That many cases of nephritis with high tension and subsequent structural deterioration must necessarily be attended by cardiac hypertrophy or enlarged powers of circulation, is at once obvious. Diminished capacity to excrete can only be compensated for by increase in the force of the blood current. In the restoration of function we have the only safeguard against the development of this complication.

In conclusion I will offer a few remarks on the precise nature of the surgical treatment of renal tension associated with albuminuria. It is hardly necessary to remind you that by anæsthetics, and the antiseptic treatment as developed by Sir Joseph Lister, we are now in the position not only to explore various organs of the body with perfect safety, but, further, we are

enabled by these means to study what I would speak of as living pathology. It would not be possible for me to illustrate the truth of this observation more vividly than in the case of renal disease. Here, by anesthetics in combination with antiseptics, a vast number of diseases have been brought not only within reach of surgery, but with a degree of success which previously would have been unattainable. The operation of exploring a kidney by an incision from the loin, so as to enable the operator to examine this organ carefully and deliberately with the finger, and, if found necessary, to proceed further, has now been so safeguarded as to remove from the mind of any careful surgeon undertaking it the feeling that he is exposing his patient to any undue risk, relative to the cause that is judged to demand it. I cannot say that I ever saw any ill result follow the exposure of the kidney by an incision from the loin for the purpose of its digital exploration. On the other hand we have seen in numerous directions the necessity for such a proceeding in many cases in which, though recovery followed, a correct diagnosis had not previously been arrived at. Such instances include the presence of pus or fluid within the kidney, morbid growths requiring the removal of the organ, stones, undue mobility, and other abnormal conditions.

In the class of cases I am now referring to, the kidney should be exposed by a moderate incision from the loin, so as to enable the operator to feel the organ distinctly both in front and behind, aided of course by pressure exercised on the kidney by the hand of an assistant from the front of the abdomen. If, in conjunction with the presence of albumin in the urine, the kidney is found in a state of tension, such as I have illustrated, three or four punctures may be made through the capsule in various directions, or should the organ be found in a state of higher tension, then a limited incision into the cortex may be practised. After one or other of these measures has been adopted, the wound should be lightly packed with gauze, or a drainage tube substituted. In either case the incision should be dressed in such a manner as to provide for the free escape of either blood or urine or whatever products may be exuded. For this practice I ventured to think some reason will be found in the illustrations which have formed the text for my observations this evening.

RECENT ADVANCES IN OUR KNOWLEDGE CONCERNING THE MALARIAL ORGANISM.

By CHARLES F. CRAIG, M.D.,

DANBURY, CONN.

MEMBER OF THE AMERICAN MICROSCOPICAL SOCIETY; CONNECTICUT STATE MEDICAL SOCIETY; FAIRFIELD COUNTY MEDICAL ASSOCIATION; PATHOLOGIST TO THE DANBURY MEDICAL SOCIETY.

It is now an almost undisputed fact among those who have investigated the subject that in the blood of patients suffering from the various forms of malarial fever there occurs the organism known as Laveran's plasmodium malariae. Sixteen years have elapsed since Laveran¹ discovered this organism, and during that time the subject has been continually worked upon, and a vast mass of literature has accumulated devoted entirely to it. As to the truth of this we have only to glance over the very complete bibliography of malaria compiled by Thayer and Hewetson,² of Baltimore, which comprises over three hundred and fifty-nine separate articles. Among the distinguished scientists who have added to our knowledge of this subject may be named Laveran and Carter, of India; Marchiafava, Celli, Golgi, Bignami, and Thommasi-Crudelli, of Italy; Mannaberg, of Austria; Manson,

Prout, and Thin, of England; and Osler, Sternberg, and Doch in our own country.

It is the purpose of this paper to bring together in a convenient form the advances in our knowledge concerning the malarial organism, especially those which have been made more recently. In the opinion of the author, such a *résumé* is of great use to the general practitioner, who, though anxious to keep abreast of the times in matter scientific, is greatly hampered by the lack of time to peruse and the inability to procure the scattered literature upon such subjects. It is for this reason that I have ventured to compile this paper presenting the recent observations concerning the malaria plasmodium, and containing necessarily but little original work.

I. Methods of Examining the Blood.—We have long since passed the time when any obscure fever, particularly if it prove fatal, can be called malarial, for, as Osler has stated,³ "the diagnosis of the malarial fevers can be made with certainty by the blood examination." All that is needed by any one to make such an examination is a good microscope, knowledge of the technique involved, and proper preliminary training.

Much has been written tending to make the searcher for the parasite believe that it is difficult to find, but if it be searched for in the right way nothing is easier to demonstrate. As to the frequency of its occurrence, it may be said to be always present in active malarial disease. Manson⁴ has never failed to find it in such cases, and Mannaberg⁵ states that he failed to find it only in three out of one hundred and thirty cases. In their recent monograph upon malaria, Thayer and Hewetson² say: "Excepting two or three instances where the patients entered the hospital during convalescence, the specific micro-organism was found in every case (616) of malarial fever treated in the wards." From his own limited experience the author would state that in all the cases which he has examined (24) he has never failed to find the organism.

As to the best time for examining the blood almost all authorities agree that the organisms are best seen about the end of pyrexia and the beginning of the fever, when they are pigmented and large. They are, however, most numerous during the fever, but are so small that they are apt to be overlooked by the beginner.

The blood can be examined fresh or staining methods may be used. I think that the examination of fresh blood is most satisfactory in diagnosis, although if permanent specimens are desired, staining is required.

Daniels⁶ claims for staining the following advantages: Ease with which the organisms can be seen, using one-fourth or one-eighth objective; one's own convenience can be followed by staining; whereas fresh blood has to be examined immediately; no danger of confusing the parasites with other appearances in the blood, as vacuoles, etc. On the other hand, many authorities believe that the organism should preferably be studied in its living condition in the fresh blood.

Method of Examining Fresh Blood.—Cover glasses and slides should be carefully washed in alcohol, just before using. The blood is generally taken from the finger, as follows: Wash the skin thoroughly with soap and water over the place to be punctured, and then with alcohol; then with a perfectly clean steel needle puncture the skin and allow a drop or two of blood to fall. Then take the glass slide and allow it gently to touch the tip of the drop of blood upon the finger, and immediately drop the cover glass upon it. If the slide be clean, the cover glass will instantly flatten the blood out, and the corpuscles may be seen lying side by side entirely unaltered. Be careful and get but a

very small drop of blood upon the slide. Such specimens remain in good condition for about an hour. Although, if desirable, a one-twelfth oil immersion may be used to examine with, I have always used in preference a one-eighth dry objective on account of the greater ease of manipulation. For diagnostic purposes the one-eighth objective is entirely sufficient.

Stained Preparation.—A staining method which is as good as any in results, and better than some in the ease of its application, is that devised by Chenzinsky.⁶ A watery concentrated methylene-blue solution, diluted one-half with water, is mixed with an equal volume of a one-half per cent. solution of eosin in sixty per cent. alcohol. The blood is collected, as described, upon cover glasses, and fixed by gently heating it over the alcohol lamp, after the blood has dried upon the slide. Place the slide in the staining solution and allow it to remain five minutes; then wash in water, and mount in balsam. The red corpuscles are seen to be stained with eosin, while the parasites are colored by the methylene blue.

There are many other staining methods, but the above secures as good result as any of them. Good stained specimens are not always secured with any of the methods, and disappointment is often the rule rather than the exception, in staining the plasmodium malariae.

In closing this section of our subject, I will give in full a method of preparing malarial-blood films recently devised by Manson,⁷ and which recommends itself to any who will take the slight labor of learning it. "Cleanse with ether as many microscope slides as are likely to be required, and place them on a table near the patient. Three or four oblong slips of very fine clean tissue paper one and a half inches by five-eighths of an inch are also prepared. The patient's finger is cleansed and pricked in the usual way. A droplet of blood is then expressed from the puncture and taken up by touching it with one of the papers, the blood being applied about one-half inch from the end of the paper. The charged surface of the end of the paper is then placed upon a glass slip toward one end. In a second or two the blood will have run out in a thin film between paper and slip. When this has taken place—not before—the paper is drawn along the surface of the glass. The same paper, without recharging, is placed in a similar way upon a second slip, and so on. When exhausted, the paper is recharged from the finger as many times as may be found necessary. In this way fifty or one hundred exquisitely fine films may be obtained in five or six minutes. Labels are then attached and the slides stowed away to await convenience. Before staining, a little absolute alcohol is dropped upon the films to fix them. In staining he uses borax (five per cent.) methylene blue (one-half per cent.) solution, for about half a minute; then washes in water, dries, and mounts in balsam.

II. Structure of the Organism.—If the blood from a case of tertian malaria be examined at various periods, the following appearances may be noted, which are slightly modified in the quartan and æstivo-autumnal forms.

Taking the blood during the chill, or just before the chill, a number of bodies, pale in color and spherical in shape, may be seen grouped around a central mass of pigment dark red or brown in color. The entire organism lies within the red blood corpuscle,

which may be distinguished as a pale yellow ring encircling it (Fig. 1). Besides this corpuscle-encircled body may be seen similar bodies unenclosed by the blood corpuscle, and we notice that the little spherical bodies do not constitute one body as before, but are separated (Fig. 2), and in some places may be seen single spherules scattered among the red corpuscles (Fig. 3). Besides the forms just noted may be seen small colorless bodies inside the blood corpuscles, possessing amœboid movements (Fig. 4). In blood examined during and after the fever stage, the only bodies to be seen are colorless amœboid bodies, inside the red blood corpuscle. These bodies are constantly changing their form, presenting sometimes very singular appearances (Fig. 5). In the course of two or three hours these bodies will be found to have enlarged, and scattered granules of dark pigment are now present (Fig. 6). These pigment granules have an exceedingly rapid trembling motion. If the blood be examined from this time on, at intervals, it will be found that the intra-corpuscular body enlarges so as to almost fill the corpuscle, the pigment congregates toward the centre, the hyaline body begins to show lines of cleavage, and at last, just before another rigor, we find the segmented masses described heretofore.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 5.

FIG. 6.

Now in order to find out the structure of these bodies, staining has to be resorted to, and various observers have added very interesting material to our knowledge on this subject.

The tertian parasite has been studied by Romanowsky.⁸ He has distinguished a nucleus containing a more deeply stained portion, which he believes to be the chromatic portion of the nucleus, lying within the nuclear fluid, and states that while the organism is segmenting, karyokinetic changes may be observed within this portion. Sacharow⁹ also distinguishes a nucleus and nucleolus in the æstivo-autumnal organism.

Mannaberg¹⁰ recognizes a nucleus and nucleolus, and states that, while the nucleus grows in common with the organism, it disappears before the organism undergoes segmentation, merging into the substance of the parasite. As the organism segments, each new spore or segment develops a nucleus of its own. The analogy here between the organism and ordinary cell division cannot but be noticed.

Thayer and Hewetson² thus admirably sum up the existing knowledge upon this subject as follows:

"In summary, then, the substance of the parasite has by careful study been shown to consist of a more deeply staining outer part, which contains the pigment granules, and an inner part which is pale and non-staining, excepting for a small, more deeply colorable

body, which is usually situated close at one side on the border line between this area and the more deeply staining outer layer. This colorless area is generally interpreted as a bladder-like nucleus, the dot on one side representing the chromatin substance or the nucleolus."

Romanowsky is the only observer who has described karyokinetic changes taking place within the nucleolus.

III. The Relation of the Organism to the Various Types of Malarial Fever.—It was not until 1885 that the subject of the relation of the malarial organism to the several forms of malaria was first approached, with the publication of the first work of Golgi¹¹ upon the organism of quartan fever.

From that time until now there have existed two main parties, differing in their views of the nature of the malarial organism.

Of these, Laveran and those who believe with him constitute one, their belief being that the malarial parasite is a single organism, and that there is no relation between the forms in which it appears and the fevers.

Laveran¹² thus states his belief: "This parasite is to be seen in a considerable variety of forms, which one can, however, resolve into the four following types: (1) spherical bodies; (2) flagella; (3) crescentic bodies; (4) segmenting bodies or rosette forms." Again he says: "I do not believe that there exists a constant relation between the forms under which the hæmatozoa appear in the blood and the clinical manifestations of paludism; one can only say that certain forms of the parasite are more often seen in certain cases. . . . The differences which one makes out in the evolution of the hæmatozoa of paludism are not sufficient to authorize one in admitting the existence of several distinct varieties of parasites."

In his latest contribution upon the subject¹³ he says that he does not believe that the malignant fevers of tropical latitudes are caused by an organism distinct in each, but that the fever germ becomes more virulent owing to its surroundings. He never yet has met with the varieties described by some authors as peculiar to tertian, quartan, and irregular fevers, and he adheres to the belief that the malarial germ is a morphological unit in all countries.

The belief of the second party, which includes the

As a *résumé* of this part of the subject, I will quote the results obtained by Thayer and Hewetson in an analysis of six hundred and sixteen cases of malaria in Baltimore. This is one of the latest and best contributions to our knowledge upon this matter, and states briefly the general views held by the majority of observers.

They say:²⁰ "We have distinguished three varieties of the malarial parasite:

"1. The tertian parasite.

"2. The quartan parasite.

"3. The æstivo-autumnal parasite.

"(1) The tertian parasite requires about forty-eight hours to accomplish its complete development, and is associated with relatively regular tertian paroxysms, lasting on an average between ten and twelve hours, associated almost always with the three classical stages—chill, fever, and sweating. Frequently, infection with two groups of tertian organisms gives rise to quotidian paroxysms; rarely, infection by multiple groups of organisms gives rise to more irregular sub-continuous fevers.

"(2) The quartan parasite is an organism requiring about seventy-two hours for its complete development. It is associated with a fever showing regular quartan paroxysms, similar in nature to those associated with the tertian organism. Infection by two groups of the parasite causes a double quartan fever, paroxysms on two days, intermission on the third. Infection with three groups is associated with daily paroxysms.

"(3) The æstivo-autumnal parasite passes through a cycle of development the exact length of which has not, as yet, been determined. It probably varies greatly from twenty-four hours or under to forty-eight hours or more. But few stages of development of the parasite are found ordinarily in the peripheral circulation, the main seat of infection being apparently in the spleen, bone marrow, and other internal organs. Infection with this organism is associated with fevers, varying greatly in their manifestations.

"Nothing in our experience has led us to believe that these varieties of the parasite are interchangeable. They are, we believe, distinct varieties, though closely allied to one another biologically."

IV. The Crescentic Bodies.—In the irregular or æstivo-autumnal fevers there occur in the blood, after a longer or shorter period, peculiar bodies known as the crescents or crescentic bodies. These bodies lie sometimes within the red blood corpuscle, sometimes partly without, and sometimes free in the blood plasma. Their structure and significance have always been matters of controversy between plasmodists, and it will be of interest to dwell briefly upon the more recent theories in regard to them.

Grassi and Feletti²¹ think that the crescents are a totally different variety from other forms occurring with them, and believe that sporulation takes place within them. They have given the name of *laverania* to them. They describe a surrounding membrane and crescents containing two nuclei.

Bignami,²² in 1889, states that this form of the parasite is possibly not a living organism but a degenerate body which does not proceed to reproduction, and neither does he think that they comprise a separate group of organisms.

Marchiafava and Celli²³ agree with his conclusions.

Mannaberg¹⁰ thinks that the crescents are formed by two of the small hyaline bodies joining together to form one, and that the process is one of conjunction or copulation. He bases his opinion upon the fact that several hyaline bodies are often seen within

majority of workers in this line, is that there may be distinguished different types of the malarial parasite, corresponding to and occurring with the chief varieties of malarial fever.

Golgi was the first to assert this theory and Marchiafava,¹⁴ Celli,¹⁵ Grassi, Feletti,¹⁵ Mannaberg,¹⁶ Romanowsky,¹⁷ Councilman,¹⁸ Doch,¹⁹ and Thayer and Hewetson²⁰ are among those who uphold it and have contributed valuable material regarding it.

They believe that there occur in the tertian, quartan, and irregular or æstivo-autumnal fevers distinct varieties of the malarial organism, associated with each form of fever, and that the variety of organism occurring in one never occurs in any other form of fever.

one corpuscle, and upon the formation of a membrane, peculiar arrangement of pigment, and segmentation.

Manson²⁴ believes that the crescent form of the parasite is a step in preparing the organism for its life outside the human body.

Laveran²⁵ in one of his latest works upon this subject, states his belief that the crescents are but ordinary parasites, which, developing under altered conditions in the blood of cachectic patients, become encysted.

Thayer and Hewetson say:² "From practical observations, then, we can say that the crescents represent a very resistant form of the organism; that their presence in the blood alone is often unassociated with fever; that in many instances where they have previously been seen without fever relapses have occurred, but always in association with small hyaline and ameboid forms; that in connection with these attacks of fever we have never seen reproductive forms; that it is clearly demonstrated that the crescents may change into the round bodies from which flagellation is frequently observed. We feel that our observations do not justify a definite conclusion with regard to the significance of these bodies."

In a recent contribution, Danilewsky²⁶ describes in protracted infections very large crescents, which he thinks might give rise to serious nervous troubles by plugging the vessels of the medulla. They were from two and a half to three times the length of a red blood corpuscle.

V. The Flagellate Bodies.—If a specimen of malarial blood be taken just before the paroxysm and placed under the microscope, in the course of from fifteen to twenty minutes certain bodies will make their appearance which are known as the flagellate bodies. These consist of a malarial organism, possessed of two or more actively moving prolongations or flagellæ, which are generally knobbed at their extremity. If these organisms be watched, the flagellæ will sometimes be seen to separate themselves from the parent body and, by means of their power of locomotion, shoot rapidly around among the blood corpuscles. As with the crescents, the nature and significance of these bodies is still an open question.

Golgi²⁷ thinks that they form a phase in the development of the crescents, and that they are degenerative forms of the parasite.

Grassi and Feletti²⁸ believe that they are involutive forms of the parasite, while Sacharoff²⁹ thinks that they develop only outside the body and are produced by the action of a low temperature upon the blood. He thus implies that they are degenerate parasites. Bastianelli and Bignami³⁰ also believe the flagellate bodies to be degenerative forms of the parasite. On the other hand, many observers tend to the opinion that the flagellate bodies are really the most highly developed organisms, and that instead of dying these are in fact reproducing new organisms.

Laveran³¹ believes that they represent the most perfect stage of development of the parasite, and denies that they have anything in common with the sarcodic prolongations of the normal red corpuscle produced by heat.

Doch³² and Mannaberg¹⁰ also believe that the flagellate bodies are not degenerate forms of the parasite, and Mannaberg says: "I suspect that the flagellate bodies enter upon the first steps of a cycle of existence outside the human body." He remarks that they do not develop until the blood has been some time withdrawn from the body.

Thayer and Hewetson³³ conclude as follows: "While our observations concerning the time at which these bodies appear, their association with undoubted degenerative forms, their persistence after disappearance of the fever and after the administration of quinine, the manner in which they are engulfed by the phagocytes, are all, it seems to us, suggestive evidence that these bodies are degenerative in nature; on the other hand, the extreme regularity in the shape of the flagella, their extraordinary activity, their power of individual motion, cause us to hesitate seriously in accepting this view."

Great interest attaches to the views of Manson³⁴ upon this subject, and in a recent paper he announces his firm belief in the theory that the flagellate body is a form of the parasite calculated to maintain the life of the organism outside the human body.

He thus forcibly describes these bodies: "It is a strange, weird-looking, octopus-like creature, with long whirling, curling, lashing, tentacle-like arms attached to a central, somewhat spherical mass, in which are black melanin particles tumbling about in a state of continual agitation. If we keep on watching this body we sometimes see one or more of the tentacle-like arms break away and swim about in the liquor sanguinis with a spirillum-like movement."

Various Forms of Flagellate Bodies. FIG. 12.—Flagellate parasite from tertian fever. FIG. 13.—Flagellate parasite from quartan fever. FIG. 14.—Flagellate parasite from æstivo-autumnal fever. FIG. 15.—Flagellate parasite from æstivo-autumnal fever.

He then describes the development of the flagellate from the crescent bodies, and states his belief that it is not a "degenerative change in a dying or dead parasite" but a "vital evolutionary change—a normal step in the life of the parasite." His reasons for so thinking are the following:

1. The movements of the flagella when attached, and their individual power of locomotion when separated from the body of the parasite.
2. The fact that flagellation occurs in the majority of the organisms, if under natural conditions.
3. The similarity in the flagellated organisms as regards their form and movements.

Manson then concludes his paper by claiming that the flagellated plasmodia are the extracorporeal germs of malaria, as follows:

"I conclude then that the crescent body and the tertian and quartan spherical bodies which proceed to flagellation are the extracorporeal sporulating homologues of the intracorporeal sporulating bodies; that the flagellum is the extracorporeal homologue of the intracorporeal spore. Both types of sporulating plas-

modium have corresponding functions, both arise from the same source; one is the germ of the plasmodium inside the human body, the other is the germ of the plasmodium outside the human body; both function in the propagation of the parasite."

VI. Reproduction, Life Outside the Human Body, and the Mosquito Theory.—Reproduction takes place, according to the majority of observers, by sporulation, which was first satisfactorily described by Marchiafava and Celli,¹⁵ and the flagellate bodies are believed to be another form of reproduction by Laveran,²¹ Mannaberg,¹⁰ and Manson.³⁰

Our knowledge concerning the life of the malarial organism outside the human body is very limited; indeed, it may be said that until the very recent appearance of Manson's³¹ papers upon the subject, our knowledge was *nil*. In these papers, which comprise a series of lectures given before the Royal College of Physicians of London, Manson states his theory of the extracorporeal life of the organism and the relation in which mosquitoes stand to malaria. As has been heretofore noted, Manson believes that the flagellate bodies are in reality the first stage in the extracorporeal cycle of the organism. Not developing until the blood is withdrawn from the body, he thinks that suctorial insects, such as the mosquito, taking blood from malarial subjects, the flagellate bodies develop in such blood within the stomach of the insect. He says: "Casting about for an agent that would meet the requirements of the case, it occurred to me as it had already occurred to Laveran, that, as the plasmodium is a passive blood parasite, its escape from the human body might be effected on the same principle as that by which the escape of the passive blood parasite is effected. As the latter obtain their opportunity by being swallowed by some flesh eater—some carnivorous animal—I thought the former might get its chance of development by being swallowed by some blood eater—some suctorial animal, such as the flea, the bug, the louse, the leech, the sandfly, or the mosquito."

He believes that the blood corpuscle in which the plasmodium is encased acts as a protective sheath from the phagocytes, while in the human body, but when the organism reaches the stomach of the mosquito the flagellate body is developed and bursts through the enveloping corpuscle into the stomach; and then, as Manson believes, by means of their active movements the flagella pierce the wall of the stomach and thus reach a suitable soil for the organism to develop. Just where this evolutionary process takes place within the mosquito is not known, probably in the blood cells. The malarial organism may then by means of the exuviae of the insect be scattered over the country, in stagnant pools especially, and, as these infected pools are the breeding-places of mosquitoes, it can be easily seen how the larvæ can in turn become infected. Man may become infected by swallowing such polluted water containing the mosquito-bred plasmodium or by inhaling the plasmodia in dust from dried-up pools. He thinks that the plasmodium upon entering man may develop into a flagellated spore and so penetrate the mucous surfaces and reach the human blood cell.

That the plasmodia upon reaching the stomach of the mosquito do develop into flagellated bodies, has been proven by Surgeon-Major Ross, who undertook experiments in this line for Manson.

Ross placed a native suffering from malarial cachexia, and whose blood contained numerous crescents, under a mosquito net, introduced mosquitoes which he had reared from the egg, and collected the insects after they had filled themselves with the patient's blood. He then examined carefully the blood in these mosquitoes' stomachs with the following results: "(a) Practically all crescents become spheres a few

minutes after being taken into the mosquito's stomach. (b) From thirty to forty per cent. of the spheres die after one to two hours, the rest having given out flagella, been eaten by phagocytes, or having simply broken up."

I have given here only a brief outline of Manson's ingenious and, it must be acknowledged, probable theory regarding the life history of the malarial plasmodium outside the body, and the reader is referred to his most interesting paper for further particulars.

VII. Phagocytosis, and the Action of Quinine upon the Organisms.—The colorless blood corpuscles act in malaria, as in various other diseases, as safeguards to the health of the body by destroying the plasmodium. This process is called phagocytosis and takes place in the blood-vessels of the spleen and liver chiefly, but also in the general circulation. If malarial blood be examined it will often be noticed that the colorless corpuscles contain within their substance malarial germs in various stages of evolution, and also isolated clumps and granules of melanin or pigment. These phagocytes are most numerous in cases of pernicious malaria, in the vessels of the spleen and liver, but may also be often observed in the tertian and quartan varieties in blood drawn from the circulation. It is not my purpose here to enter into a detailed description of the process known as phagocytosis, but simply to define it as the engulfing and destruction of hurtful organisms by the colorless corpuscles or leucocytes.

The process, as it occurs in malaria, has been carefully studied by many observers recently.

Bignami³² describes the process in pernicious malaria, and states that he has seen the leucocytes engulf not only free plasmodia but also red corpuscles containing them. He thinks that it is largely due to the protecting action of the phagocytes that all cases of malaria do not become pernicious.

Bastianelli³³ found that in tertian, quartan, and æstivo-autumnal fevers phagocytosis occurred periodically, beginning at the time of the paroxysm, and states that the bodies occurring within the phagocytes are the following, in order of frequency: (a) pigment; (b) sporulating forms and spores; (c) red corpuscles containing sporulating forms or pigmented bodies; (d) red corpuscles containing parasites; (e) free bodies with central pigment clumps; (f) red corpuscles containing free amœboid bodies; (g) crescentic bodies. He does not believe that the phagocytosis is the chief factor in hindering the development of simple into pernicious malaria, but thinks that the important element in spontaneous recovery is the oscillation in the virulence of the plasmodium itself.

Mannaberg³⁰ makes the following statement upon this subject: "The spontaneous cure of malaria depends upon three factors, namely: the activity of the macrophages of the spleen and bone marrow; on the circumstance that many parasites remain sterile; finally, on the destructive action of the febrile paroxysm which is manifested by the fragmentation of numerous half-grown and full-grown parasites."

Manson³⁰ notes the fact of the very rare occurrence (which he himself has never witnessed) of intracorpuseular parasites within the leucocytes. He says: "I have seen a phagocyte move up to one of these crescent bodies (enclosed by the red corpuscle), touch it with its pseudopodia, first at one point, then at another, move round about it—feeling, as it were, if all were right within, suspicious apparently that things were not quite as they should be. But the corpuscular capsule seemed to deceive the phagocyte: for, after a time, the vigilant watchman would leave the masked parasite and move away, satisfied apparently, to some other part of the field. Should, however, the crescent proceed to development in the direction of becoming

a flagellated body, to attain which state it has to burst and leave the sheltering blood corpuscle, it is then, being no longer protected by its corpuscular sheathing, exceedingly liable to be set on and devoured by the phagocytes." He uses this liability of the flagellated organism to be devoured by phagocytes as an argument that it does not pre-exist in the blood as such, and that it is a distinctly extracorporeal phase of the plasmodium, the ensheathing red corpuscle protecting the crescentic body, from which the flagellate body develops, from the phagocytes while in the circulation.

Regarding the action of quinine upon the malarial organisms not much has been added recently to our knowledge. All observers agree that in the tertian and quartan fevers quinine markedly affects the parasite, while its influence is not so marked in the æstivo-autumnal fevers.

Romanowsky⁴¹ and Mannaberg,⁴⁰ in stained preparations, note the loss of staining properties in the chromatin substance in the nucleus and believe the change to be due to necrosis when quinine is administered, and also that the spores show no nucleoli.

Golgi⁴² found that in tertian and quartan fever quinine destroyed the young free spores most easily.

Quinine is best given just before a paroxysm, when, although it will not destroy or hinder segmentation, it will almost entirely destroy the young spores. Given at any time during a paroxysm in sufficient dosage (gr. v. to x.), quinine will delay or even prevent the next chill, but the parasites will not be wholly destroyed. In either case continued doses should be used for a week or so entirely to drive the disease from the system. Quinine, to secure the best results, should be in solution in the blood when segmentation takes place and the young spores are liberated, and accordingly should be given several hours before the chill.

VIII. Modes of Infection and Experimental Infection.—Though we know much of the evolution of the malarial parasite within the body, we know but very little of the manner in which it enters into the human organism. Various observers have differed in their theories regarding the mode of infection, but the following, as given by Thayer and Hewetson² are the most important: By the respiratory tract; by the digestive tract; by the skin (insect bites, etc.).

It is but reasonable to suppose that infection may occur through inspiring air containing the malarial germ. Anderson,⁴³ in a recent discussion before the Royal Medical and Chirurgical Society upon this subject, noted numerous examples in which malaria occurred in houses which were exposed to wind passing over newly turned earth. We must, however, admit that we have no positive proof of malaria caused by infected air.

The question of the rôle of the digestive tract in malarial infection has received much attention, and many authorities believe that infection is often introduced in this way. Anderson⁴³ (quoted above) believes that water, either inhaled as vapor or swallowed, is the vehicle of infection, and Manson⁴⁴ thinks that the ingestion of water may be productive of infection. On the other hand the negative evidence of infection through the digestive tract is very strong, many investigators having proven that water from ponds and marshes in malarial localities may be swallowed without danger. Curnow,⁴⁴ in support of the theory of infection through water, states that sailors often contract malaria after water has been taken in at ports where they have not landed, and that at the Panama canal ships which took in water became infected, while vessels that condensed their drinking-water escaped. He also quoted an observation where one hundred and twenty soldiers partook of water from a

malarious locality and one hundred and three of them had malaria, while sailors under similar conditions, but drinking water from another source, escaped without a case.

I have already given in some detail Manson's theory of infection through mosquitoes, and as inoculation of malaria through the skin has been proven easily possible, his theory is not without many staunch adherents.

No one as yet (save Coronado, who asserts that he has cultivated organisms from water) claims successfully to have cultivated the malarial plasmodium, but many have produced the disease artificially, and so proven the relation of the organism to it.

Marchiafava and Celli⁴⁵ in 1884 inoculated five patients with malarial blood and secured results in three.

Antolisei and Angelini,⁴⁶ having inoculated two patients with blood from a case of tertian malaria, found eleven days afterward that malaria was present in both cases and tertian organisms were found in the blood.

Sacharoff⁴⁷ obtained blood from leeches used in a case of pernicious malaria and inoculated himself in the arm with one centimetre of it. In twelve days chills and fever came on, there being two paroxysms on successive days, and the organisms were found in the blood.

Di Mattei⁴⁸ inoculated four patients with blood from a case of quartan fever, and in two of them, after incubation of seventeen and eleven days respectively, typical quartan ague developed with organisms. He also inoculated one case with organisms from æstivo-autumnal fever, which was followed by irregular fever after a period of fifteen days, and the characteristic organisms were found in the blood.

An interesting experiment, cited by Manson⁴⁹ as supporting his mosquito theory, was made by Surgeon-Major Ross. He administered to a perfectly healthy native a certain quantity of water in which a couple of malarial mosquitoes had died after depositing their eggs. The remains of the insects had been removed, but the eggs and grubs were swallowed. Eleven days afterward the man had fever, headache, etc., but no chill. This fever lasted three days. In the blood the ring form of the plasmodium was found. Ross states that there could be no doubt of the malarial nature of the disease.

The above are a very few of the more recent experiments showing the relation of the plasmodium to the disease and the fact that it can be inoculated.

IX. Identity of Malaria in Man and in the Lower Animals.—Hæmatozoa, as is well known, occur both in cold and warm blooded animals, and in many instances closely resemble the malarial parasite. Especially in birds is this so, and they are subject to a disease very much like malaria as it occurs in man. Grassi and Feletti⁵⁰ claim that the organisms found in the blood of birds suffering from malaria are the same as those found in man.

Dambewsky⁵¹ has devoted much study to the malarial blood of birds and distinguishes two varieties, one producing acute malaria and going through the same stages as the parasite in man, and the other causing a chronic malaria. In his latest work⁵² he affirms his belief that the malaria of birds and man is caused by identical organisms.

In closing this paper the author wishes to express his indebtedness to the splendid work of Thayer and Hewetson upon "The Malarial Fevers of Baltimore," and to acknowledge his free use of many data therein.

PRIMARY MUSCULAR DYSTROPHY IN TWO BROTHERS.¹

By THEODORE DILLER, M.D.,

PITTSBURG, PA.,

VISITING PHYSICIAN TO ST. FRANCES' HOSPITAL; PROFESSOR OF PHYSIOLOGY IN THE PITTSBURG DENTAL COLLEGE.

THE term muscular dystrophy is now generally employed to designate those forms of progressive muscular weakness, attended with atrophy or pseudo-hypertrophy, in which the seat of the disease is in the muscles themselves and not in the cord or nerve trunks. The dystrophies include pseudo-muscular hypertrophy, characterized by enlargement of muscles, on the one hand; and simple idiopathic muscular atrophy (Gowers), characterized by muscular atrophy, on the other hand. This latter form of muscular dystrophy is subdivided into two types, distinguished by the muscles chiefly involved in the atrophy, viz.: the juvenile form or Erb's type, characterized by atrophy of shoulder girdle, upper arms, and thighs; and the infantile or Landouzy-Déjerine type, characterized by involvement of the face. This last-named type is, as pointed out by Sachs,² nothing more than the Erb type

plus involvement of the facial muscles, which atrophy is usually first to appear.

It is now well established that pseudo-muscular hypertrophy is, like the two types of simple idiopathic muscular atrophy, due to disease in the muscle itself, and is not dependent upon a spinal lesion at all. There is in this disease, as in the atrophic forms of muscular dystrophy, a progressive muscular weakness, in spite of the hypertrophy which is due to fatty and connective-tissue deposits. "There is practically no other distinction between these various types of myopathies than the mere distribution of atrophy or hypertrophy."³

These primary muscular dystrophies are distinguished clinically from progressive muscular atrophy of spinal origin by their onset in childhood or youth; by the presence of the disease in more than one member of a family (heredity); by the absence of qualitative electrical changes and of fibrillary twitching; and by the fact that the atrophy does not begin in the small muscles of the hand.

While the three types of muscular dystrophy are closely associated and many atypical forms have been described, showing the gradation of one type into another or the presence of different types in several members of a family, yet they are, by the points just given, sharply distinguished from progressive spinal muscular atrophy. This is certainly true for the most part, but it is well to bear in mind that the neuron with its axis-cylinder process (the nerve) and the muscle constitute a trophic unit. Erb has, indeed, concluded that these dystrophies are tropho-neuroses, and may result from disturbances of trophic centres.

It is not surprising that this trophic unit should at times be involved in more than one of its component parts, and a symptom-complex result which should represent a blending of muscular dystrophy and progressive spinal muscular atrophy. As a matter of fact, Strümpell⁴ has reported just such a case, in which atrophy began in the hand muscles. The autopsy disclosed muscular, nerve, and spinal-cord lesions. He believed that the disease originated in the muscles and ascended the nerve trunks to the neurons in the cord.

The hereditary feature of the muscular dystrophies strongly points to their being due to developmental defects; and this heredity, as has been pointed out, is one of the chief clinical characteristics of the muscular dystrophies. But Hoffman⁵ has reported two brothers in two families (four children) affected with spinal atrophy. Autopsies on one child in each of these families revealed neuron, nerve, and muscle degeneration, most advanced in the cord and diminishing toward the periphery—thus forming the exact counterpart of Strümpell's case.

Just why one part rather than another of this trophic unit should be involved, we possess no means of knowing; and while the disease may, in the great majority of instances, confine itself to one part of the trophic unit, cases like those of Strümpell and Hoffman show that parts other than the one first attacked may be subsequently involved. So, while the clinical and pathologic features of the spinal atrophies and muscular dystrophies are, for the most part, quite distinct, they do occasionally merge into each other, as one might, from *a priori* reasoning, expect.

With these brief considerations, I wish to report the cases of two brothers affected with progressive muscular dystrophy. The parents are healthy and besides these two boys have one other child (a girl), who is a twin of the elder boy and who seems to be quite healthy.

⁵ "Brain," Winter, 1893.

CASE I. (Fig. 1).—Referred to me by Dr. McGrew, of Alleghany. L. S—, boy, aged thirteen years. There was no trouble at birth and he was quite healthy up to the age of three years. He learned to walk as

FIG. 1.—Erb's Type of Progressive Muscular Dystrophy.

soon as infants usually do. At three years he contracted measles and was in impaired health for several weeks afterward; but he ultimately recovered his usual health and strength. When he was about five years of age some muscular weakness began to be noticed, but its beginning was so insidious that the exact time is not certain. This muscular weakness has steadily progressed up to the present time. There was no pain or other sensory symptom at any time. At about the age of eight, the boy began to stumble, and from this time up to the age of twelve his legs frequently

gave way in walking, so that he often fell; and during this time, in rising from the floor, he would climb up his own body, supporting hands on thighs, in the manner described by Gowers.

By November, 1895, the weakness had increased so much that he was unable to stand, and about this time contractures of knees, thighs, and ankles were noticed, which have progressively increased up to the present.

Soon after the muscular weakness was noticed, the parents observed that the upper arms and thighs were disproportionately thin; they state there has been a progressive wasting in these parts ever since it was first noted. There has never been fibrillary twitching at any time. Mentally the boy is quite bright. It was not thought that the calves were enlarged at any time.

Examination, May 20, 1896: The boy is of quite large frame for his age. There are no mental symptoms. The lower jaw protrudes, and the front teeth do not come in contact, because of the fact that the molars strike first. He is quite helpless, unable to stand; but he can make some progress about the room by the use of his hands on the floor. There are marked contractures of legs and thighs; marked wasting of thighs and upper arms. The calves seem to be about normal in size. There is some atrophy of the forearms, but much less than of the upper arms. Pronation is much stronger than supination. There is marked atrophy of shoulder and hip girdles. The deltoids stand out prominently, being either actually or apparently much hypertrophied. Knee jerks absent. No fibrillary twitching.

MEASUREMENTS.

	Right.	Left.
Thigh	11½ in.	11½ in.
Calf	10½ "	10½ "
Upper arm	6 "	6¼ "

In calling upon me to examine his brother, the mother at first stated that her other son (Case II.) was healthy. Only upon examination and direct inquiry was I enabled to obtain the following history and examination. Then the mother stated that her younger

son did not seem to be so strong as he ought to be, and that he was pretty clumsy at times; that he always held to the railing in going up-stairs. She said that several of the neighbors, observing these points, had predicted that he would be like his brother—helpless in time. But she had not laid these fears to heart, for she had noted large calf muscles in the boy.

CASE II. (Fig. 2).—Boy, aged seven; bright, intelligent looking. For about two years past it has been noted that he does not seem to have as much strength as other boys of his age; that he is somewhat clumsy in his movements. Other boys of his age outstrip him easily in running and in various games. He holds on to various objects to assist himself, e.g., to the rail in going up-stairs.

Examination reveals weakness in various movements. For example, when told to run up-stairs as rapidly as possible, he is able to go up only in a slow, labored manner. In walking he has a slow, waddling gait. There is considerable weakness in arms and forearms; more in the latter than the former. Supination is much weaker than pronation.

Inspection reveals atrophy of upper arms and shoulder girdle. The deltoids are, in contrast with other arm and shoulder muscles, enlarged. (This is not nearly so marked as in Case I., and is not well shown in the photograph.) There is moderate atrophy of the thighs and of the pelvic girdle, while the calves are quite distinctly hypertrophied. There is marked lordosis. The knee jerks are absent. There are no fibrillary twitching and no sensory symptoms. The forearms and arms on both sides each measure six and one-half inches; each thigh, twelve and one-half inches; each leg, ten and one-half inches. All measurements were taken at widest circumference and at corresponding points.

Remarks.—The diagnosis of progressive muscular dystrophy in both these cases can, I think, scarcely be questioned. The slow onset in childhood and the progressive features; the atrophy affecting chiefly the shoulder girdle, upper arms, and thighs; the presence of the disease in two brothers with non-involvement of the face in both cases and the absence of fibrillary twitchings taken together make this diagnosis certain. The contractures in Case I. exclude the Landouzy-Déjerine type.

Case I., with atrophy of upper arms, shoulder girdle, and thighs, and with deltoid hypertrophy, makes it conform quite closely to Erb's type.

Case II., with the very considerable hypertrophy of the calves, suggests pseudo-muscular hypertrophy. The lordosis and waddling gait present are also features belonging to this form of dystrophy. But the marked atrophy of upper arms and shoulder girdle, with apparent moderate hypertrophy of deltoids and

FIG. 2 (Brother to Fig. 1).—Progressive Muscular Dystrophy, representing a mixed type—one between muscular pseudo-hypertrophy and Erb's type.

slight atrophy of thighs, are features distinguishing Erb's type.

The enlargement of the infraspinati, according to Gowers¹ and Jacobi² a distinguishing feature of pseudo-muscular hypertrophy, is absent.

On the whole, I am inclined to regard this second

FIG. 3.—A Case of Progressive Spinal Muscular Atrophy, showing wasting of hands, forearms, upper arms, and shoulders; more marked in right arm.

case as one representing an atypical or mixed type of muscular dystrophy—one possessing features belonging to Erb's type and to muscular pseudo-hypertrophy.

These two cases together afford another illustration of what has been insisted upon by Erb, Gowers, Sachs, Jacobi, Dana, and other recent writers upon this sub-

FIG. 4.—Posterior View of Patient represented in Fig. 3, showing very marked atrophy of scapular muscles and of deltoids.

may be seen in a single individual. They afford support, too, to the view that the different types of muscular dystrophy are only forms of the same disease.

There can be little doubt that the muscular dystrophies attack boys very much more frequently than girls. The exemption of only one of the three children of the family in which my cases occurred, and that child a girl, a twin of the elder boy, affords a curious and interesting support (so far as it goes) to this rule.

As a sort of appendix to this paper, I wish to call attention to the photographs (Figs. 3 and 4) of a case of progressive spinal muscular atrophy, an account of which was recently published.¹ Although the case was atypical (having begun suddenly), it will serve well to bring into relief certain features distinguishing this form of atrophy from the progressive muscular dystrophies.

The patient, a man aged forty-eight years, suffered palsy of the right arm three years ago, soon followed by atrophy affecting a group of radial muscles, those of the thenar eminence and of the deltoid and biceps and scapular muscles. Some months later, loss of power and atrophy in corresponding muscles of the left arm set in and progressed slowly. The muscles of the neck have recently become involved. Although for a time the progress of the disease seemed to have been checked by treatment (strychnine), the loss of power and atrophy in the hands, arms, shoulders, and neck are now progressing. There is no involvement of the lower limbs.

WESTINGHOUSE BUILDING.

A BRIEF NOTE AND REMARKS UPON A CASE OF EMPYEMA OF THE VERMIFORM APPENDIX.

By GEORGE R. FOWLER, M.D.,

BROOKLYN, N. Y.,

PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC, SURGEON TO THE METHODIST EPISCOPAL HOSPITAL AND TO THE BROOKLYN HOSPITAL.

THERE is scarcely room for doubt in the minds of those who have been brought much in contact with the disease appendicitis that surgical measures, and these alone, are competent to deal effectually with the disease when the latter is progressive in character. In mild cases of catarrhal appendix or endo-appendicitis, with but slight interference with the blood supply, and in the absence of virulent infection, the inflammatory action may not extend beyond simple thickening of the mucosa and submucosa, or at the most involve but slightly destructive alterations in the organ; hence these cases should quickly clear up under saline purgation and rest in the recumbent position. One condition is occasionally found, however, as a result of these so-called "catarrhal" attacks (which, by the way, are not catarrhal in the true sense, since they almost invariably involve at least the submucosa), and that is the occurrence of narrowing or even complete obliteration of the lumen of the appendix at one or more points. If the inflammatory action is of a sufficiently high grade and extensive enough to involve the entire length of the organ alike, the subsequent dangers to the patient are not nearly so great, since under these circumstances obliteration of the entire lumen may take place, as when this is limited to one or more points, particularly at its base or point of attachment to the cæcum, the site of the appendiculo-cæcal orifice. Occlusion at this point constitutes a source of danger not heretofore sufficiently dwelt upon by writers upon the subject, and which is illustrated by the following case:

¹ "Pseudo-Hypertrophic Muscular Paralysis," London, 1879. Also, "Diseases of the Nervous System," vol. i., p. 519.

² "Nervous Diseases by American Authors," p. 865.

¹ New York Medical Journal, June 6, 1896.

J. E. S.—, Jr., aged twenty-one years, was taken suddenly ill at about 1:30 A.M. while on a visit to Shelter Island. His hostess administered a dose of so-called cholera mixture which contained a liberal quantity of opium. Dr. W. E. Butler, of this city, saw him a few hours later and found him quite comfortable, with a practically normal pulse rate and temperature. The entire abdominal wall was relaxed and absolutely without tenderness upon pressure, save at a point which could be covered with the end of the finger, somewhat below the centre of the right iliac region.

I saw the patient at 7 P.M. of the same day, and found him entirely free from pain; the local tenderness had also decreased, both of which conditions were probably due to the opium taken. The temperature by the rectum was 100.6° F. and pulse 80. He expressed a general feeling of well-being, and was cheerful and unconcerned about himself. The following points were related to me by Dr. Butler as a part of his previous history: Two years before he had suffered from an attack commencing in the same manner, and one year later from another, for both of which he had been treated by a physician for "cold in the bowels." The last attack necessitated a week in bed.

In view of this portion of his history I decided to have him removed to the city at once for operation, in spite of the fact that the then present attack appeared to be already upon the wane. Accordingly he was carefully transferred to an easy mattress and cot and transported by special train to Brooklyn and taken in an invalid coach to the Methodist Episcopal Hospital. Preparations were made for immediate operation, and at 12:30, just twenty-three hours after the first acute symptoms, the abdomen was opened and the appendix removed. The latter lay in the S. E. position (downward and inward), crossing the brim of the pelvis and lying upon the peritoneal covering of the iliac vessels. No adhesions were at first apparent. The organ was uniformly enlarged to about one and a half times its normal size, but in other respects presented a normal appearance. The walls of the organ fluctuated upon palpation, and the enlargement was evidently due to a distention of the organ by fluid, and extended from its base to the distal extremity.

With proper precautions to protect the peritoneal cavity from infection, by thoroughly walling off with gauze compresses, the cæcum with its attached appendix was brought into the wound. The meso-appendix was ligated *en masse* close to the base of the appendix, the latter separated, a purse-string suture passed upon the cæcal wall about half an inch from the base of the organ, and the latter amputated, after the precaution of encircling it near its proximal extremity with a ligature to prevent its contents from escaping had been taken. As the section was made there welled out from the short stump a purulent fluid. An attempt was now made to pass a small probe into the cavity of the cæcum, when it was found that the orifice leading to the latter was wanting; the communication was entirely shut off by a stricture, the result of one of the previous attacks, probably the last.

Subsequent examination of the organ revealed the following: The appendix was unusually long. Upon opening it lengthwise it was found to be filled with purulent fluid, the result of hypersecretion from its living mucous membrane; this was undergoing suppurative changes. Its mucous membrane was thickened and at the extreme tip the latter was ulcerated for an area slightly larger than a pin's head. At this point the submucosa, as well as the wall of the organ, had taken part in the ulcerative action, only the serosa remaining intact. Upon the serous covering opposite this point of ulceration the remains of an adhesion were found, which had evidently given way with the

slight traction exercised in bringing the organ into the wound.

The significance of the location in which the appendix was found, as well as that of the infection of its wall and serosa at the tip, became apparent later on. The case pursued an uneventful after-course until the eighth day, when a left femoral phlebitis made its appearance, which in all probability commenced as an infectious iliac paraphlebitis and finally resulted in a phlebitis, the infection having its origin in the tip of the appendix at the point where the ulcerative action was in progress. This infectious process extended to the right iliac vein finally, as evinced by a subsequent right femoral phlebitis. These complications delayed the patient's convalescence to at least double the length of time required for recovery from an average uncomplicated operative case of appendicitis.

The case related is one in which all the symptoms of a mild endo-appendicitis, with its promising favorable termination under nature's efforts, disclosed upon operation an astonishingly dangerous condition of affairs. The lumen was shut off from the cavity of the cæcum by the presence of a stricture, the result of a previous attack. The infectious agents thus imprisoned had remained in an innocuous quietude for a time, when finally an irritation emanating from these micro-organisms, and with the predisposition furnished by some casual interference with the blood supply to the organ, such as probably results from changes in position in the organ when freely movable in the peritoneal cavity—an attack of so-called "catarrhal" inflammation, followed by increase of secretion—furnished the pabulum for the proliferation of the micro-organisms present. This proliferation initiated suppurative changes in the exudate, and pressure and infection combined to set up the ulcerative changes in the tip of the organ, where the vital resistance is reduced to the minimum by the absence of proper blood supply in an organ whose vestigial character and evident final fate through evolutionary changes stamp it as the most dangerous of that class of which it and the tonsils and the wisdom teeth are the types.

The fact that the appendix lay across the brim of the pelvis and rested with its point, at which perforation threatened, lying upon the left iliac vein furnishes the explanation of the subsequent occurrence of the femoral phlebitis. The infection extended from the serosa of the organ to the posterior layer of the peritoneum and thence to the connective-tissue layer surrounding the iliac vein. The infectious paraphlebitis and subsequent phlebitis thus set up extended first in the direction of the left, and finally to the right, femoral vein.

The case scarcely requires further comment. It is published with the hope of attracting attention to a class of cases not frequently alluded to, and to show the fallacy of relying upon the train of fortuitous circumstances which are believed to hedge in these so-called "catarrhal" cases and lead to a favorable termination in apparently mild attacks of appendicitis, particularly when the history of the case includes a statement of previous attacks of the disease. The links in the pathological chain are so unmistakably and uninterruptedly connected that it would certainly seem as if "he who runs may read."

Warts.—Dr. Laubenburg has discovered that if a spot is touched with fuming nitric acid, and then immediately afterward with pure liquid carbolic acid, there is a strong chemical action, the effects of which penetrate deep into the tissues, and completely and permanently cure warts, condyloma, angioma, etc.—*Centralblatt für Chirurgie*, August 8th.

SOME THOUGHTS ON DISORDERED MEMORY AND KINDRED CONDITIONS.

BY C. A. DREW, M.D.,

ASSISTANT PHYSICIAN, ASYLUM FOR INSANE, MEDFIELD, MASS.

It is held by some physiologists whom we honor that all healthy ganglionic nerve cells have memory; *i. e.*, are subject to permanent impressions by every temporarily acting stimulus. In this sense, memory is conceived of as possible independent of consciousness; the idea being that memory consists of the impressions registered on the ganglionic cells of the cerebral cortex, irrespective of whether those impressions are recognized and correctly interpreted by the individual consciousness or not. If we conceive of memory as the recognition by consciousness of impressions made on the ganglionic cells by external stimuli, our conception will harmonize with the general idea of that intellectual function commonly recognized as memory; not complete nor entitled to the name, divorced from consciousness.

Whether we conceive of memory as commonly recognized, or in a modified or broader sense, we naturally associate a good memory with healthy well-nourished nerve cell of the cerebral cortex. It is believed that the assumption of such a relation, as a rule, will be supported by the observation of every medico-psychological student. As a rule, I say, because there are some notable exceptions that add much to the interest as well as to the difficulty of solving the problem and fixing the relationship between ganglionic integrity, and consciousness.

It is interesting to note that certain specialized memories are represented by different cerebral convolutions. We know that a more or less complete loss of memory for articulation, motor aphasia, almost surely follows any considerable lesion of the posterior part of the third frontal convolution; and that a condition known as "word deafness," the subject of which can understand written but not spoken words,

while expressing himself freely by both written and oral speech, commonly follows a circumscribed lesion of the superior left temporal convolution. Again, it has been demonstrated that a circumscribed lesion of the superior occipital and angular gyri is followed by a condition known as "word blindness," in which the individual cannot recall the name of a printed or written word nor associate it with its object, although he can express himself correctly and has no trouble in understanding oral speech. "In right-handed people all the memory centres are in the left cerebral hemisphere; in left-handed people they are in the right hemisphere."

We know that these functional disturbances from pathological conditions are compatible with so much mental integrity that the subject may not be considered insane; but we also consider complete loss of any specialized memory as strongly indicating circumscribed organic brain disease.

A partial failure of any form of memory may be reasonably considered physiological, and, perhaps, explained on the hypothesis that excessive action of the ganglionic cells of one convolution would naturally cause anamia and decreased functional activity of other convolutions, representing different faculties of mind. He who can turn quickly from intense exercise of concentration of attention and the reasoning faculty, supposed to depend on functional activity of the anterior portions of the frontal convolutions of the brain, to recall without hesitation the name of an individual not frequently met, or a technical term foreign to the subject on which the mind has been dwelling, may congratulate himself that the vasomotor

mechanism of his brain is nicely adjusted and quickly responsive indeed.

It is highly probable that the energizing functions of certain cortical areas are practically quiescent while faculties represented by a distant brain area are especially active; and this serves at once as a rational guide for mental therapeutics and indicates the danger to mental health from the mind dwelling unremittingly on one thought or closely related thoughts.

Besides the disorders of memory belonging to well-recognized forms of mental derangement, those rare anomalies of mind function known as "loss of personal identity," "double personality," and "double consciousness" are especially interesting. Frequently the news columns of our dailies have accounts of some man, perhaps not manifestly insane nor delirious from fever or toxic agents of any kind, who cannot, or claims he cannot, give any clew to who he is or where he came from. It is highly probable that some of these persons are dissemblers, individuals hungry for notoriety; and yet it is a fact, well established, that through some obscure pathology not well understood an individual's mind may become as a blank from which all the impressions have been erased. It is believed that the impressions which have been potent in the evolution of that man's mentality are still indelibly impressed on that brain cortex, to last while that brain retains its structural integrity; yet the connecting link binding past to present has in some way been broken. "The light of consciousness" is no longer able to illuminate those myriad images hidden among the tortuous cerebral sulci.

Among the cases of lost personal identity recorded by members of our own profession, H. C. Wood¹ tells of a man who was brought to the hospital suffering from sunstroke, from which he recovered promptly and was entirely rational, but for several days could not tell his name nor give the slightest clew to his own identity or where he came from. "Double consciousness" is a periodic failure of memory, sometimes associated with a coincident change of disposition. A typical case is quoted by Dr. Wood from Dr. Mitchell, of New York, from which I cannot do better than to quote. A highly educated young woman fell, without warning, into a deep sleep lasting several hours. On waking she had lost all former knowledge. "It was necessary for her to relearn everything—the alphabet, to read, write, and reckon. Some months later she again fell into a deep sleep and woke in the normal state. Then she remembered all that she had learned in her original condition but remembered nothing that had occurred in her abnormal state. For many years after this she alternated between the first and second condition, in each state knowing only what she had learned in previous periods of the same state. When she made acquaintances she recognized them only when she was in the state in which she had been at the time of their first meeting. Her handwriting, which was good in the first condition, was very bad in the second state."

Each case of "double consciousness" will present some atypical features and individual peculiarity. It is common for a deep sleep and intense headache to usher in the abnormal state; although the duration of the sleep may not be more than a few minutes. It is a rule for all the experience of the abnormal period to be utterly forgotten when the subject passes again into the natural state. There is great variation in the comparative memory and activity of the intellectual faculties of different individuals while in the unnatural state; some, like Dr. Mitchell's subject, are conscious only of impressions made during former similar abnormal conditions, while others remember, with an exalted acuteness, not only the experiences of former

¹ "Nervous Diseases," C. L. Dana, p. 320.¹ "Nervous Diseases," H. C. Wood, p. 372.

like attacks, but all the events of the normal life as well.

Along with a changed consciousness, comes a changed personality in many cases. One naturally of a melancholy temperament, passing into a mental world of new memories, may take on a vivacious, light-hearted, thoughtless disposition. The moral qualities may also be equally changed for the worse, or possibly, for the better.

When we say that "double consciousness" is a periodic failure of memory, we state only part of the truth; because, while memory for the past is obliterated, new impressions are "registered and reproduced in sufficient number and intensity to serve as a guide to rational action," as is evidenced by the fact that eminent members of our profession have not classed individuals manifesting pure double consciousness as insane.

While pure cases of well-authenticated double consciousness are rare, every large hospital for the insane will furnish incomplete mixed cases.

The conditions known as "double personality," in which the subject believes himself to be two distinct individuals, to have "a double," which may follow him about constantly talking to him, is so identified with delusional insanity that we may safely class these subjects as having passed the border land of sanity into the domain of mental aberration.

We know the border line between sanity and insanity is very indefinite and shadowy, and that there are many psychological phenomena which, so far, have puzzled progressive experimental physiologists and pathological microscopists.

When tottering reason and failing memory come to us in a cracked and weakened vessel; and, after a time the pathologist reports a shrunken, waterlogged brain, gummatous tumors, or congested gray substance with milky arachnoid; or obliterated lumina of important cerebral arteries; or ganglionic cells with softened walls minus processes and nuclei, then we feel a satisfied congratulatory thrill; our theories are so far vindicated. The mental condition was consistent with a demonstrated cause. The organ of mind was diseased—corresponding dementia was natural and inevitable.

Mental confusion with emotional depressions, and memory almost *nil*, may come to us in a body weak from inanition. We naturally expect its brain cells to be also starved. The mental attitude precludes a fair quantity of nourishment being taken. A heavily coated tongue, foul breath, and parched lips tell of wanting normal secretion, with probable toxic products, in the place of needed peptones in the digestive tract. A saline purge, perhaps an irrigation of that mucus-coated stomach, a pint of beaten milk and eggs twice or thrice daily through a stomach-tube, and in a few weeks apparently almost a miracle is wrought. Mind and memory come again when toxic products are eliminated and nutriment is furnished those starving cells of the central nervous system. We congratulate ourselves again and mentally say, brain is the organ of mind; see that metabolic debris does not obstruct and poison the life current from which those brain cells drink constantly, supply the needed pabulum, and mind with memory will not desert the intellectual throne. True, we acknowledge that every mechanism has its limitations, and we realize how frail some nervous mechanisms are. We also insist that for long service no one part of the mental machinery shall be in constant use.

We can understand why all organic diseases of the brain should cause dementia with loss of memory. We explain the almost entire loss of memory for recent events with good memory for the experiences of early life, by saying that the softened ganglionic cells

have lost their power to register impressions, while the power to reproduce impressions made when the brain was at its best is still retained.

It is not uncommon for one with acute mania or confusional insanity to wake from a sleep entirely rational, to ask where he is, how long he has been in the hospital, etc.; he may remember the events of his delirious period as one remembers a bad dream, or all the impressions of his abnormal period may be lost to rational consciousness. After remaining rational a few hours, he may pass again into a maniacal state, to be dominated by the same irrational ideas, begotten of his morbid fancy. Indeed, according to the writer's observation, one passing suddenly from the utter incoherence of acute insanity to perfect rationality is very apt to relapse; while it is a good omen for the mental cloud to lift gradually.

These alternating rational and irrational periods of the insane seem to be closely analogous to "double consciousness." It is another witness to the shadowy line of demarcation between the sane man with a neuropathic constitution and the man who is mildly but legally insane.

Occasionally we are confronted by psychological phenomena seeming to throw doubt on the entire dependence of memory on healthy well-nourished cells of the cerebral cortex. There is a popular belief that before the mind of a drowning man, whose nerve centres must be suffering for want of oxygen, at least, the minutest events of his life pass in rapid panorama. However this may be, there is authentic evidence that, under certain conditions, memory is uncommonly active when the body is weakened by disease, and there are individual cases of insanity with memory exalted above the normal.

When the higher faculties of judgment and volition are paralyzed by the hypnotic state, the individual frequently manifests a phenomenal memory, reciting poems without an error, speaking in a language entirely lost to memory in the subject's normal state, etc.

These exceptional and apparently paradoxical cases have been made the most of to support many kinds of occult psychological theories. One of the recent and most interesting attempts at solution of these extraordinary manifestations of mind is by T. J. Hudson under the title of "The Law of Psychic Phenomena." It being, in the language of the sub-title, "a working hypothesis for the systematic study of hypnotism, spiritism, mental therapeutics, etc."

The basal proposition of this unique and well-written book is that man's mind is dual, in function at least, and may be considered, for purposes of study, as consisting of two distinct entities, which for convenience and in harmony with carefully observed phenomena, he designates the subjective and objective minds. The former is identical with the soul of man, it is constantly amenable to control by suggestion, and is incapable of inductive reasoning. But when dominating the individual, as it does in the hypnotic state, trance, and certain conditions of insanity, it accepts as verity any suggestion from without or any disordered sensation from within, and may reason deductively, from a false premise, with unerring accuracy.

In the language of the author: "The objective mind takes cognizance of the objective world. Its media of observation are the five physical senses. It is the outgrowth of man's physical necessities. It is his guide in the struggle with his material environments. Its highest function is that of reasoning.

The subjective mind takes cognizance of its environments by means independent of the physical senses. It perceives by intuition. It is the seat of the emotions and the storehouse of memory. It performs its highest functions when the objective senses are in

abeyance. In a word, it is that intelligence which makes itself manifest in a hypnotic subject when in a state of somnambulism."

Belonging to the subjective and objective minds are subjective and objective memories, between which there is a wide and distinctive difference. The objective memory, being a function of the brain, "has an absolute localization in the cerebral cortex." And the different varieties of memory, such as visual memory, auditory memory, memory for speech, etc., can be destroyed by localized disease or by surgical operation.

"Subjective memory, on the other hand, appears to be an inherent power and free from anatomical relations. At least, it does not depend upon the healthy condition of the brain for its manifestation."

It is foreign to my purpose to defend Mr. Hudson's position, nor do I wish to attack it. One cannot help feeling that there is much doubt of the reliability of many of the alleged facts on which his clever hypothesis is based. But I deem his theories sufficiently interesting to be considered in relation to phenomena which many will recognize, and few, if any, attempt to explain.

The tendency of modern thought, particularly in our profession, is toward a strictly materialistic explanation of all the phenomena of mind.

In an excellent paper on "The Treatment of Insanity,"¹ Dr. Hornibrook voices the belief of a vast majority of the most progressive in our profession, when he says: "I informed him that the immaterial mind was 'beyond my ken,' and that, with my limited capacity, it was impossible to conceive of an insane mind in a perfectly healthy and properly developed physical organization."

It is certainly true that the history of mental disease is a history of brain disease or nervous derangement. We note the coincident evolution of mind with cerebral development. We observe that the mental states of well-being, depression, joy, or misery are dependent on or are modified by the condition of the different organisms, and that many of the intense pleasures of the highly gifted intellects come through the agency of the material organs of special sense.

It is possible to err by giving attention only to one class of evidence; and we are all the more likely to throw out competent evidence tending to prove an immaterial or spiritual element in the human intellect because it is so mixed with the chaff of duplicity and pretension offered by so-called spiritualistic mediums and the like.

That the brain is the organ of the mind or soul is not questioned. That the mind cannot manifest any of its higher capacities under normal conditions, except through the material nervous organization, is not doubted. It is observed, however, that the plausible explanations of mentalization on the hypothesis of ganglionic reaction to external and auto-stimulation assumes consciousness as an endowment, "latent in the new-born infant." And to assume the highest and most distinctive attribute of mind, "without which," in the language of Dr. Cowles,² "there can be no mental action," seems like begging the whole question. And there are many thoughtful observers of intellectual phenomena who will not assent to the proposition, growing logically out of the position taken by some psychologists, that the mind or soul of man is but a convenient term for the product of physical and chemical action; and that all the manifestations of mind—hopes and fears, love and aspirations—are products of the brain alone, as bile is the product of the liver.

"Attraction plus repulsion of molecules," says Maudsley, "constitutes our conception of matter; and, in observation of its mode of energy, attraction is rec-

ognized in gravitation, cohesion, magnetism, affinity, love; while repulsion is found in centrifugal force, heat, electricity, antipathy, and hate."

This gifted writer sees no contrast between vital action and the kind of action exhibited by inorganic nature.

From a different standpoint Noah Porter writes: "The excitement of a nervous organism does not and never can be made to signify the same thing as to know, to feel, or to will. Its excitement a second time can never be the equivalent of to remember. The partial excitement of many nerves or nerve products, limiting or helping one another, can never signify to reason." . . . These are psychic activities, and no amount of research will ever elucidate anything further than that certain corporal organs take a certain parallel action when the soul externalizes its own activities."³

To the question, What is mind? science gives a very imperfect answer; and this is true, whether the explanation follows the teaching of the ancient Aristotelian philosophy—includes the more modern metaphysical idea of immaterial "primitive forces," modified and organized to form the faculties of mind, coincident with the growth and evolution of the nervous organism, or accepts the propositions of the strictly materialistic psychologist, who holds that, by the expenditure of a sufficient amount of energy, inorganic may be raised to organic, and the lowest organic to the highest organic matter.⁴

It is natural for physicians to give most weight to the conclusions of those who reason from a purely physiological standpoint. Indeed, the very terms used by those who begin the study of mind by an analytical examination of their own consciousness seem to most of us but the introduction to a "meaningless metaphysical haze." This may, however, be due largely to the fact that our education has been along entirely different lines of thought, and it is to be regretted that there are physicians, having a very limited knowledge of the writings of Spencer, Bain, and Maudsley, who use these names as a justification for shallow and offensive ridicule of those who believe in the theological idea of an immortal soul and a future life beyond death, etc.; and it would not lessen the prestige of our profession if ridicule of a religious faith was delegated to those alone who have weighed all the evidence for and against such a faith.

Inasmuch as Maudsley is an authority often quoted by those who believe all the phenomena of mind are adequately explained on the hypothesis of nervous ganglia reacting to external stimuli, and that the idea of an immaterial soul is a ghost of superstition—laid beyond peradventure—the following, from the pen of Maudsley, is quoted:

"Without speculating at all concerning the nature of mind—which, let me distinctly declare at the outset, is a question science cannot touch, and I do not dream of attempting to touch—I do not shrink from saying that we shall make no progress toward a mental science if we begin by depreciating the body. . . . The portion of the universe with which man is brought into relation by his existing sentiency is but a fragment; and to measure the possibilities of the infinite unknown by what he knows is very much as if an oyster, judging all nature by the experience gained within his shell, should deny the existence on earth of a human being, because its intelligence cannot conceive his nature or recognize his works. Encompassing us and transcending our ken is a universe of energies. How, then, can man, the feeble atom of an hour, pre-

sume to affirm whose glory the heavens declare, whose handiwork the firmament showeth! Certainly true science does not so dogmatize."

POSTURE IN LABOR.¹

By THOMAS W. HARVEY, M.D.,

ORANGE, N. J.

IN every field of muscular effort we find that there has been a careful and scientific study of the best and most efficient methods for making the effort tell for the greatest results. We seek for a maximum of effect from a minimum of effort. The oarsman, the soldier, the cyclist, the boxer, the athlete generally, the workman lifting or carrying burdens, have all been studied and their muscular movements analyzed. They have been taught how to stand, how to hold the body, when to put forth the greatest exertion so as to apply the muscles in the most efficient way.

When we come to the most necessary muscular effort of all, the one for which women were created, without which all things human end—the labor of parturition—we do not find that any effort is made to train the young woman how to use her natural forces; and while in savage and semi-civilized nations continuation of the species is thought of such importance that the young girls are taught in their childish dances the proper feminine posturing and movements that make sexual congress most successful, there has been no training for the important function of motherhood—the idea being that instinct should direct the method of putting forth her strength most efficiently. But many young women seek a posture that will relieve them of their pain, and do not seek, but rather avoid, a posture that will allow them to use their voluntary muscles most efficiently. The whole subject of childbirth is still obscured by the cloud of traditions and old wives' tales, and the darkness of superstition of the "wise woman," who has either forgotten her own experience or who dropped her babies like kittens, without special effort. Under her advice, a woman is prevented from assuming such postures as nature indicates, but must have her baby in the traditional posture of her particular *gens*.

If we review the history of obstetrics, we find that here, as in other matters, fashion reigns, and a woman is put in one or another posture to suit the fad. To any one who has attempted to introduce the forceps with the woman lying on her side, it will ever be a mystery why our English brethren continue that position for operative work. In all other gynecological work the English operator recognizes the value of the dorsal position, but when the forceps are to be applied over the patient goes on her side—and only the conservatism of fashion can account for it.

If we study the postures assumed by the women of different lands, it is surprising to learn how many and various, and often how artificial and complicated, are the observances and postures that they assume. In civilized nations, where medicine is more scientific, tradition may not govern, but fashion does; among the semicivilized, where the midwife reigns supreme, we have the inflexible laws of her craft, founded only on ignorance and superstition. If we go among the wild women, we find still that the same influences are active.

It seems that the most natural position for the mother during the expulsion stage would be squatting on the feet, with a firm hold on a post or tree in front of her. This is the attitude assumed by the women of many of our Indian tribes. Many of us have found the rude peasant woman of continental Europe in the same position.

Among the Africans and also among American tribes this is often modified to a kneeling position; but if we put a woman in a semi-recumbent position, with her knees flexed, the feet firmly implanted on the bed against a box or the foot of the bed, and something that she can take hold of with her hands to steady the body, we place her in a position to use her muscular powers to the utmost degree, for the one purpose of forcing out the child.

This position was prevalent in the days of the obstetric chair, and is found modified in many ways among different people. The Japanese woman is confined reclining on a wicker framework covered with matting. The French Canadian turns a chair back down, and on this inclined plane lays a mattress, on which she reclines. The South American is confined in her hammock. Many women of many lands work the husband into their service, and use his lap for a couch. Often another woman assumes this position; and again, with arms encircling her abdomen, the hands pressing on the fundus, an auxiliary force of much effect is brought to the assistance of the parturient.¹

The posture of general flexion is the most effective. You will often see a woman straining in her labor—her legs extended, her head thrown back, and the body arched forward. If you make an examination during a pain, you will find very little descent of the child. This is a trick that the woman has learned during the first stage of labor, to keep the child from pressing too hard upon the undilated cervix, and during that stage is of value and assistance to her; but if the time has arrived for the descent of the child, then such posture is harmful and delays the labor. And if you will have her change her position to one of general flexion, chin on the chest, back bent, legs and thighs flexed, an examination during a pain will show a descent of the head.

This is to be borne in mind when the head reaches the perineum in a primipara. If there is danger of rupture of that part of the canal from the violence of the labor, the woman may be turned over to her side with benefit, with the effect of prolonging her labor and giving the parts a chance to dilate.

This last suggestion brings us to a part of our subject which will bear careful study and which presents many unsolved problems, viz., the effects of posture upon the mechanism of labor.

The factors of our problem are the pelvic inclined planes and the leverage that may be brought to bear upon the foetal head through the long axis of the foetal ovoid.

If you have a certain inclination of the long axis of the foetal ovoid to the plane of the brim, you certainly can change the relation of the foetal head to the pelvis by changing such inclination, *i.e.*, by rolling the woman over. And you can effect such a change up to the time when the head becomes tightly fitted to the pelvic planes, and when, by the escape of the waters and the moulding that takes place as labor progresses, the influence of posture is diminished. Then it is easier to bend the foetus on itself than it is to turn the head. It is, therefore, in the early stages that we can affect the mechanism of labor.

The knee-chest position, in the early treatment of prolapse of the cord, is classical.

There is a class of cases in which labor is tedious, without there being any very apparent reason why it should be delayed. In these we shall find the following condition of affairs: A multipara is having weak, inefficient, and infrequent pains; the os is well dilated, but not retracted; the membranes may be intact or not, but the head remains at the brim. Examination shows deflexion of the long axis of the foetal

¹ Paper read before the Orange Mountain Medical Society.

¹ Engelmann: "Labor among Primitive Peoples."

ovoid, very much exaggerated, either laterally or in front. Now, if the woman be placed on her back in a semi-recumbent position, the uterus straightened up, and pressure with the hands made upon the fundus, assisting the pain, the child will be found to descend very rapidly.

In occiput-anterior labors, it will often be found that a change of position of the mother, thus changing the inclination of the fetal axis to the pelvic planes, will facilitate labor. This is a wrinkle that it is well to remember in cases of labor with delayed first stage, when we often find the cervix driven down before the advancing fetal head, which condition is one of danger, because of the thinning of the uterus wall just above the internal os. The body retracts, the cervix is held down by the head, and this point in the uterus wall becomes thin and frail.

When we find the os in this condition, labor may be facilitated by observing which lip is being pushed before the head and turning the mother accordingly. If she is on her back and the anterior lip is the one in trouble—a very common condition, by the way—she should be turned on that side which frees the lip most completely. If it is a lateral lip and she is on her side, a turning on to the back or other side will often free the lip.

When we try to apply the effects of change of posture in occiput-posterior cases, we are confronted with a class of cases many of which I have always considered should be treated by manual interference as early as possible—those cases in which the os is not well dilated and the cervix is not retracted. Associated with this there is very little descent of the child's head. This condition may be recognized very early, and in such cases the introduction of the hand, with or without ether, will enable one often to change the position of the head, either by rotation or by flexion. With a little care in changing the posture of the mother, in such a way as to counteract the influence of the position of the child, the difficulty of retaining the head in a proper position may be overcome.

In all positions of the head there is a deviation of the long axis of the fetus from the vertical axis of the brim of the pelvis, and consequently a deflexion of the head—the finger touches the parietal bone instead of the sagittal suture in the median line of the pelvis. Now, if the mother's posture be shifted to the other side, and the uterus and its contents shifted to the other side, the relations of the fetal and pelvic axes must be changed also; and the relation of the head to the pelvis must be appreciably affected.

In advanced cases, when the os is well dilated and retracted over the head and the head is well down in the pelvis, it is not so easy to affect the relations of the head to the pelvis by changing the relations of the fetal and pelvic axes, the body of the fetus bending too easily.

Reynolds recommends the knee-chest posture in occiput-posterior cases, if seen early, even recommending the posture before labor begins, as a prophylactic measure when occiput posture has been diagnosed. We have the influence of gravity, the head recedes, and as the head recedes there is a tendency for the heavier posterior half of the child to rotate forward. After rotation has taken place, the patient should lie in the latero-prone position, upon the side to which the occiput is directed, and should remain in that position until the head is firmly engaged in the new position.

In breach or footling cases, changes of posture of the mother will often facilitate labor when delay is due to deviation of the long axis of the fetus.

In shoulder and arm cases, the proper posture is of very great importance. You can facilitate the bringing down of the head or of the feet very materially

by making the woman lie on the side toward which you wish the other extremity to go. The knee-chest position has been advised for version, and I can recall cases in which that position would have been of assistance in introducing the hand; but ordinarily I think that the dorsal posture is the best for the introduction of the hand and for reaching the feet, to be changed to the lateral with advantage when the feet have been seized.

Theories are useful, but their application at the bedside is the crucial test. In abnormal labors there are so many factors that may be causing the unusual condition that we must study each case by itself; but the recognition of the effects of maternal posture upon the position of the fetus will often help us out of a serious complication. I have two cases of midwifery which illustrate the value of such a means of assisting nature, which I will detail.

The first was a brow presentation, which is one of the most serious forms of malposition of the head, and which, if not remedied early, will certainly end in the death of the child.

The second was a face presentation, with chin backward, which has an equally serious prognosis for the child.

Mrs. B—, aged thirty-seven, American, a multipara, sent for me about 1 P.M. She felt that labor had begun, but she was having little pain. The os was about half-dilated. Mrs. B—'s previous labors had all been of a very easy character and of short duration. Examination, at three o'clock, showed the os well dilated, and the membranes ruptured, but that there was very little pain. The head was presenting, but was at the brim. A further examination showed that the presenting part was the brow, with the chin directed backward and toward the right sacro-iliac synchondrosis. The woman was lying on her left side. The examination stimulated the pains, so that they began to appear about once in fifteen minutes. The right hand was introduced into the vagina, and the child's head rotated so that its chin pointed toward the right thyroid foramen of the mother's pelvis. When the pain came on, the head was twisted back to its previous position. This was repeated three times. I then took the head of the child in my hand and rotated the chin as before; and while I held the head in that position I had the woman roll over on to her right side, and held the head in position until the next pain came on, when I had the satisfaction to feel the chin slip down to the lower edge of the symphysis pubis, where it remained. The labor made good progress until the forehead reached the perineum, when, the force of pains becoming inefficient (they had never been very strong during the labor), I put on the forceps and delivered her quickly. A healthy living child was born about five o'clock. The manipulation of the head was done without anæsthesia, and did not cause much distress; the forceps operation was done under chloroform. The woman made a rapid and an afebrile recovery.

The second case was that of an Irish woman, of thirty, with her third child. The first labor had been very long, ending in instrumental delivery; the second was tedious but normal. She had been in labor for about two hours when I arrived; the membranes had ruptured early; there was now good dilatation; the head was at the brim, the face presenting with chin directed toward the left sacro-iliac synchondrosis. Examination was made while the woman was lying on her right side. When she had a pain, the chin of the child was pushed down into the hollow of the sacrum, fortunately returning to its first position between pains. Birth is impossible in face presentations with the chin backward. Accordingly, the woman was placed upon her back and the uterus straightened up.

The mere change in posture rotated the child, so that the long axis of the face was transverse, the chin pointing to the left. During the next pain the chin slipped down toward the symphysis pubis, and with a little encouragement of the hand was held there until well engaged. The delivery after this was rapid, and a healthy child was born, the mother making a good recovery. The labor was over in less than an hour. I think that in both of these cases the effect of changing the posture of the mother was of the greatest value in determining speedy delivery of the mothers and the birth of living children.

Progress of Medical Science.

Physiology of the Cervix Uteri.—Dr. Keiffer (*Medical Week*) discusses the question as to whether the cervix uteri is similar in structure and functional activity to other sphincters, and the results of his researches are that: 1. The cervix uteri is a genuine sphincter with circular and radiating fibres: that is to say, composed of a constricting and a dilating muscle. 2. The tonus of the cervix uteri is maintained by the reflex activity of the lumbar spinal cord. 3. The tonic centre of the uterine sphincter is situated at the level of the fifth lumbar vertebra in dogs. 4. Experimentally, contraction and dilatation of the cervix uteri may be determined by excitation of the spinal cord and of certain peripheral sensory nerves, more particularly the crural nerve. 5. The pneumogastric is not a direct motor nerve of the muscles of the cervix uteri, its action being purely reflex. 6. Acute anaemia determines complete relaxation of the cervix, while transfusion of blood results in its constriction and in that of the entire body of the uterus. 7. Asphyxia exerts a marked constrictive action on the body and neck of the uterus, followed by an inhibitory effect on the entire organ. 8. In co-ordination of the muscular actions on the body and of the neck, opposite effects may be produced.

Congenital Narrowing of the Mitral Orifices as a Cause of Dwarfed Lives and Irritable Heart.—Dr. Curtin's reasons (*Boston Medical and Surgical Journal*, September 3, 1896) for considering the disease due to constriction of the mitral orifice, are: 1. The chronic congestive lung trouble found associated with this condition. 2. The chronic lung disease almost always found on the left side. 3. The venous stasis and weak arterial circulation. 4. The character of the murmur. It is presystolic, mitral, or with the early part of the first sound. 5. The location over the left border of the heart. 6. The loudness of the murmur would indicate that it required the force of the blood current found only in the left side of the heart. 7. It is a short, sharp, whiffy murmur, which sounds quite near to the chest wall. 8. It is never transmitted except when the lung is consolidated. 9. The symptoms generally tally with those of cases having acquired mitral stenosis of a mild character. 10. The hypertrophy of the left auricle, which almost always accompanies mitral obstructive disease. 11. The accentuation of the pulmonary second sound; for, if we have constriction of the mitral orifice, the stopping of the current of the blood, when hurried, dams the blood backward, causing a sudden shutting down of the pulmonary valve and causing the pulmonary second sound to be accentuated.

Injections of Guaiacol and Iodoform in Sterilized Olive Oil for Tuberculosis.—Dr. Breton (*Journal des Praticiens*, No. 9, 1896) has used this method for fourteen months, having under his observation thirteen patients, who received in all one hundred and fifty

injections. Five of these patients, being in the last stage of the disease, died. The injections are made into the abdomen or flank, with all antiseptic precautions. The formula is: Guaiacol, five parts; iodoform, one part; sterilized olive oil, one hundred parts. The amount is gradually increased from fifteen drops to three or four times that amount. The injection is repeated every eight or ten days. The inconvenience is a persistent, burning pain. During congestive attacks, when there is fever or hæmoptysis, or even when there are small masses of blood in the expectoration, then there is intolerance or momentary saturation; or when albuminuria supervenes, this treatment is contraindicated. The results are a diminution and, later, disappearance of the thoracic pain; the dyspnoea is relieved, the cough becomes less frequent and less painful; the expectoration is less abundant, less discolored, but the bacilli are not diminished in number: the appetite is reawakened, and the general condition improves. The sweats are less abundant, and, finally, auscultation shows that real progress is being made.

Clinical Significance of the Hand.—Dr. Wohlman (*Bristol Medico-Chirurgical Journal*) remarks that the diagnosis between gout, rheumatism, and rheumatoid arthritis is often one of extreme difficulty, and that the observation of the hands is of the greatest utility. The hand affected by chronic rheumatism may be distorted into all sorts of curious shapes, partly due to pressure of bony outgrowths, or to changes in ligaments and atrophy of supporting muscles. In rheumatoid arthritis the same lesions may be exhibited, due to the same forces at work; but, above all, the original deformity is generally to be seen—the characteristic swellings, once soft and impressible, now hard, calcareous, and fixed. Tuberculous dactylitis may at first sight closely simulate rheumatoid disease in children; but the spindle swelling is caused by bone expansion and is accompanied by suppuration, in both of which points it differs essentially from the latter disease.

Examination of Unmarried Women.—The *Philadelphia Polyclinic* remarks that in supposed pelvic disease in young unmarried women, a pelvic examination is too often proposed and carried out. It should be remembered in this connection that the large majority of diseases peculiar to women are sequences of coition and its results, either pregnancy or specific infection. Neoplasms are, of course, excepted. Consequently it can usually be predicted that a pelvic examination will result negatively, and is consequently unnecessary. Dr. Baldy finds this to be true in the majority of cases, and urges the advisability of paying more attention to the patient's general health and antecedents. This is the more important, as an hysteric or neurotic girl's attention being once pointedly directed to her pelvis as the seat of her trouble, she often becomes a chronic pelvic sufferer. As is the case with opium eaters and chronic alcoholics, the medical profession is also responsible for making a large class of pelvic sufferers.

Neuritis.—Dr. Bondurant (*Medical News*, October 3, 1896) says the causes of neuritis are many and varied, and, used as a basis of classification, give rise to a number of more or less easily recognizable clinical varieties of the disease, some of them being: 1. The neuritis occurring as a result of direct injury to the nerve trunk—wounds, blows, pressure, as from sleeping on the arm, from dislocation of bones, from tumors. 2. That form resulting from exposure to cold. When the trunk of the seventh cranial nerve is involved, as is often the case, we have a familiar form of facial paralysis. 3. The forms resulting from direct extension to adjacent nerves of the infection of

bacterial diseases, as pneumonia, diphtheria, tuberculosis. 4. Those forms due to the presence in the blood of the poisons of these infectious diseases, especially syphilis, diphtheria, typhoid fever, malaria, variola, and tuberculosis. 5. The varieties resulting from introduction into the blood of toxic agents from without, as alcohol, arsenic, lead, opium. 6. The endemic or epidemic forms frequent in Asia and the islands of the Pacific, as the kakke of the Japanese and the beriberi of the Malay peninsula. 7. Certain forms affecting especially the cutaneous nerves, and accompanied by trophic disorders of the skin in the areas supplied by the diseased nerves, of which herpes zoster is a familiar example.

Marriage of Epileptics.—Connecticut has enacted a law which provides that no man and woman, either of whom is epileptic, imbecile, or feeble-minded, shall intermarry or live together as man and wife, when the woman is under forty-five years of age. The penalty is not less than three years' imprisonment.—*Southwestern Medical Record*.

Angina Pectoris.—Sir Benjamin Ward Richardson (*The Asclepiad*) concludes, from a study of forty-three cases, that the affection is a sympathetic neurosis, bearing much the same relation to the sympathetic nervous system as epilepsy does to the brain. Heart lesions and coronary disease are often absent, and when present are probably merely coincidental.

Unconsciousness from Constipation.—Very stout women have suddenly become unconscious from a long-continued constipation. A physician relates a case in which unconsciousness, with stertorous breathing in the night, simulated an apoplectic attack. By the aid of mustard to the feet and abdomen, with ice to the head, and a large enema of soap, water, and castor oil, a large evacuation was procured, with speedy return to consciousness. The slow poison from the retained faecal matter probably brought on unconsciousness.—*Health Magazine*.

Etiology of Serous Pleuritic Effusion.—Dr. Aschoff, in the *Zeitschrift für klinische Medizin*, discusses this subject, and considers the following three questions: 1. Is every idiopathic pleurisy, i.e., a serous pleuritis without known cause, tuberculous in its nature? 2. Is there such a thing as an acute isolated rheumatic pleurisy, which is to be looked upon as equivalent to a preceding attack of acute rheumatic arthritis? 3. Do serous pleuritic effusions ever contain pyrogenic organisms, without the latter becoming purulent? Bacteriological examinations of two hundred serous exudates gave the following results: Serous effusions are nearly always free from pus-producing micro-organisms. If the latter are present, the exudate will become purulent, except, possibly, when pneumococci are present. Purulent pleuritic effusions sometimes heal completely without operation. The occurrence of isolated rheumatic pleuritis is questionable—at least, it is very rare. Pleuritic effusions occurring in rheumatism are usually the result of a cardiac lesion. The administration of salicylic acid has given no special benefit. The so-called idiopathic effusions are almost always tuberculous. They may, however, disappear entirely.

Phthisis.—Dr. Tidey (*British Medical Journal*) advises: 1. In early phthisis (catarrhal stage) to give comparative rest and relaxation to affected lung tissue. 2. In the stage of consolidation, to secure the same results, thereby limiting the risk of extension, and to promote elimination of the disease products by improving the circulation in and about the diseased area, and to facilitate expectoration. 3. In the stage of cavitation, to promote closing of cavi-

ties by directing healthy lung to encroach on the diseased area, instead of relying on natural processes of cicatrization. 4. Diminished tendency to hemorrhage by reduced tension on vessels and cicatricial traction on vessel walls. 5. The ultimate object is to obtain a smaller thoracic cavity filled with healthy lung, instead of an enlarged thoracic cavity partly filled with diseased lung.

Thyroid Therapy.—Dr. Herrick (*Medicine*, vol. ii., No. 8) reaches the following conclusions concerning thyroid extract: 1. It is curative in myxedema (idiopathic, cretinism, operative). 2. Many cases of obesity are cured by it. 3. Simple hyperplastic struma, particularly if in the young, is frequently cured or improved. 4. In 1, 2, and 3 the remedy has to be continued for an indefinite time to prevent relapse. 5. It may prove of value in some cases of tetany. 6. In skin diseases it is of doubtful value, to say the least. 7. The same is true of mental and nervous diseases. 8. In exophthalmic goitre it is contraindicated. 9. The results are practically the same, whether fresh glands, extracts, or dried glands are employed. 10. This is probably true also of the thyroiodine of Baumann.

Diet in Bright's Disease.—Dr. Elliot (*North American Practitioner*, June, 1896, p. 248) says: "It is agreed that the most rational diet is a mixed one. The estimate commonly given is that meat should constitute one-fourth and vegetable food three-fourths. This is often overstepped, and the proportion brought to two to four. Such indulgence throws into the circulation a large amount of nitrogenous waste, which it is the office of the kidneys to remove from the system. An increased amount of organic excretives, continually demanding removal, throws a considerable tax upon these organs, which is frequently rendered more severe by a hyperacid concentrated condition of the urine, as these subjects seldom drink an adequate amount of water. This irritation, if long continued, eventually leads to functional and, finally, organic impairment of the kidneys. To these sources of irritation must be added the deleterious effects upon the renal structure of the excretion of the by-products of faulty gastric and intestinal digestion, frequently present from the dyspepsia so common among those who overindulge at table."

New Method of Diagnosis in Typhoid Fever.—Dr. Widau (*La Presse Médicale*, July 29, 1896) describes his method of testing the diagnosis of typhoid fever, which has not failed in eighty cases examined. The test is based upon the action of the serum of a typhoid patient upon young cultures of coli bacilli growing in bouillon. It is performed in several ways. From a finger tip, carefully sterilized by bichloride-of-mercury solution and ether, a small quantity of blood is drawn into a glass receptacle and allowed to clot. If a few drops of the serum (one to every ten drops of bouillon) are introduced into a young bouillon culture of coli bacilli, they will in a short time gather themselves together into little balls, sometimes visible to the naked eye, easily seen by the aid of the microscope. The reaction may be seen in a few minutes, but is more evident in a few hours. The culture used should be only a day or so old, but if no fresh one is at hand another method may be used. A tube of bouillon is sowed with some of the old coli bacilli culture and the typhoid serum is added, in the proportion of one drop of serum to three cubic centimetres of bouillon. After twenty-four or forty-eight hours at 37° C., the same reaction described above is seen. A control tube is recommended, the coli bacilli being omitted, as the blood serum may not be sterile.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 7, 1896.

THE LEPER COLONY.

AT length New York can boast of being one of the leper centres of the country. At least the public press has within the last fortnight mentioned this city as one of the three locations of leper colonies in the United States. From the frequency with which cases are reported as having been presented to medical societies, the number of lepers must at least be decidedly upon the increase. A discussion took place at the last meeting of the County Medical Society upon whether the commissioners of health should be upheld in their determination to turn out the few patients in their charge. For five years this body has taken care of such cases as other institutions wished to turn over to it, but now for some reason it wishes to cease such responsibility. The matter is an important one and we agree with a correspondent, whose letter will be found in another column, that the County Medical Society would assume grave responsibility in taking the step proposed. The public idea of the leprosy question is erroneous, in spite of the oft-repeated assurance that there is little or no danger in sitting beside a leper in a street car or from shaking him by the hand. We are not, however, in a position to say that infection does not take place under much the same conditions as those in which syphilis is disseminated. This being the case, the leper must be looked upon as a source of danger, aside from his being an undesirable neighbor and an unappetizing cook, as our correspondent puts it. We regret that the board of health did not act upon the suggestion which we threw out in our editorial comments upon "The American Leper" in the *MEDICAL RECORD* of March 14th, and send its little colony down to the new Louisiana Leper Hospital, which was anxious for inmates. By the way, what has become of the resolutions passed at the last meeting of the congress of American physicians and surgeons in Washington and entrusted to Surgeon-General Wyman of the Marine Hospital service to bring to the attention of President Cleveland and lay before Congress? Would it not be well to have a national leprosy commission appointed to determine what is to be done with the leper here at home before we send delegates to an international leprosy congress in London to decide upon what to do with the lepers of the entire world? It might be proper for those here who continually

preach the safety of this country from invasion to remember that New Orleans is located within the confines of our possessions, and that the spread thereabouts among natives of Louisiana is sufficient to occasion comment if not alarm. It might also be well for these gentlemen to remember that the Baltic provinces of Russia considered themselves free and safe from invasion until recently four hundred cases of leprosy were found to have originated there, necessitating the opening of three leproseries. No one can tell what the future may have in store for this country if we continue our present attitude of hospitality toward foreign lepers. One of the speakers is reported to have said at the meeting that within a week he had seen a leprosy patient who had just arrived in New York from a foreign port. What of our laws covering such cases? What of our quarantine inspection?

IMMORALITY IN CANADA.

WE have been distressed and shocked beyond measure to learn that large and increasing numbers of women in Canada are giving themselves up to the vilest form of immoral practices. The report that comes to us, indeed, is such that, were it credible, we should be led to despair of the future of the country, for, compared to Canada, or at least to Toronto, Sodom and Gomorrah were as pure as Salvation Army shelters. It appears that cycling, which with us is adding so much to the health and the beauty and the charm of our women, is in Canada, or at least in Toronto, merely a means of gratifying unholy and bestial desire. We hesitate to believe such a report, but we have it on the authority of the editor of the *Dominion Medical Monthly*, and he is on the spot and speaks as one with absolute knowledge of the facts.

After referring to the advantages claimed for the bicycle, which he refutes by the statement that the average woman gets about all the exercise she wants in looking after her home, our esteemed contemporary says that "the consensus of opinion is increasing overwhelmingly day by day that bicycle riding produces in the female a distinct orgasm . . . and even if an orgasm is not produced the continued erethism is decidedly more injurious and tends to the production of nervous diseases and the general breaking down of the system. The only contention that can be made is that the orgasm or erethism is not produced. This we know to be absolutely untrue." The writer adds more of the same kind, and pictures the mothers, wives, and daughters of his neighbors as scorching through the country, stooping low over the handle bars, and "subjected to continued erethism as well as an occasional orgasm."

There is but one of two conclusions to be drawn from this statement. Either the wheelwomen of Toronto are the vilest of their sex, or they are the victims of a contemptible slander. Unless our contemporary has a mass of facts sufficient to establish beyond doubt the sweeping generalization contained in the article from which we have quoted, he has smirched the fair name of his countrywomen in a

reckless fashion that calls for the strongest condemnation. The question of the healthfulness of cycling, for men as well as for women, is one that still admits of discussion; but the man who can assert or even suggest that the thousands, perhaps millions, of women throughout the world, who ride the wheel, are giving themselves over to self-abuse, puts himself beyond the reach of argument.

POLITICS AND MEDICINE IN RUSSIA.

THE organization of the Moscow Congress has met with many trials during the past year. First it offered what was by many regarded as a deliberate insult to the English-speaking physicians of the world by excluding the use of their language in the scientific meetings. Then this was hardly settled by the restoration of English to its proper place, when Virchow presented an ultimatum to the officers of the congress, giving out that he would have nothing to do with it unless Russia abandoned her discrimination against Jews who wanted to enter the country. This danger was averted by the publication of an order that all physicians should be admitted to the country on equal terms, no discrimination being made on account of race or religion. Now the most serious blow of all has come in the enforced resignation of Professor Erismann from the position of secretary-general of the congress. This is more of disaster than might be supposed by those unacquainted with Dr. Erismann's unusual ability as an organizer and executive officer. His resignation has followed his dismissal from the chair of hygiene in the University of Moscow. It appears, from the account given by the St. Petersburg correspondent of *The Lancet*, that Professor Erismann was tainted with liberalism. He was one of forty-two Moscow professors who, two years ago, signed a petition to the Russian government in which relief was asked for certain wrongs under which the students of the university were suffering. The result was the usual one of such appeals in Russia. All the signers were formally censured and four, including Professor Erismann, were severely reprimanded. The reasons of Professor Erismann's enforced resignation of his chair are not at present publicly known, *The Lancet* correspondent says, but there is little cause to doubt that the incident just narrated—or, rather, the "liberal" leanings of Professor Erismann, of which the incident was, perhaps, one out of many proofs—were the real reasons. This explanation, which is the one most generally accepted, is further supported by the rumor that two of the other three professors who were reprimanded at that time have also been requested to resign their chairs. The circumstances of Professor Erismann's resignation were the following: It is the custom of the Russian government every summer to send a certain number of professors to foreign countries to study foreign methods and systems and so to keep in touch with the progress made in other countries. Among those sent this summer was Professor Erismann. He visited Berlin and then went to Switzerland. While there he was officially informed that

his services in the chair of hygiene were no longer needed, the retirement to date from July 1st. No reasons were given, but three days were allowed during which a voluntary resignation would be accepted. The loss is Russia's and not the deposed professor's, for the latter's abilities will make him welcome anywhere; but the University of Moscow and the International Congress can with difficulty supply his place.

DON'T DIE IN THE HOTEL.

THE expense attending the misfortune of dying in a foreign hostelry is such that it should be avoided whenever practicable. In commenting upon this item in the bill presented by a continental landlord, and the difficulties encountered by the English consul in securing its reduction to reasonable proportions, the editor of the *Press and Circular* suggests that the guide books insert a schedule rate by which travellers could be governed. This seems eminently fitting. Plain deaths, so many pounds and so many shillings. Complicated, ditto, etc. Or would it not be better: death of a plain person, so and so much; of a person of title, *pro re nata* (the *re* of course referring to the title)? The *Press* puts the matter in a very apt and practical manner. It says if the editors of guide books took the matter up, "then travellers would only have themselves to thank if they deliberately placed themselves within the clutches of unscrupulous and overreaching landlords." This is quite right. Any man who would deliberately pick out a hotel for this purpose where the death rates, so to speak, were exorbitant, would have only his surviving friends to thank him accordingly. His only safety would be in finding the rate actually prohibitory.

News of the Week.

Obituary Notes.—DR. W. W. PALMER, of Keansburg, N. J., was instantly killed on October 27th, the carriage in which he was driving with his daughter and granddaughter and a friend having been run into by a train as it was crossing the track. Dr. Palmer was a graduate of the Albany Medical College in the class of 1855.—DR. GEORGE HARLEY, of London, died on October 27th, at the age of sixty-seven years. He was M.D. Edinburgh in 1850, and was elected a member of the Royal College of Surgeons, London, in 1850, and a fellow of the Royal College of Physicians in 1864. He was well known for his writings on diseases of the kidneys and of the liver.—DR. GEORGE W. MARTIN, of Augusta, Me., died at his home in that city, on October 26th. Dr. Martin, who was born in 1830, was graduated from the University of New York in 1858. At the breaking out of the war he went to the front as assistant surgeon of the Sixth Maine Regiment. He subsequently served as surgeon of the Fourth Maine and the Second Maine Cavalry. Later he became government medical inspector. In 1873 he was made medical director of the military forces in Maine, serving until 1879.—DR. JAMES B. MURDOCK, late dean of the Western Pennsylvania Medical Col-

lege of Pittsburg, and one of the best-known physicians in Pennsylvania, died October 27th. He leaves a widow and five children. He was born in Glasgow, Scotland, in 1830. He graduated from the College of Physicians and Surgeons, New York City, in 1854. For a time Dr. Murdock practised medicine in Oswego, N. Y. He settled in Pittsburg in 1877, and had amassed a fortune.—DR. HARRIET W. SMITH died at Galveston, Tex., on October 27th, at the age of thirty-two years. She was a graduate of the Woman's Medical College of Pennsylvania, and the wife of Dr. Allen J. Smith, professor of pathology in the University of Texas. Both were formerly residents of Philadelphia, and they had been also resident physicians in the Philadelphia Hospital.—DR. LEVI H. THOMPSON died on October 23d, at Reading, Pa., at the age of seventy-three years, in the sequence of a carbuncle upon the neck. He was a graduate of Jefferson Medical College. After practising at Fleetwood and Lyons, Dr. Thompson removed to Reading, where he had lived for more than twenty years.

September's Death Rate in the State.—The bulletin of the State board of health for the month of September shows that there were five hundred fewer deaths reported than in the corresponding month of last year. The mortality from all diseases of the digestive organs is diminished. There were eight hundred fewer deaths under five years of age. Compared with the preceding month of August, the total reported mortality is decreased by three thousand. The death rate from all causes was 17.50, against 18.50 in September last year. The September prevalence of typhoid fever is excessive in the Hudson and Mohawk Valley districts, and in the southern tier and east central districts. Diphtheria caused fewer deaths than in September of any year for ten years.

The "Divine Healer."—He has come again. The last glimpse the public had of August Schlatter, he appeared scantily clad, mounted upon a snow-white steed, and going toward the great Southwest. Now he has turned up in Philadelphia, whose citizens were not slow in recognizing his abilities, and by the constant sending of handkerchiefs to be blessed and importunities to renounce his seclusion finally induced him to make this city of brotherly love his abiding-place and field of labor. A chair of "spiritual therapeutics" is likely to be established for him in one of the medical schools. His advent was unostentatious and unobserved. Indeed, the modesty of the healer is such that it is announced no one besides his landlady knew of his presence until he had been in the city for a considerable time. Were it anywhere but Philadelphia, there would arise a supposition that he had entered by night. After his miraculous cures sufficiently aroused Philadelphians, he distributed his benedictions in Bayonne, N. J., and has now struck us here. We trust he will not draw heavily on the clinics.

Photography of the Larynx was the subject of a paper read by Dr. Thomas R. French before the section on laryngology of the Academy of Medicine, October 28th. The author demonstrated apparatus for

this kind of work, and gave a lantern exhibition of photographs of the larynx in health and disease. Among the cases shown was one of tuberculous tumor of one vocal cord; also one of papillomatous tumor, one of unilateral, and one of bilateral paralysis of the cords; further, some photographs of the posterior nares, representing hypertrophic and atrophic rhinitis. The demonstration proved conclusively the value of photography in studying the pathology of the larynx.

"Dr." Walter May Rew, who was exposed some time ago by the *Herald* as a manufacturer of physicians' and nurses' diplomas, has just been convicted of bigamy. He is said to have enjoyed the blessings of having been five times wed.

Pyrantin is the newest antipyretic. Piutti obtained it by melting together hydrochlorate of phenacetin and succinic acid. It is extracted with boiling alcohol, from which it crystallizes in colorless prismatic needles. It is soluble in 1,317 parts of cold water and in 86.6 parts of hot water, but insoluble in ether.—*La Méd. Mod.*, October 14th.

County Medical Society.—In the election which took place on the evening of October 26th, Dr. Landon Carter Gray was elected *President*. The only other candidate was Dr. Jacobus; Drs. Chapin, Peterson, Garrigues, and Van Santvoord having withdrawn. Dr. Robert A. Murray was elected *Vice-President*; Dr. Nathan E. Brill, *Second Vice-President*; Dr. Charles H. Avery, *Secretary*; Dr. William E. Bullard, *Assistant Secretary*; Dr. John S. Warren, *Treasurer*.

The Pan-American Medical Congress.—It is estimated that from three hundred to four hundred physicians from the United States will take part in the congress to be held in Mexico City, November 16–19, 1896. Dr. H. L. E. Johnson, of the committee on transportation, has obtained an offer from the railroads throughout the country, except in certain parts of the East, of a one-fare rate for the round trip to Mexico and return. From New York City to Mexico and return direct the entire cost will be: Fare, \$78.50; berths in sleeping-car, \$46; meals, \$32; total cost, \$156.50. Living in Mexico, \$2.50 per day extra. A special train has been arranged for through the American Tourist Association, with Reau Campbell, manager, to leave Cincinnati on Tuesday, November 10th, 9 A.M., via St. Louis and Eagle Pass, and make a twenty-one day tour from there through Mexico and return for \$189; from Chicago and return, \$190; from St. Louis and return, \$183.55. This will include railroad fares and all necessary expenses of the trip. The Baltimore and Ohio railway will carry the delegates from the North and East to meet the special train at Cincinnati. From New York the trip can be made by sea, in the boats of the Ward line, the total cost of which will be, including meals and stateroom, \$78. Nine days are required each way for this trip. The journey can be made by rail from this city to Mexico in five days. The registration fee, \$5, should be sent to Dr. Francisco Bustillos, Calle de Tabuco, No. 7, Mexico City, Mexico.

The New York State Association of Railway Surgeons will hold its sixth annual meeting at the New York Academy of Medicine, on Tuesday, November 17, 1896. Several very interesting and practical papers are promised.

Small-Pox in Marseilles.—The *Presse Médicale* reports that from January 1st to July 30th there were four hundred and sixty-eight deaths from variola in the city of Marseilles.

The Pittsburg Dental College, a newly organized department of the Western University of Pennsylvania, opened its doors in September last, with one hundred and twelve students enrolled. A three years' graded course of instruction is offered.

Vaccination against Serpent Bites.—A gentleman by the name of Oleta is reported to have arrived in Paris from Guiana, with a vaccine against serpent bites. The remedy has been known by the native negroes, it would appear, for many years, but has only of late received scientific study.

Pellotine is one of the latest hypnotics, an active principle obtained from a Mexican cactus. The hydrochlorate is employed by the mouth or subcutaneously in dose of from four to six centigrams. It is thought that it may occasionally replace other hypnotics with advantage.

The Hartford Medical Society.—The fiftieth anniversary of the Hartford Medical Society was most appropriately celebrated in Hartford, Conn., October 26, 1896 (having been postponed from the anniversary day, September 15th), by an afternoon meeting, at which addresses were made by Dr. Gurdon W. Russell, one of the original fifteen members, of an historical character with incidents and reminiscences; Dr. Horace S. Fuller, upon "Our Deceased Members and Incidents Connected with the Later Years of the Society;" Dr. Henry P. Stearns, upon "Esprit de Corps;" and the president, Dr. Melancthon Storrs, upon "The Present and Future of the Hartford Medical Society." The present active membership is seventy, and over sixty present and past members partook of a banquet at Hotel Hartford in the evening. Dr. P. H. Ingalls was toastmaster, and Drs. Russell, Hudson, Mayer, Jarvis, Page, Law, St. John, Cook, and Storrs responded to the toasts. An improvised glee club of twelve members varied the proceedings by selections sung, some of which were original and arranged for the occasion. It is purposed to have the proceedings published, marking as they do an important epoch in the history of this flourishing society.

An Unwise Charity.—The Salvation Army has announced its intention to establish a number of shelters in New York for homeless persons, and has thereby aroused the fears of those who think it unwise to make this city more attractive to tramps than it is at present. The army proposed to provide not only beds and a bath, but also a meal to the lodgers before letting them go forth in the morning. The commander of the army was recently waited upon by the committee on vagrancy of the conference of charities, and was urged to recede from this plan, which was so cer-

tain to promote vagrancy, if not to spread disease. The conference of charities has been working to rid the city of vagrants, and one of its steps was to suppress those provisions for homeless persons where there was no methodical scrutiny of the applicants. They did succeed in having the police-station lodging-houses abolished, and were just getting the city in a state unattractive to tramps, when the Salvation Army started this scheme. The leader of the Salvationists promised to weigh the arguments presented to him by Mrs. Josephine Shaw Lowell, but gave little hope that he would act in accordance with them, for he said that the Lord, who was with him, wanted shelters for the homeless.

Dr. Tanner, for whom starvation had no terrors, has perished by flame, according to a dispatch from Akron, O., he having been burned to death in a conflagration in that city on the 21st instant.

Cremation in England is gaining ground. As we have noted, Mr. George Du Maurier was cremated at Woking, on October 10th, and during the past few weeks the remains of Dr. J. L. H. Langdon Down and of Surgeon-General Sir William George Moore have also been cremated.

Yellow Fever in Sugar.—In the latest issued report of the Marine Hospital service, Dr. D. M. Burgess, sanitary inspector at Havana, writes, under date of October 17th: "I am informed that the government here has appropriated, and is already using for hospital purposes, the extensive 'almacenes' or sugar store-houses of Regia, which structures are situated contiguous to the wharf on the opposite side of the harbor from this city. This measure, of course, will infect these buildings and probably such sugar as may or will be stored in them." Dr. Burgess adds that yellow fever in Havana continues with all its malignancy, and perhaps is increasing among the Spanish soldiers. Passengers recently arrived from Havana say that both yellow fever and small-pox are increasing in that wretched city, and the Spanish authorities are absolutely supine in the face of the spreading pestilences.

Maternal Impressions.—A hen in Vermont, after looking at a three-pound potato grown by a neighbor of her owner, went to the barn and laid an egg measuring eight and one-half by six and one-half inches.

Another Office Fraud.—A young, middle-sized man, with dark moustache, calls at the office, sends in his card as "Dr." Morton, informs the doctor in waiting that he has recommended a case to him, that the patient is a good one, pays promptly, and needs an operation or other special treatment, and that said patient will call on the morrow. The fraud then informs the doctor that he is about to take a vacation in the Maine woods, and would like to purchase some medicines. He asks the doctor to give him an introduction to some neighboring druggist, which being done, the said stranger passes a bogus check and gets surplus change. We have received several complaints from friends in this city who have been victimized, and publish this notice accordingly.

Centennial Commemoration of the Paris Medical School.—Dr. A. Corlieu, assistant librarian of the Paris Faculty of Medicine, has just completed a history of the faculty during the century of its existence from 1794 to 1894. The work was published free of expense to the faculty by a committee of the medical publishers of Paris. It contains one hundred and thirty portraits of eminent medical men who have been connected with the medical school.

The Ship Captain as a Diagnostician.—A bill has been introduced into the New Zealand legislature, the object of which is to exclude all persons suffering from tuberculosis. The bill provides that on the arrival of any ship in a port of New Zealand, the master of the ship shall deliver to the health officer a true list of all passengers and a declaration as to whether any of them are suffering from tuberculosis, the penalty for a false declaration being \$250. No passenger suffering from that disease is to be allowed to land, and should any such person do so both he and the master of the vessel are liable to a penalty of \$50. If within three months of landing in New Zealand any passenger is found to be suffering from tuberculosis, he shall, until the contrary is proved, be deemed to have been suffering from that disease when he landed in New Zealand, and the penalty will be enforced accordingly. The master of a ship is liable to a penalty of \$250 if he allows a tuberculous patient to occupy the same cabin as another passenger.

Hospital Management in Chili.—In an extract from a letter from an English physician in Santiago de Chile, published in the *British Medical Journal*, the writer says, speaking of the local profession: "Their notions of hospital management are the queerest in the world, though most of the professors have been trained in Europe. The largest and most up-to-date hospital in the republic, St. Vincent de Paul (about one thousand beds), contains neither bathroom nor watercloset. The bath is known only as an antipyretic, and patients are brought into the operation theatres (the one reserved for abdominal surgery, by-the-by, is next to the erysipelas ward) in all their native dirt, though they are placed on the brass table without any covering whatever, because blankets are too septic to come into the room. Stools, etc., are kept for twenty-four hours in the locker at the head of the patient's bed, together with his food and wine. After the physician's visit they are all emptied into the open 'asequias,' which run through the hospital 'patios.'"

Pasteur Celebration at Alais.—A series of *fêtes* have been celebrated at Alais, in the centre of the great mulberry and silkworm district of France, in commemoration of the services rendered by Pasteur to sericulture. The silk industry covers an enormous area, and its extension is owing to the studies conducted by Pasteur at Alais, in 1865 and the following years, into the diseases of silkworms and the method of eliminating them. The *fêtes* lasted from September 25th to September 28th. The unveiling of a statue of Pasteur took place on September 26th. Monuments

to Florian and the Abbé de Sauvage were also unveiled. On Saturday a solemn service was celebrated in the cathedral, in commemoration of the first anniversary of Pasteur's death, which occurred on September 28, 1895.—*British Medical Journal*.

Dr. Montalvo, who has recently been arrested in Havana as an insurgent suspect, has been hitherto considered one of the most prominent members of the Cuban autonomist party.

A Cardiac Tonic.—Dr. M. C. Jennings, of Chicago, writes to the *New York Medical Journal*, of October 10th, that he has employed a fluid extract of *Crataegus oxyacantha*, or hawthorn fruit, in over forty cases of failing heart from various causes, and always with gratifying result. The force of the cardiac contractions is increased and the pulse rate is reduced in frequency. The dose employed was from ten to fifteen drops after meals.

Experiments on School Children.—The filter in the Chicago public schools has been a burning question for the past few months between the health commissioner and the board of education. These latter gentlemen have exercised an amount of discretion unworthy of a four-year-old, and, in view of the fact that they probably all took precautions with the drinking-water used in their own households, have knowingly subjected the hundreds of thousands of school children to the danger of intestinal disease, including typhoid. They have finally permitted various filter manufacturers to place their filters in some of the schools on a sixty days' test. We trust that the children who are made the unfortunate victims of these tests may look upon it in a purely scientific spirit, and that their parents may feel fully repaid for their loss.—*Chicago Medical Recorder*.

The Late Dr. William Muir McLaury.—*Whereas*, It has pleased divine Providence to take from us one of our oldest members, a former president of this society; and

Whereas, We, the members of the Northwestern Medical and Surgical Society, desire to place upon record our appreciation of the character of our deceased brother; be it

Resolved, That in the death of William Muir McLaury this society has lost a devoted, able, and faithful colleague, whose earnestness of purpose and loftiness of motive peculiarly fitted him for the profession which he adorned.

Resolved, That the loss, which we thus mourn, is not limited to our society, or even to our city.

Resolved, That we most respectfully and sincerely extend our heartfelt sympathy to his family, wishing for them that consolation which is the outcome of his noble life.

Resolved, That a draft of these resolutions be spread upon the minutes of this society, and that duplicates be sent to the medical press, and that a copy be transmitted to the family of our deceased friend.

HENRY LING TAYLOR, M.D., *President*.

JOSEPH COLLINS, M.D., *Secretary*.

One Physician Shoots Another.—Dr. Alfred Holt, of Hayes, Miss., on October 16th shot and killed Dr. P. S. Rhett, of Jonesville, La., at Natchez, Miss.

Philadelphia Polyclinic.—The faculty of the Philadelphia Polyclinic and College for Graduates in Medicine has established a lectureship on defects of speech and Dr. G. Hudson Makuen has been elected to the position. Dr. A. O. J. Kelly has been elected adjunct professor of pathology.

In Russia there are 18,334 physicians or 1 to about every 6,000 inhabitants, while in Germany there is 1 to each 3,000, in France 1 to 1,800, and in England 1 to 1,600. In America they have not been accurately counted of late, but there is a strong belief among New York physicians just now that the proportion must be somewhere in the neighborhood of 1 to 16.

Pathological Society of Philadelphia.—At a meeting of the Pathological Society of Philadelphia, held on October 22d, Dr. H. W. Cattell read the report of a case of "Internal Strangulated Hernia of the Small Intestine through the Omentum." Dr. John M. Swan presented "Specimens from a Case of Arthritis Deformans." By special invitation, Dr. Joshua M. Van Cott, of Brooklyn, read a paper on "Malignant Endometritis." Dr. J. P. Arnold presented "Tuberculous Suprarenal Glands from a Case of Addison's Disease." Dr. A. E. Taylor exhibited a specimen of conglomerate neoplastic involvement of the stomach and omentum, of epithelial character but of obscure origin. Dr. James H. McKee presented fragments of a macerated four-months' fetus, the product of a criminal abortion. Dr. A. Hand, Jr., demonstrated ulceration of Peyer's patches in the small intestine from a young child. Dr. J. Dutton Steele exhibited specimens of carcinoma of the stomach and omentum. Dr. Alfred Stengel presented a specimen of mitral stenosis with pulmonary infarction; and one of primary carcinoma of the head of the pancreas with secondary involvement of the stomach, biliary obstruction, and gall stones.

The Colony Treatment of Epileptics.—At the annual meeting of the board of managers of the Craig Colony, held at the colony on October 13th, some interesting facts were stated in the report of the medical superintendent, Dr. William P. Spratling, bearing on results obtained in the treatment of the patients and the economy of the colony plan in caring for this class of patients. The first fifty patients who were under treatment five months and over before the close of the fiscal year had collectively, during the first month of their residence at the colony, seven hundred and eight seizures. The same fifty cases, after five months' treatment, had collectively, during the fifth month, three hundred and fifteen seizures—a reduction of 55 $\frac{3}{4}$ per cent. During the first month each case averaged fourteen attacks; during the fifth month, each case averaged six attacks. The cost for maintenance was more than half met in the value of the products of the farm and garden and miscellaneous earnings, the value of such articles being \$14,230.20. The managers will ask a large appropriation of the coming leg-

islature, in order that they may meet, in a measure, the demands made upon the colony for the admission of hundreds of indigent epileptics in the State. There are at present one hundred and thirty-five patients in the colony. Dr. Frederick Peterson was re-elected president of the board of managers, and Mr. H. E. Brown secretary.

Diphtheria Spread by Rabbits.—A report comes from Webster City, Iowa, that an epidemic of diphtheria has been spread by rabbits in that neighborhood. The disease is said to have recurred annually in a school house in which the rabbits hibernated and whence the disease was disseminated. The wise decision was reached to destroy the building by fire.

Physicians Victimized.—A young and prepossessing woman has been soliciting contributions, and receiving them as well, from susceptible and unsuspecting Brooklyn physicians for a hypothetic home or some other charity. The lady has so far called herself Mary Cole, but it is probable that if she comes across the bridge she may change her name as well as that of the institution she claims to benefit.

Philadelphia County Medical Society.—At a business meeting of the Philadelphia County Medical Society, on October 21st, Dr. John Lindsay was elected secretary, to succeed Dr. T. B. Schneideman, who had resigned; and Dr. Elwood Kirby was elected assistant secretary, succeeding Dr. Lindsay. Eleven new members were elected, and nominations were made for officers for the ensuing year, as well as for delegates to the American Medical Association and the Medical Society of the State of Pennsylvania.

College of Physicians of Philadelphia.—At a meeting of the section on ophthalmology on October 20th, Dr. John T. Carpenter, Jr., read the report of "A Case of Recovery from Unilateral Optic Neuritis," and exhibited the patient. Dr. H. F. Hansell read for Dr. Charles A. Oliver the report of "A Case of Probable Intra-ocular Growth in the First Stage of Development." Dr. Edward Jackson read a paper on "The Corneal Reflex." Dr. B. A. Randall read a paper entitled "Rhinitis as a Factor in Phlyctenular Ophthalmia, with its Therapeutic Consequences." Dr. S. D. Risley made a brief communication upon "Defective Coquille Glasses," pointing out that many of these exert disturbing refractive effects.

Cumberland County (N. J.) Medical Society.—The Cumberland County Medical Society convened at Hotel Cumberland, Tuesday, October 13th, with President Dr. D. H. Oliver in the chair. Dr. G. E. Day, of Millville, was elected to active membership, after which a very interesting address was delivered by Dr. Theophilus Parvin, of Philadelphia. Addresses were also made by Dr. O. H. Adams, of Vineland, on "Eye Strains;" and Dr. A. W. Sullivan, of Shiloh, on "Dysentery." After the report of Dr. S. M. Wilson, as delegate to the American Medical Association, and the election of Dr. J. C. Applegate as reporter to the State society, the society adjourned, to meet at Hotel Cumberland, the second Tuesday in January, 1897.

An Association of Urologists has been established in France among the physicians interested in this branch of medicine. Among the originators are Albarran, Audry, Chevalier, Desnos, and Malherbe of Nantes.

International Exposition of Hygiene, of alimentation, and of industrial arts will take place at Lille in the months of March and April, 1897, under the auspices of the municipality. The Rameau palace has been placed at the disposal of the committee on organization.

The Graefe Gold Medal of the German Ophthalmological Society has been awarded to Prof. Theodore Leber, of Heidelberg, in recognition of his work on inflammation. This medal is given every ten years, in recognition of the greatest advance made in ophthalmological science during that time. The first one to receive the medal was von Helmholtz, for his discovery of the ophthalmoscope.

Yellow Fever has appeared at the New York quarantine. A patient, removed from the steamship *Yucatan* on the 21st, died the same night. All passengers from Havana and other infected ports will be carefully inspected. Dr. Doty reports that cold weather is too near to admit of any fear of the disease gaining a foothold here. It is said that four hundred new cases were reported in Havana two weeks ago. Small-pox was also prevalent.

The Green Cross.—In addition to the Red Cross Society and the White Cross, which gives aid to sick or convalescent soldiers, there has just been established at Vienna a new order which will be known as that of the "Green Cross." Its object and aim is to give succor to Alp climbers and excursionists in mountain regions. It originated in the Austrian Alpine club. The intention is to establish huts upon high mountains and to keep supplies and relief stores, or boxes containing articles apt to be required in emergencies at conveniently located points. Besides this guides are to be instructed in first aid to the injured and trained in the application of splints and antiseptic dressings. We wish the society with its new-colored cross all success in its humane undertaking.

Antivenin.—Dr. Fraser, of Edinburgh, has attempted to render animals immune to the bite of serpents by making injections of one-tenth the fatal dose and gradually increasing the quantity of venom. The serum of animals thus immunized is antitoxic and is named antivenin. In case of poisoning by serpent bite, he says, first shut off the circulation as much as possible by ligature; increase the size of the open wound; suck out with the mouth or better still with an aspirating pump; inject antivenin into and about the wound beneath the skin, and do not remove the ligature for at least half an hour. To save a man's life three hundred and thirty cubic centimetres of antivenin are required, provided it can be injected within half an hour of the accident. The treatment has as yet, so far as we know, not been tried on man.

A Chair of Massage has been established in the University of Berlin with Dr. Zabloudovsky as professor. This is, we believe, the first instance in which a great university has given such recognition to this branch.

The Loomis Sanatorium for Consumptives, at Liberty, Sullivan County, N. Y., is now open for the reception of patients. The institution, which is a memorial to the late Dr. A. L. Loomis, is intended for patients in the early stage of pulmonary tuberculosis, who cannot afford to sustain themselves and pay for medical attention at expensive resorts. The sanatorium is at an elevation of about twenty-two hundred feet, and the buildings are substantially constructed and beautifully located. Patients are received at a nominal rate for board and medicines, but there is no charge for medical attendance. There are no free beds. Before patients can be admitted they must be examined by either Dr. H. P. Loomis, 58 East Thirty-fourth Street, or Dr. Charles E. Quimby, 44 West Thirty-sixth Street, New York; or by Dr. J. E. Stubbart, at the sanatorium. There are at present twenty-seven patients in the institution. The public dedication will take place in November.

Pruritus Vulvæ.—The editor of *The Medical Press* has been struck with the apparent frequency of this complaint among American women, and says that one hardly ever glances through an American medical journal without coming across the most harrowing accounts of its severity and refractoriness to treatment. Every-day gynecological practice in England, he continues, does not reveal pruritus vulvæ as a common or intractable affection, so that an explanation of its greater incidence on this side of the Atlantic "must be sought in ethnological or climatological peculiarities, unless, indeed, there are more individual reasons associated with the prevalence of a highly strung, quasi-neurotic temperament." He throws out the suggestion that this would be a profitable subject of study by American gynecologists.

The Dispensary Abuse in London appears to be as aggravated and aggravating as it is here, if we may judge from the plaint of a correspondent of the *Medical Times and Hospital Gazette*. He writes: "A patient of mine, who holds a good position, was thrown from a trap when out driving recently, and received a severe scalp wound. He was taken to the nearest hospital and his injuries were attended to, and when sufficiently recovered he was sent home in a cab. Instead, however, of being told to send for his regular medical attendant as soon as he reached home, as he would have been told when I was a hospital dresser, he was requested to return to the hospital on the following morning. He has continued to attend the hospital almost daily since, being driven to the institution in a cab, which waits to take him back to his place of business. In order that he may not be kept waiting for any length of time, he has, I believe, to tip the porters, and it may be that he tips every one all round, as he is mightily generous and liberal to every one but his poor outraged doctor."

Therapeutic Hints.

Treatment of Constipation.—1. With regard to the prophylaxis of constipation, we should abstain from administering cathartics in slight transient disturbances of digestion; rather let nature take its own course. Never put a patient on a one-sided diet for too long a time; the exclusion of vegetables, fruits, and starchy foods in general, from the diet is frequently the cause of marked constipation. A hygienic mode of living, regular habits, less business strain and worry, and more out-door life and exercise are of greatest importance to prevent constipation. 2. The treatment of habitual constipation will be composed of the following factors: (a) Of the just mentioned hygienic mode of living. (b) Of correcting a faulty diet; increasing the amount of vegetables, fruits, starchy food, and also fats (butter). (c) Of impressing the patient with the importance of not worrying and not bothering much about his bowels. (d) Of training the patient to have an evacuation once a day at a certain time, either giving no drugs whatever, or administering a very slight cathartic for a short period, then gradually diminishing and ultimately discontinuing its use.—DR. MAX EINHORN, *Post-Graduate*.

Elixir of Peptonate of Iron.—

R Chloro-peptonate of iron.....	100 gm.
Alcohol, 90%.....	150 "
Simple syrup.....	450 "
Distilled water to make one litre.	
Aromatize at discretion.	

—*Rev. Intern. de Méd. et de Chir.*, September 25, 1896.

Tellurate of Sodium ten to twenty centigrams, and alcohol fifty grams, makes a solution of which a teaspoonful may be given in sweetened water morning and night in the night sweats of phthisis. Dr. Joguet says it was successful in sixteen out of twenty cases.—*Lyon Méd.*, September 13, 1896.

Typhoid Fever.—Dr. Bignami employed phenacetin to the exclusion of all other treatment in two hundred cases of typhoid fever, out of which number there occurred but six deaths. In the first week three grams per diem were administered in six doses. In infants and old persons the dose was reduced to two grams. He considers that by this treatment the symptoms were reduced to those of a simple gastric fever.—*Gaz. d. Osped.*, No. 35, 1896.

Régime During Pregnancy.—Dr. Eichholz (*La Rev. Méd.*, May 16, 1896) believes many complications accompanying and following pregnancy are due to errors of régime. While pregnant the woman should avoid excesses of water and albumin; the one causing excessive development of the fœtus, the other giving rise to an excessive secretion of liquor amnii. Based upon twenty-five observations he prescribes the following régime: Fresh meat once daily in small quantity; green vegetables, salad, potatoes, bread and butter. Avoid eggs as much as possible, peas and beans. Wine, beer, and alcohol are forbidden, and only enough liquids should be taken to allay thirst. The advantages are: 1. Activity is preserved up to time of delivery; sensations of fulness, fatigue, thirst, and constipation disappear early. 2. Rapidity and facility of deliverance even in cases in which previously it has been difficult. 3. A limited quantity of amniotic fluid. 4. Possibility of nursing offspring, the milk being of good quality and quantity. The medium weight of the children was six pounds and the circumference of the head thirty-three to thirty-four centimetres.

Anal Pruritus, pure and simple, is treated by Brocq in the following manner: 1. An alimentary regimen of the most strict order and avoidance so far as at all possible of all overexertion. 2. Regulate the passages, and before going to stool cover over the margins of the anus with pure vaseline or cold cream. 3. Wash the painful points morning and night with a decoction of coca leaves as hot as can be borne and to which has been added a solution of phenic acid in glycerin. 4. Keep the anus constantly powdered with a mixture of talcum and oxide of zinc. 5. Every third day apply a five-per-cent. solution of nitrate of silver. 6. In case of very severe attacks, take at dinner time and on retiring fifty centigrams of antipyrin. 7. Give hot sedative douches or apply static electricity.—*Journal des Praticiens*, March 21, 1896.

Obesity.—An obese patient consulted his physician in reference to the treatment of his obesity, and was given the following advice: "Eat three francs' worth a day; but earn the money, and you will get thin."—*Lyon Médicale*.

[An American physician of note gave similar advice to a dyspeptic: to saw wood for a living, and live on the proceeds.—ED.]

Bromoform, in dose of half a gram in capsule, four or six times daily, is found efficacious in chronic bronchitis, pneumonia, and especially in emphysema and the attacks of asthma associated with this condition.—STEPP.

Vomiting of Pregnancy, in three cases in which it was severe and persistent, was quickly relieved by ichthyol tampon applied against the neck of the uterus.—DE LA TORRE.

Pharyngeal Diphtheria.—

R Atropine sulphate.....	0.045
Cocaine hydrochlorate.....	0.75
Bitter-almond water	300.00
M. S. One drop every hour for each year of the child's age.	

For adults, according to the patient's constitution and the severity of the disease, from ten to fifteen drops every hour. The frequency of administration is important, and at first it should be kept up even at night; consequently great care is necessary on the part of the nurse.—ELSAESSER, *Therapeutische Monatshefte*.

Nervousness and General Malaise.—Especially recommended at the period of the menopause:

R Ammonii bromidi	3 ij.
Sodii bromidi	3 iv.
Spt. ammonii aromat.....	3 vi.
Aque camph.....	3 vi.
M. S. Tablespoonful every four hours.	

—PARVIN.

Balsamics should not be used in the acute stage of bronchitis, as they can at this period only irritate the already inflamed mucous membranes. Congestion of the respiratory passages has often been seen to follow a too free administration of syrup of tolu.—GINGEOT.

Phthysical Sweatings may be treated by crystallized acetate of lead, of which one decigram is given in pill form twice daily. This may succeed after atropine, white agaric, tribasic phosphate of lime, camphoric acid, and hydrastis canadensis have failed.—*Journ. des Praticiens*.

Hydriodate of the Iodate of Quinine has been found by Assaky (*La Presse Médicale*, September 12, 1896) beneficially to influence in a brief period the local condition and cause prompt disappearance of the lesions in fourteen cases of syphilis associated with paludism. The author does not know if it would be prudent to subject such patients to a lengthy exclusive

course of this drug, but that it is capable, probably by reason of the iodide, of causing the secondary and secundo-tertiary lesions to disappear seems positive. It is administered in pills containing twenty-five centigrams, of which from eight to twelve are given daily.

Thyroid in Middle-Ear Disease has given Dr. Vulpius (*Le Scalpel*, September 27th) such encouraging results as to lead him to continue its use. He was led to employ it by the favorable results upon the hearing in myxœdema patients with sclerosis of the middle ear, in whom the thyroid was being employed.

Gall-Stone Colic.—In one case nitroglycerin had a promptly beneficial effect attributed to the paralyzing action upon unstripped muscular fibre.—TURNBULL, *Lancet*, February 8th.

Methylene Blue, in daily divided dose of ten or twenty centigrams, relieves, after three or four days, hyperchlorhydria and other nervous troubles of the stomach, such as gastralgia and hyperæsthesia of the mucous membrane.—BERTHIER.

Arterio-Sclerosis is itself improved by tepid baths, as well as the affections which accompany it, such as gout, chronic rheumatism of the muscles and joints, arthritis deformans, and neurasthenia.—GROEDEL, *Gaz. hebdom. de Méd. et de Chir.*, September 13, 1896.

Paralysis Agitans.—

R Strychnine sulphat. gr. i.
Acid. arseniosi gr. ij.
Ext. belladonnæ gr. v.
Quinine sulphat. ℥ij.
Pil. ferri carbonat. ℥ij.
Ext. taraxaci ℥i.
M. et ft. pil. No. xc. S. One pill three times a day.
—S. W. GROSS.

Sick Headache.—

R Sparteine sulphate. 0.02 gm. ($\frac{1}{2}$ gr.).
Caffeine. 0.1 gm. ($1\frac{1}{2}$ gr.).
Antipyrin 0.5 gm. ($7\frac{1}{2}$ gr.).

Taken at intervals of two hours until four have been taken, even though the pain has disappeared.—ARTZMAN, *Presse Médicale*.

Antipyrin and Calomel.—Dr. J. Schuh, of Munich, claims that the mixture of antipyrin and calomel in the quantities usually prescribed causes in the stomach juice the formation of corrosive sublimate in sufficient quantity materially to exceed the maximum dose of this chemical.

Chronic Diarrhœa and Dysentery.—

R Sulphate of copper. gr. i.
Sulphate of morphine gr. i.
Sulphate of quinine. gr. xxiv.
Fl. pil. No. xii. S. One t. i. d.

Chronic Pyelitis.—Dr. A. Robin uses the following when pain is present:

R Venice turpentine ℥ iss.
Powdered camphor. ℥ iss.
Extract of opium gr. v.
Extract of aconite root. gr. iij.
Mix and make into twenty pills. S. One pill to be taken every eight hours, and at the same time a small glassful of infusion of uva ursi, slightly sweetened.
—*Le Progrès Médical*.

Ointment for Rheumatic Joints.—

R Salicylic acid,
Oil of turpentine,
Lanolin. āā ℥ iiss.
Lard. ℥ iij.
—*Journal des Praticiens*.

Citric Acid in Diphtheria.—Ten-per-cent. solutions are given every two hours in dose of teaspoonful to dessertspoonful. Within twenty-four hours in slight cases the false membranes cease spreading and begin to detach themselves. In one hundred and fourteen cases, thirty-one of which were severe, the mortality was 9.6 per cent. Of the eleven patients who died, five had been brought into the hospital from four to seven days after the début of the affection.—BLOCH, *Deutsche med. Zeit.*

Heart Disease.—

Alcohol 10 gm.
Syrup ipecac compound. 100 gm.
Syrup opium. 100 gm.
Syrup cherry-laurel 190 gm.
Mix in the order indicated to obtain a clear mixture. Dose, three or four tablespoonfuls daily, between meals.
—ROLLAND.

Vaginitis.—The following combination is made use of at the Vanderbilt Clinic:

R Pulv. alum,
Zinci sulphatis,
Sodii biboratis,
Acidi carbolic. āā ℥ i.
Aq. ℥ vi.
M. S. A tablespoonful to a quart of lukewarm water as a vaginal injection, twice daily.

Iodoform and Diiodoform are after all found to be much more active than any succedaneum of the many so far proposed, none of which can replace iodoform completely.—STOKVIS.

Borax does not seem sufficiently efficacious in epilepsy to warrant its use, especially since, if long continued, it has an injurious action upon the kidneys.—CLAUS, *Belgique Méd.*

Simple Goitre.—In a case showing no improvement from the iodine treatment a rapid cure was effected in a man of forty-four years by the use of glycerin extract of the thyroid body. From one to one and a half teaspoonfuls were given daily, each teaspoonful representing thirty centigrams of the fresh organ.—SABRAZES ET CABANNES, *Gaz. Hebdom.*, No. 28.

Syphilis Cured by Thyroid.—In a patient whose condition did not improve under mercurial treatment, but in whom ecthymatous and ulcerating lesions appeared in the early secondary stage, destroying the alæ nasi and portions of the ear, Dr. Gouladsé (*Pratch*, No. 30, 1895) administered two grams of beef thyroid cut into small pieces and triturated, subsequently increasing the daily dose to as much as fourteen grams.

After the third day improvement was noted, and at the end of five months all the phenomena had disappeared. During the first days of administration there were nausea, palpitation, trembling of the upper extremities, and pulse running up to 120 beats. Just how the thyroid is supposed to exert its beneficial action in such a case is not stated.

Lichen.—In a girl of ten years thyroid tablets in dose of two daily caused at first an increase in the pruritus and desquamation, but the plaques became paler. When four tablets per day were given, headache and vomiting supervened. When six tablets were given the eruption became less marked and finally disappeared entirely. The urine contained some sugar but no albumin.—KISSEL, *Gaz. Hebdomadaire*, October 8th.

Gelsemium in combination with belladonna or morphine, or both, greatly increases their anodyne powers. As a relaxant, in rigidity of the os uteri and sphincter perinaei, and in puerperal convulsions, dysmenorrhœa, and nausea and vomiting in pregnancy, it will be found of great value. In after-pains it will be found a valuable substitute when opium is not tolerated.—ROOP.

Hæmoptysis.—When blood is vomited it is important to discover its source, but if large quantities are being lost we may treat the symptom first and make an accurate diagnosis afterward. Place the patient in a quiet position and forbid movement. Raise the head and place mustard plasters upon the lower extremities. Give pieces of ice to suck, and if it is possible let the patient take a teaspoonful of ether in a little sweetened water. Above all give a hypodermic injection, deep into the muscle by preference, of the following solution:

R Ergotin (Yvon)	5 gm.
Morphine chlorohydr.	0.04 cgm.
Antipyrin	1.50 gm.
Sparteine sulph	0.20 cgm.
Atropine sulph	0.002 mgm.
Aq. dest.	q.s. ut ft. sol. 10 c.c.

This injection may be repeated, giving a syringe-ful every half or quarter hour until four or five have been given. If the patient can drink he may be given every hour or every half-hour a soup-spoonful of the following potion:

R Ergotin (Bonjean)	2. gm.
Acidi gallici.	0.5 gm.
Syr. terebinthinæ	120 gm.

—CAPITAN, *La France Méd.*, September 25, 1896.

Pilocarpine in Bright's Disease.—It has been established, and cannot be controverted, that pilocarpine is a marked cardiac depressant and a dangerous remedy to administer in uræmia; that its sphere of usefulness is but a limited one; that it should be banished from our therapeutics of Bright's disease, and that its application should be relegated to another sphere.—PROBEN, *New York Medical Journal*, July 18, 1896.

Ringworm in Institutions.—Strict isolation of actual and suspected cases is called for. Clippers should not be used for cutting the hair of any inmates. Ringworm patients should have the hair cut close or the scalp shaved at frequent intervals. Scissors should be sterilized after use. Epilation should be done only in limited patches and then done thoroughly by a trained assistant. Bichloride solution, 1 to 500 up to 1 to 100, can be used for washing the scalp when it is free from open lesions. The best anti-parasitic remedy employed in this affection is chrysarobin, which gives an efficient and prompt result. Care must be exercised that the face and eyes do not become irritated. A caoutchouc cap can be worn or the drug

can be incorporated in collodion or traumaticin. Occlusive dressings have the advantage of shutting out air, which would seem to favor the growth of the fungus. Another formula used was nitrate of mercury and ichthyol, each one drachm, and collodion, one ounce. When seemingly well the patient must be kept under surveillance for a time before being allowed to mingle with the other children. Close cutting of the hair and careful examination is recommended upon admission to hospitals, asylums, etc.—ALLEN, *Pediatrics*, August 15, 1896.

Xeroform is a tribromphenol bismuth and is intended to replace iodoform. It is not toxic, has neither taste nor odor, and does not irritate skin or mucous membranes. It unites in itself the properties of phenol and bismuth, being bactericidal, antipruritic, and a moderator of secretions. It is not only an intestinal antiseptic of great value but also a topical dressing for wounds inducing cicatrization. Not decomposing at 120° F., it may readily be sterilized.—HEUSS, *Therapeutische Monatshefte*, No. 4, 1896.

Lupus Erythematosus.—Good results were obtained by the local application twice daily of Fowler's solution diluted four to six times. After six days there was local reaction in the form of tumefaction, in which case it is well to apply an indifferent ointment. In nine cases thus treated cure was effected within the space of eleven weeks.—SCHULTZ, *Gaz. Hebdomadaire*, October 8th.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, October 19, 1896.

JOSEPH E. JANVRIN, M.D., PRESIDENT, IN THE CHAIR.

The Treatment of Follicular Abscess of the Fossa Navicularis with Attendant Fistula.—DR. CHARLES H. CHETWOOD read the first paper of the evening. He said the condition of which it treated was not infrequent, and was difficult to cure. The cases of follicular abscess of the fossa navicularis could be divided into three classes: 1, those with abscess and blind internal fistula; 2, those with abscess and blind external fistula; 3, those with abscess and complete fistula.

The etiology of all these varieties was the same, being an extension of inflammation during an acute urethritis or traumatism. There was a certain amount of purulent discharge, especially on pressure upon the meatus, the fluid escaping internally or externally according to whether the fistulous opening leading to the abscess was internal or external. The treatment commonly resorted to or recommended was surgical, opening the fistula, packing, or scraping and suturing. But this did not always effect a cure, and might make a complete fistula which was difficult to heal. The method which the author employed in all cases had failed in none. It consisted of injecting a little of a twenty-five-per-cent. ethereal solution of peroxide of hydrogen, called pyrozone, into the abscess at intervals of a few days several times until the secreting surface healed. The injection was made with a glass pipette having a bent and very fine opening. Cocaine was used for local anæsthesia at the first and possibly subsequent sittings. Six to eight weeks was long enough to effect a cure of the most obstinate case.

DR. H. F. NORDEMAN had seen all sorts of follicular abscess of the fossa navicularis, had found it rarely

necessary to slit it up, and had been able to cure the cases by what he regarded as a simpler method than that described in the paper. It was to curette the follicle.

Cardiac Disturbances from Gastric Irritation.—DR. HENRY ILLOWAY read the histories of three patients, two women and one man, who had suffered one or more attacks of cardiac embarrassment which he suspected to be due to gastric irritation, the treatment confirming his diagnosis. One of the women had attacks of despondency, was pregnant five months, and had been told by her physician that she had heart disease. The apex was somewhat pushed up; at times there was a blowing sound, which, however, he believed to be extracardiac, or at least not valvular and not the ordinary anæmic murmur. Like the other two patients, she abused her stomach. On relief of gastric irritation her symptoms disappeared, she had an easy labor, and subsequently no signs of cardiac trouble could be discovered. In the case of the man it took longer to overcome the gastric irritation and control his faulty methods of eating, but after a time all symptoms attributed by another physician to heart disease disappeared. The explanation suggested was irritation of the gastric fibres of the pneumogastric transmitted centrally and back through the cardiac fibres, the effect on the heart being the same as if there were originally a central irritation.

DR. ROBERT NEWMAN was reminded by the paper of some post-mortem examinations which he had made in coroner cases as far back as 1867. They were four in number, all had died suddenly, with a feeling of uneasiness and the development of cyanosis. No disease of the heart nor of the brain could be found—nothing but a stomach filled with a large amount of debris of recent ingestion. If they had been given an emetic and the stomach relieved of its contents they might not have died.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, October 20, 1896.

REYNOLD W. WILCOX, M.D., CHAIRMAN.

Effects of Treatment of Enteric Fever with Cold Tub Baths.—DR. W. GILMAN THOMPSON read a paper on this subject, based on a personal experience with the bath in some two hundred and fifty cases. Every three hours, if the patient's rectal temperature rose over 102.5° F., he was lowered, covered with a cloth, into water of a temperature of 72° F., was rubbed while in the water, removed after fifteen minutes, covered with a blanket immediately, dried, and rubbed. It was sometimes best to omit the bath in the early morning hours to avoid possibility of exhaustion. The object of the rubbing was to apply friction over a large cutaneous surface, stimulate the nerves, and diminish the shivering and discomfort. It also served to pass the patient's time and divert his attention from the cold. Dr. Thompson said he had been familiar with the old method of applying cold and was prejudiced against the new or Brandt method until Dr. Peabody had taught him to carry it out systematically, since which time he had been its advocate and had submitted to it himself when he had typhoid fever. The bath should be preceded half an hour by half an ounce of whiskey. No time should be lost in drying the patient on removing him from the bath, and the limbs, back, and chest should be rubbed immediately. He should then be allowed to sleep. Usually he micturated after the bath, for the treatment induced diuresis.

The bath was in nowise curative in the sense that medicines were. It was a strong stimulant, mechanical and thermic, to the nervous system, and, as was well known, enteric fever was pre-eminently characterized by depression of the central nervous system. It was not a question of reducing the temperature, for there were many cases in which the temperature did not fall more than half a degree after the bath, yet delirium disappeared, the tongue became clean, the pulse improved, the action of the kidneys and bowels became more nearly normal—all in striking contrast with what was seen when the expectant plan was pursued. The average reduction of the temperature while the patient was in the bath was from two to two and a half degrees.

While in this country we did not get as good results from the Brandt treatment as were claimed for it in Europe, still they were very gratifying. Our patients did not enter the hospital as soon as those did abroad. The average death rate given by Osler, Wilson, and others in this country was about 7.25 per cent. At the Presbyterian Hospital in this city there had been two hundred and eighty-four cases treated by different methods since 1892, only one hundred and ninety-three of them by the Brandt method. But many of these were severe cases, and the death rate was nearly as great as from other methods. But if the cases were analyzed as they should be, then the death rate from the Brandt treatment in the Presbyterian Hospital would be about 7.25 per cent., corresponding with that in other hospitals in this country. There had been relapses in 13.5 per cent. of the cases, somewhat more than under the other methods of treatment. It had been objected that the bath tended to nephritis, but he had seen nephritis as often when the bath was not employed. One of his patients was put into the tub one hundred and thirty-nine times, but the average number of times was fifteen to twenty-five. Pregnancy was not a contraindication. Dr. Thompson stated in his conclusions that the cold-bath treatment caused enteric fever to run a shorter and a milder course, reduced the mortality by one-half, and did not interfere with other modes of treatment. It did not prevent relapses nor the occurrence of ordinary complications.

Treatment of Typhoid Fever by Antitoxin and by Antiseptics.—DR. MORRIS MANGES was announced to read on other methods of treating typhoid fever, but for want of time confined his paper to the so-called specific or antitoxin treatment and the antiseptic treatment. Were we, he asked, in a position to pass final judgment upon any treatment of this disease, whether hydrotherapy, antiseptic, or antitoxin? He thought not. While it was generally believed that the cause of typhoid was a bacillus, yet it was not settled whether it was due to the typhoid bacillus alone or what part might be taken by the colon bacillus, whether it was a local effect or whether toxic. One must distinguish between the bactericidal and immunizing power of the blood. It had been shown that the blood serum of persons who had had typhoid fever retained immunizing properties a long time, but not beyond ten years. Experiments had been made on animals with sterilized cultures of typhoid bacilli and with the serum of immunized animals and persons, but little had yet come from it clinically. As to intestinal antiseptics, Stern and others had shown that they were not effectual even on micro-organisms less resistant than the typhoid bacillus. Among those mentioned were, after rectal enemata, the administration of calomel, corrosive sublimate, salol, etc. The author had tried corrosive-sublimate enteric pills, as recommended by Waldstein, and which did not melt unless the intestinal contents were alkaline. The use of the pills had been followed by improvement of the general condition, the stools became less offensive, and the amount

of indican in the urine was diminished; but this had been only one part of the treatment.

Tubbing Preferred—Experience with Other Methods.—DR. FRANCIS DELAFIELD said that to his mind the tubbing treatment of typhoid fever was altogether the best which we now had. In employing it one did so for the disease and not for the temperature. Do not wait for an excessive rise of temperature. But it must be admitted that the bath treatment was absolutely impossible for a considerable number of patients. Therefore we had to look around for some other method, and this was a good time while the mortality rate from typhoid in New York was low. His own experience during the past winter was limited to thirty cases with the Woodbridge treatment, carried out literally at first, afterward in modified form. The modified form consisted in continuing only the calomel and carbonate-of-guaiacol ingredients of the pill, and of these he gave one-twentieth instead of one-sixteenth grain of calomel, and five instead of three grains of carbonate of guaiacol. Later, finding that calomel given so frequently was producing sore mouth, he substituted for it drachm-doses of sulphate of magnesium and continued the guaiacol. He could see no particular change in the patients under the different methods. Of the thirty patients, four died, two of them at least plainly from the disease and not from complications. Seventeen were convalescent in three weeks, and none had a relapse. While the figures seemed to speak well for the treatment, yet, when at the end of the winter he came to analyze them, he concluded that, although in the mild cases the duration of the disease might have been shortened a little, in the severe ones there had been no influence. It was not at all probable that the drugs would at all diminish the mortality of the disease.

Tubbing a Doctor.—DR. A. B. BALL thought the reason why the doctors at Bellevue, including himself, had given up the bath treatment some years ago was that they did not employ rubbing. Everybody who had tried the more recent method, and for which we were indebted to Dr. Simon Baruch, adding friction, had been convinced that there was no other method at command which was so valuable. When he had attended Dr. W. G. Thompson he observed the gasping for breath which the bath produced, and remarked then that the influence upon the respiration, causing deep inspiration, must be among the most beneficial effects. With women he had continued the treatment during menstruation, and it had received the approval of some of his gynecological friends whom he had consulted about it. With some patients it might be best to give the bath at 85° or even 90° F. The great mistake was to suppose that it was intended simply to reduce the temperature. Some believed a high temperature was beneficial in typhoid, tending to kill bacilli.

DR. W. P. NORTHRUP said the beauty about the bath treatment of typhoid cases was, to quote Dr. Delafield, that they ran such a comfortable course. He had applied it in all cases for three successive autumns at the Presbyterian Hospital, except in a few cases in which at the strong recommendation of a doctor in the city he allowed Fraenkel's toxin to be tried. These patients, although recovering, suffered such great discomfort from their disease as long as the baths were withheld that he made up his mind, if he were forgiven for thus allowing them to suffer, never to repeat the offence. He thought in some cases it might be well to devise a means of applying warmth to the extremities during the cold bath, as they did when sponging scarlet-fever patients at Willard Parker's.

May Typhoid be Aborted?—DR. LOUIS WALDSTEIN referred to the fact that Dr. Manges seemed to doubt whether typhoid could be aborted. German clinicians like Wündelrich and Friedreich had insisted

for years that it was possible to abort this disease, and they resorted to calomel. The difficulty was to say that a patient who got well after three doses of half a drachm of calomel had had the incipient stage of typhoid. All of us had seen cases of continued fever, with more or less coated tongue, headache, backache, general malaise, with or without intestinal symptoms, with or without indication of tumor in the splenic region, cases which seemed to be tending toward typhoid. He had seen quite a number of such cases, had always thought it was possible they were cases of beginning typhoid, and had at once put them upon liquid diet and given them calomel. They were closely watched, and within a week or less were well. But a few cases, after remaining well two or three weeks, became ill again and had real typhoid fever. Was it not possible they had typhoid in the first attack, that this was aborted, and that the second attack was simply a relapse?

DR. NEWTON, of Montclair, N. J., had seen pneumonia rapidly clear up under large doses of calomel. This was in accord with the teaching of the late Dr. Leaming. If pneumonia could be cleared up under calomel, why might not some cases of typhoid fever? If we should live to see the diagnosis of typhoid made as it was in diphtheria, we could tell more about the effect of treatment. In the army he had seen many cases of so-called mountain fever, which autopsy proved to be typhoid with intestinal lesions. The origin was not clear. He had used calomel and thought he had aborted an occasional case of typhoid, and he had seen such favorable results as had been attributed this evening to the cold bath—clearing up of the tongue, disappearance of tympanites, etc. It was not necessary for an antiseptic to kill all of the germs of a disease to be of benefit.

Condemns the Cold-Water Treatment.—DR. A. P. DUDLEY had passed through two epidemics of typhoid fever, and treated quite a number of cases, more than ten, fifteen, or twenty; he had lost none, but he had not employed the tub bath. He held that this had no anatomical or physiological basis relative to typhoid fever. The disease depended upon germs in the intestinal tract, their multiplication, and the production of a poison. The scientific treatment was eliminative. The bath did not eliminate the poison; it subjected the patient to unnecessary shock and endangered the heart, whose muscular fibre was weakened by the disease. It was well known that death in this disease was usually attributed to heart failure. The treatment which had proven so successful in Dr. Dudley's hands was citrate of magnesium, to wash out the intestinal tract. He did not hesitate to move the bowel two or three times a day if necessary. The patient took two or three quarts of milk a day, and was given quinine and nux vomica to keep the heart going. Within a year one of his friends died in a German town under the Brandt treatment, he being one of two who died out of twenty-four patients so treated.

DR. SIMON BARUCH upheld the Brandt treatment, and pointed to the charts shown by Dr. Thompson as proof that the bath was the best heart tonic. The temperature fell and the heart's action always became slower and stronger. Further, the bath was eliminative, for the urinary secretion was increased and with it the poisons in the circulation. The great bugbear was shock, but there could not be reaction without shock, and reaction was wanted for its stimulating effect.

DR. THOMPSON confirmed the statements made by Dr. Baruch in response to Dr. Dudley's assertion that the bath was not eliminative and was weakening to the heart. Dr. Manges also made some closing remarks.

The Phonendoscope.—DR. MANGES presented a

phonendoscope, the device of an Italian physician for increasing the normal auscultatory sounds of the organs of the body and also the percussion note.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, October 26, 1896.

E. D. FISHER, M.D., PRESIDENT, IN THE CHAIR.

Report of the Treasurer.—DR. JOHN S. WARREN read his report as treasurer, by which it appeared there was a balance of \$1,745. The disbursements for the year had been \$5,894.

Report of the Committee on Ethics.—DR. T. E. SATTERTHWAIT, chairman, read the report. Eight cases of alleged violation of medical ethics had been presented by members and others. In one case the committee advised that the attorney prosecute the offender, if satisfactory evidence could be obtained. In one it was advised that the offender be disciplined by the society. In two it was recommended that the consideration of the cases be deferred until matters relating to them had been adjudicated in the city courts. In four it was stated that the charges were not sustained. The report stated that the committee's efficiency would have been greatly enhanced and the labors of the *comitia minora* lessened, if the chairman of the committee on ethics had been a member of the *comitia minora*. The committee unanimously recommended that the constitution of the society be amended to that effect.

Report of the Counsel.—DR. SENECA D. POWELL read the report of the board of censors, or that part of it which embodied the report of the counsellor for the society. The total number of persons arrested during the year was seventy-three; the total number convicted so far was forty-six; the amount of the fines imposed was over \$3,000.

The committee on prize essays reported through its chairman, DR. W. H. KATZENBACH, that but one essay had been received, and, while it was deserving of favorable mention, the committee thought it was not worthy the prize.

Report of the Committee on Hygiene.—DR. J. W. BRANNAN read the report. The committee had co-operated with some of the city departments in promoting the public health. It was thought that better arrangements had been made for night lodgers, those out of work, and tramps than had formerly existed. Through the board of health an effort had been made to stop expectoration in cars and public buildings. It was thought that within a year a building would be set aside, on Blackwell's Island, for tuberculous patients, thus separating them from others in public hospitals and placing them where they could receive the advantages of any improved methods of treatment. DR. E. S. PECK, a member of the committee, contributed that part of the report relating to contagious ophthalmia in the city. The State law bearing on the subject had had a more or less wholesome effect.

Amendments to the Constitution.—Amendments to the constitution were adopted, permitting the election *via voce* of members recommended by the *comitia minora*, except when three members asked for a ballot. A two-thirds vote would elect. Also the chairmen of standing committees were made members of the *comitia minora*, but the chairmen of the committee on ethics and of the committee on hygiene were to have no vote.

Remarks on Some of the Practical Phases of the Leprosy Question.—DR. PRINCE A. MORROW read a

paper with this title, and threw on the screen lantern slides of leprosy and other diseases. The term leprosy had crept into our literature as standing for all that was most foul and unclean. If a leper were seen at large, the public press set up such a clamor that he must be immediately isolated. Quarantine of this disease meant imprisonment for life, as practised in this city. Tuberculous patients were not quarantined, yet they were far more numerous, and the danger of spreading the disease was far greater than in the case of leprosy. For a given number of years in New York there had been sixty thousand deaths from tuberculosis to two deaths from leprosy. There was no surveillance of syphilis, yet the danger of its propagation was immensely greater, and the number of cases, even of repulsive external lesions, far exceeded those of leprosy. Indeed, there were many other diseases, as was shown by the photographs, which were more repulsive than most cases of leprosy. In New York there was no disease which granted its victims so long a lease of life; there was no instance here in which it was known to have been communicated to another person; yet because of the public clamor the board of health had felt itself compelled to quarantine leprosy patients, which really meant imprisonment for life. DR. MORROW had three cases under observation, in one the disease being of twelve years' duration, in the other two of seven years'. In one there had been apparent cure; in the other two the patients were not worse than when he first saw them. While leprosy was a contagious disease, he believed the degree of contagiousness was influenced by climate and other local conditions, so that in New York there was no known instance of contagion. What should be done with leprosy in New York? As it was almost exclusively a disease of exotic origin, it might seem the easiest solution of the problem to return the patients to the country whence they had come; but this had been found impractical in most instances. As already stated, to send them to North Brother Island was practically to imprison them for life—a punishment which was assigned only to desperate criminals after due trial. If they were isolated, it should be by the State or nation in colonies, with such surroundings and conditions as were adapted to their needs, not unduly restricting their liberty and giving them the advantages of any improvement in treatment.

DR. G. H. FOX felt that it was unnecessary for him to add anything to what DR. MORROW had said. He had expressed similar views some years ago, and they had not changed. In New York the chances of leprosy being conveyed to the healthy were extremely slight. The danger in some other countries was much greater. He would rather live in a hospital for lepers here than to travel through certain countries where leprosy was common, so far as the risk of contracting the disease was concerned. Here the rights of lepers should be maintained. He did not believe there was any danger to the public from allowing them their freedom.

An Outrage.—DR. GEORGE B. FOWLER said the interest which he felt in leprosy dated from the moment that he took office as health commissioner, when he found five lepers on North Brother Island, confined, disfranchised, restricted in their mode of life, feeling that they were going to die, in every way subdued. Although knowing then but little about leprosy, he felt that it was an outrage and wrote for information to noted specialists in this country and abroad as to the contagiousness of leprosy in our climate. Backed by the answers received to those communications and by the opinions expressed to-night, he felt that these men ought not to be deprived of their liberty, and he proposed to release them. They were an expense to the city, and, since confinement meant imprisonment for

life, it was a question whether the community had a legal right to quarantine them.

DRS. C. W. ALLEN, A. Y. REID, and J. A. IRWIN asked some questions regarding the comparative contagiousness of leprosy in New York and other countries, and expressed doubt as to the propriety of the society adopting a resolution at once approving of setting at liberty the lepers on the island, until a committee had investigated and reported on the subject. It should be remembered that the action of New York would be looked to as an example for the rest of the country. Dr. Reid made a motion, which was amended by Dr. Irwin, providing for the appointment of such a committee, with Dr. Fowler as chairman.

DR. JOHN A. FORDYCE gave a lantern-slide exhibition of some rare and interesting forms of skin lesions, including rare cases of lupus erythematosus, multiple epithelioma, multiple fibroma, papillomatous tumors of various parts of the body, psoriasis, rupia, etc.

The annual dues were continued at \$3.

Correspondence.

HAS MACKENRODT ABANDONED VAGINO-FIXATION?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am so frequently asked the question: "Is it true that Mackenrodt has abandoned vagino-fixation?" and I am so frequently confronted with the statement in print that he has done so, that I beg the indulgence of a short space in your valuable and extensively read journal to place the matter before your readers in its true aspect.

To the question of the abandonment of vagino-fixation by Mackenrodt, I will now give the same answer I have given before, notably in a discussion before the obstetric section of the Academy of Medicine, on February 27, 1896, called forth by a series of papers on the indications for Alexander's operation, ventral fixation, and vaginal fixation, by Dr. Paul F. Mundé, Dr. G. M. Edebohls, and the writer, respectively. I stated then (not exactly in the same phraseology) that Mackenrodt had not discarded vaginal fixation any more than Edebohls, Cleveland, and Kellogg had given up Alexander's operation because each of them had changed the technique from time to time; nor any more than Howard Kelly had abandoned ventro-fixation because he had modified very materially his method of operating. I stated that Mackenrodt had not given up vagino-fixation, but had modified the technique, baptizing the modification by a new name, "vesico-fixation" which he considered an improvement upon his former technique. The ventro-fixationists have followed a similar procedure in labelling their modification ventro-suspension of the uterus. I am not finding fault with these actions, but merely wish to draw attention to the analogy between the two courses, and to emphasize the circumstance that, though the name be changed, the underlying principle remains the same—in the one instance the fixation or suspension of the uterus carried out through a vaginal operation, in the other through an abdominal one. Be this as it may, let us hear what Mackenrodt himself has to say in reply to a feuilleton by Flaischeln, in the *Monatschrift für Geburtshilfe und Gynäkologie* (Bd. II., Heft 5, November, 1895), in which it was stated that vagino-fixation had been condemned by the Berlin gynecologists. Mackenrodt's reply appears in the same journal for January, 1896. (Be it remembered this was subsequent to the publication of the cases of dystocia in vagino-fixation, in which a faulty technique had been followed.)

"The gynecologists who took part in the discussion

(Berlin Gynecological Society) were divided in two groups, one group consisting of men who discussed the subject in a purely objective manner, from their own experiences, and who, like myself, passed a favorable opinion upon the operation, and who would not think of discarding it. To this group belonged A. Martin, Wendeler, G. Winter, and Kossman, while Olshausen assumed an entirely unpartisan attitude and considered the technique of vagino-fixation as not yet closed. Even J. Veit, on the whole, considered the operation as a triumph (*segenreich*), and that it should not be allowed to fall into disuse. The second group of speakers were those gynecologists who, from the very first, expressed an unfavorable opinion of the operation, and who had little or no experience with it. To this group belonged Flaischeln, Paul Ruge, and Bokelmann, whose remarks partook more of a personal attack than of a scientific discussion upon an important subject."

To the unbiased person the above must be conclusive evidence that Mackenrodt has not abandoned vagino-fixation, and that the operation has not met with general condemnation in Germany. On the contrary, every one concedes its value, no matter which technique is followed, in cases in which pregnancy does not come into consideration; and there is a growing tendency in its favor even in fruitful bearing women, when a certain technique is employed. Of my own experience with the operation, and of the modifications that I have from time to time adopted and devised, I forbear to speak, as I have written of them on former occasions. This much I may add: that I have not as yet met with any accidents during gestation and labor, and there have been five cases of labor in my patients; that I am well pleased with the results; and that the solicitude expressed by Edebohls for the welfare of the women in this city on whom vagino-fixation had been done has thus far proven to be a waste of sentiment.

HIRAM N. VINEBERG, M.D.

127 EAST SIXTY-FIRST STREET, October 15, 1896.

"A CASE OF HERMAPHRODISM."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: On my return from Europe I find in the issue for August 8th letters from Dr. Paul F. Mundé and Dr. William Keller on the case of "Hermaphrodisim," reported by me on July 25th. When I wrote that article I added an interrogation mark to the title; subsequent events, however, showed that I might have omitted it and let the case stand as the second in literature of true hermaphrodisim.

It is not surprising that so careful a searcher as Dr. Mundé should have taken scientific exception to my diagnosis, especially in view of the extreme rarity of such blending of the sexes. But Dr. Mundé labored under the disadvantage of distance. Had I been favored by his presence at the operation, his letter would never have been written. He would then have seen and felt the uterus, as did those of our colleagues who were present at the removal of the testicles that had been retained and which had undergone sarcomatous degeneration.

Again must I deplore Dr. Mundé's absence from the laparotomy, as he would then not have said that I missed the "glorious opportunity" more thoroughly to examine the female reproductive organs contained in this male (?) subject. Even had my colleagues not urged me, I would have been driven by the hemorrhage, the pulseless condition, and the cessation of respiration to close the abdomen as quickly as possible, after the removal of the testicles from their many adhesions. I am more than confident that Dr. Mundé

would have justly reproved me for unnecessarily exposing the patient's life, had I deferred acting for the sake of scientific exploration. In my article these facts were alluded to. The presence of the testicles gives additional male aspect to the penis, which in its flaccid state measured more than two and one-third inches.

The patient acquired pneumonia eighteen days after the operation and died three days thereafter. The autopsy not only corroborated my statement in regard to the presence of the uterus, but showed also ovaries, tubes, and ligaments. Unfortunately, I being absent in Europe at the time of the autopsy, the attention of the gentleman who made it was not sufficiently called to this most important point and the ovaries were cut off. The tubes and ligaments, however, are so well preserved that even the mutilated specimen demonstrates the facts. If the patient had not died, I would have hesitated to say that I was positive in having palpated the ovaries, appreciating the hiatus left by the insufficient examination at the time of the operation. But had nothing but the presence of a uterus been proven, this case would have been an extraordinary one.

Dr. Mundé's well-known sense of justice and courtesy to his colleagues, is, I fear, put into a wrong light through the shortness of my clinical report. Now, having the specimen, I shall be able to write a fuller description of the case.

As to Dr. Keller's letter, I heartily agree that a much more extensive description would be of interest. A vast number of observations could have been made in fact, but I had intended to write only a clinical report, the limits of which forbade this. The microscopical examination was not only made by myself, but also by a prominent pathologist, who would not have been able to determine whether the tumors represented testicles or ovaries, as the tumor tissue had taken up all the normal structure, were it not possible to regard them as testicles on the basis of the facts described.

There was no enlarged clitoris, but a well-developed penis, as described in my article. The arrangement of the pubic hair was decidedly not feminine; it was not continued up to the umbilicus. According to a recent information, obtained through the kindness of Dr. F. G. Lusk, the patient was treated last year in a hospital of this city for syphilis, the initial lesion having been under the observation of Dr. Lusk.

CARL BECK, M.D.

HOW SPECIMENS OF URINE MAY BE SENT TO INDIA FOR DIAGNOSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The following letter which I received recently from a native physician in Bombay, India, will interest your readers. It presents gratifying evidence of the progress that urinalysis is making in that country in the interpretation of disease. But, more than this, it throws the door wide open for the interchange of professional courtesies between physicians in the United States of America and India in a unique way, by facilitating the safe sending of samples of urine from one country to the other. Now that the only difficulty in consulting Bombay experts has been removed, I have little doubt that "close-packed and properly sealed" bottles of urine will be exported from this country to India in numbers to compete successfully with "bottled Bass" from England.

The patient referred to in the letter was admitted to the New York Hospital last spring. The case was one of hysterical trance, and was well advertised in the papers for some time before admission and after-

ward. It was a "bonanza" for reporters of sensational newspapers, and the grossly exaggerated and absolutely false reports that appeared daily for some time were a disgrace to modern journalism. I was made to pose as an expert in the cure of hysteria by removal of the ovaries; to cap the climax the case was reported also in a Bombay newspaper, and then came the following letter:

"BOMBAY, INDIA, July 26, 1896.

"DEAR SIR: I was surprised to read in one of the local papers a report of a patient, Mrs. —, who is suffering from hysteria, and who is under your treatment. I, belonging to the medical profession, am naturally led to inquire into the details, and so I beg you to put down all the particulars. I want to know the real disease and to diagnose it properly if I can.

"I generally diagnose all the diseases by examining the urine; so will you be kind to send the patient's urine in a close-packed and properly sealed bottle to my address? The whole quantity of urine passed early in the morning just after getting up should be carefully collected and sent in the bottle.

"With this the history of the whole case will be very useful, if you can conveniently send it.

"Let me remind you that the bottle should be kept on ice in order to prevent decomposition.

"Hoping to be excused for the trouble

"I remain, sir, your obedient servant

"—————"

A. BRAYTON BALL, M.D.

NEW YORK.

CORRECTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In my recent article on "Preparation of Blood," etc., the formula for eosin solution should read one gram instead of "one grain," as given. Since the article was published I have received a large number of letters from different parts of the country, evincing a deeper and more widespread interest in hæmatology than I had any idea of. Despite the fact that Hayem has given us over a thousand pages about the blood, what we don't know about the subject would make a much bigger book than what we really do know. Nearly a century and a half ago Henry Baker ("The Microscope Made Easy," London, 1754) wrote as follows:

"We cannot employ the Microscope to any more useful Purpose, than to view the natural Course of the Blood within its Vessels, or examine the Texture of it when extracted from them: for the Preservation or Restoration of the Health of Man may be greatly advantaged by such Enquiries."

H. G. PIFFARD, M.D.

WHAT SHALL WE DO WITH THE LEPER?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have already claimed a small portion of your valuable space to discuss this question, and do so now again because of my sincere belief that, having strong convictions in the matter, it is my duty to express them. At the last meeting of the County Medical Society Dr. Fowler, commissioner of health, expressed his determination to turn out the lepers constituting the colony on North Brother's Island, believing that the disease is not contagious and hence not dangerous to the health of the community, and for the further reason that the New York board of health had no funds to apply to the purpose of maintaining a lazaretto. The commissioner asked the society to endorse this proposed action. I opposed the motion

made to this effect, because I did not think a leading medical body, such as the County Medical Society is known to be by the country at large, should endorse the view so unqualifiedly expressed that the disease is not contagious. No one more than myself recognizes the slight degree of danger from contagion, and I quite agree that there is more danger to-day from syphilis and phthisis in the community than from leprosy; but to give the impression to the profession at large, to the public, and to the world that the New York County Medical Society looks upon leprosy as a disease which is not transmitted from person to person, that, in other words, it is not a bacillary disease, and that a new case depends upon some other cause than a case of leprosy which has gone before, is contrary to the belief of a vast majority of the members of this society.

The only objection I raise to turning these five lepers out upon our streets is that, if they belong to the pauper class and must therefore be cared for by the people somewhere, we had better continue to care for them where they are. If some have been taken from occupations in the city to which they will return when released, such as cooking and baking, I object upon personal grounds that I prefer my bread kneaded by healthy individuals, and, if we cannot compel or induce syphilitics and consumptives to give up these unappetizing pursuits, let us at least do what we can by moral suasion and mild show of assumed power of control over lepers, giving them always the privilege, if they do not like the restraint placed upon them, of returning to the country from which they came.

Why should we scatter these patients about among the hospitals instead of keeping them where they are, since I have been informed their surroundings are all that is to be desired and not the prison or living tomb which they have been represented to be? I have formerly opposed the assumed power of the board of health in shutting up these unfortunates, because it has been represented to me that the first man thus isolated was treated in a barbarous and inhuman manner, being confined in a tent without companionship and left literally to die alone. I hope I have been misinformed in the matter. The fate of one or two Chinamen, likewise isolated, as reported to me, seemed unnecessarily severe. A local board of health cannot in my opinion permanently give proper care to this class of patients, but it can at least keep them under the conditions mentioned, until the national government establishes suitable asylum homes in which to isolate all lepers.

I have urged such a measure for this country because I believe we are so situated that the United States can be made and maintained leper free. For phthisis and syphilis it is futile to think of such a thing, but because we cannot do it for all infectious diseases there is no reason why it should not be done for so loathsome a disease as leprosy, which is still so limited in distribution that the proposition is practical.

CHARLES W. ALLEN, M.D.

126 EAST SIXTIETH STREET.

The Population of the Earth.—The quinquennial census of different nations was recently completed. From 1874 to 1895 the total population seems to have increased from 1,391,000,000 to 1,480,000,000. The increase at the rate of five per cent. should give 1,549,000,000 in 1900, and 2,548,000,000 in the year 2000. The fear expressed in Malthus' essay on population, that in course of time one portion of the population will be reduced to famine, seems not incredible, since the producing powers of the soil are limited, while those of reproduction of species are practically without limit.

New Instruments.

A NEW TRACHELORRHAPHY KNIFE.

BY D. TOD GILLIAM, M.D.,

COLUMBUS, OHIO.

This knife, devised by me some months since, has proven most satisfactory. It not only expedites the freshening, but enables one to do smoother work than is usually obtained with the straight knife or scissors. It consists of a handle, seven inches long, with a blade

at either end. The blades are set at an angle of 45° to the handle, and are turned in opposite directions, thus giving the instrument something of the appearance of the letter S. One of the blades is narrow and pointed, and intended to transfix the tissues up near the angle of the tear and cut outward. The other is bellied and used for clearing the angles. This blade may often be conveniently used for the entire denudation of the right side. The accompanying cut is self-explanatory. The knife is made by George Tiemann & Co., New York.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 31, 1896:

	Cases.	Deaths.
Tuberculosis.....	148	113
Typhoid fever.....	29	6
Scarlet fever.....	96	7
Cerebro-spinal meningitis.....	0	0
Measles.....	53	2
Diphtheria.....	200	20
Smallpox.....	0	0

Thermal Baths have a diagnostic worth, aside from therapeutic results. In Wiesbaden, after six or seven baths, rheumatic subjects are rendered worse, and gouty subjects have a typical attack. After some twenty baths, the quantity of uric acid excreted is reduced, in gout, to about one-half. In differential diagnosis these almost constant results have an importance in distinguishing rheumatism and gout from other painful affections simulating them.—*PEIFFER, Berlin klin. Woch., No. 12.*

His Message.—The long, gloomy operating-room of the hospital is hushed and still; soft-voiced, gentle-eyed nurses move quickly here and there, and a skillful attendant arranges the cruel-looking instruments upon a table. Before administering chloroform to the patient, prior to the amputation, the kindly doctor leans over and asks him if he has any message for his friends. "Naw!" he murmurs wearily; "jest tell 'em dat you saw me, an' dat I'm losin' flesh."—*Sam.*

A Scaremosquito.—A New Jersey man has applied the principle of the scarecrow to that other rapacious bird, the native mosquito. He suspends two or three imitation dragon flies by a fine cord from the ceiling of his room, and claims that no mosquito will remain within sight of them.

RECENT AIDS IN THE DIFFERENTIAL DIAGNOSIS OF TYPHOID FEVER (DESCRIBING THE AUTHOR'S MODIFICATIONS OF EHRLICH'S TEST, WITH A PRELIMINARY REPORT UPON THE SERUM TEST OF WIDAL).

By CHARLES LYMAN GREENE, M.D.,

INSTRUCTOR IN PHYSICAL DIAGNOSIS AND CLINICAL MEDICINE IN THE UNIVERSITY OF MINNESOTA; VISITING PHYSICIAN TO THE CITY AND COUNTY HOSPITAL, UNIVERSITY FREE DISPENSARY, ETC., ST. PAUL, MINN.

THE perennial interest in typhoid displayed by our profession is to be accounted for, not only by the fact that we all meet it frequently in practice, but also because we have learned that there is no acute disease more insidious in its onset, more deceptive in its manifestations, and more beset by troublesome and unexpected complications.

We ought, therefore, to welcome all tests which seem to make clearer our way to a positive diagnosis, and more particularly those that aid us in early diagnosis.

The accurate diagnosis of typhoid is not always easy, and is never to be made with certainty before the end of the first five to ten days after the onset of fever. Yet, in the discussion of this subject by a medical society, we often hear of diagnoses made in the first few days of the disease; and expressions such as "the characteristic countenance," "the characteristic pulse," or "the characteristic temperature," assail our ears, and make us wonder what early signs are so truly characteristic or diagnostic as to warrant these positive opinions.

In our student days all things were made so plain to us that we were astonished, perhaps, to find in our hospital practice after graduation that error in the diagnosis of a disease so commonplace as typhoid was not uncommon, even in the practice of the most acute clinicians. I have seen some of the greatest diagnosticians refuse to commit themselves to a positive diagnosis in a certain case until the disease had nearly or quite run its course—this conservatism being due to the chastening effect of frequent autopsies and the growth of caution in diagnosis which results from a large clinical experience.

If we could trust the older text-books and if our disease would be obligingly typical, we should have no trouble. But the symptom complex of the text-book is by no means common, and even its individual components are often illusory or ubiquitous.

Allow me to pass some of these symptoms in review, with a running commentary upon their value. Commencing with the prodromal and early first-week symptoms, these are said to be: "Headache, nausea, epistaxis, injected conjunctivæ, lassitude, pain in the back and legs, anorexia, tenderness and gurgling in the right iliac fossa, diarrhœa, fever."

The foregoing group contains the earlier symptoms which, by their different combinations, constitute the general malaise preceding the onset of fever, and are the ones upon which the very early snap diagnoses

must, of necessity, be based. Collectively they are important, as indicating an insidious onset; but the individual symptoms are of little value, all being frequently found in diseases other than typhoid, and no one of them being at all characteristic of this disease. For example, many of our cases in the city hospital are constipated upon admission and give no history of diarrhœa. Gurgling in the right iliac fossa may be found in any diarrhœa. Tenderness in the right iliac fossa may be due to appendicitis and many other conditions. Epistaxis is lacking in a majority of our cases, and the other symptoms are common to all general infections.

If we pass on to the signs of the established disease, there are:

First, fever. Much stress is laid by the text-books upon the "characteristic temperature record," yet we know that a case in St. Paul, with the step-ladder temperature of the text-book, is a curiosity. The general features are present and are important aids to diagnosis, but that is all.

Second, rose spots. These are important, and, if found, are typical. They are absent, however, in at least thirty per cent. of our cases, and do not appear until the eighth or tenth day.

Third, pulse. The pulse of typhoid is not necessarily characteristic and certainly not pathognomonic, though dicrotism is here more frequent than in almost any other acute disease, and a disturbed pulse-temperature ratio is often interesting (the pulse rate may be only 100 to 110, with a temperature of 105° F.).

Fourth, enlargement of the spleen. This is a most important sign. The spleen is palpable at the end of the first week, if there is not too much tympanites, and the engorgement disappears promptly as the fever lessens. It is found, however, in malaria, septicæmia, and miliary tuberculosis, and is far from being a pathognomonic sign.

I will not prolong the discussion of symptoms, because my object is merely to indicate the somewhat gauzy texture of ordinary diagnoses, and to point out the fact that not one of the foregoing signs is pathognomonic, that they do not permit of any positive early diagnosis, and that it is only in their grouping that they become important. Knowing that this is true, it might be expected that the profession would grasp eagerly at any new and important sign, even if it were not pathognomonic; but such has not proven the case with the diazo reaction of Ehrlich, a sign both early and constant.

In a paper read before the Minnesota Academy of Medicine, in 1893, I described both the original method of Ehrlich and my own modification of his method, which seemed to me to yield more accurate results. I intend to demonstrate this test to you to-night, and beg that you will follow me closely at this point.

The formulæ are as follows. I shall describe my own method only, as I believe that it furnishes more definite and less confusing results than in the original.

Solution A.—Hydrochloric acid, 50; distilled water, 1,000; sulfanilic acid, q.s. ad sat. This solution should be most thoroughly saturated, allowed to stand some days before being used, and shaken up from time to time.

Solution *B*.—Five-tenths solution of sodium nitrite in distilled water. Should be kept in a cool place, and black bottle, and renewed every week or ten days.

Solution *C* (test solution).—One part of solution *B*; one hundred parst of solution *A*. This solution should be freshly made for each day's testing.

Method of Applying Test.—Equal parts of the solution *C* and the suspected urine are thoroughly shaken up together in test tube, and from one to two cubic centimetres of ammonium hydrate allowed to flow gently down upon the surface. If the reaction be present, a beautiful crimson or carmine band appears at the junction of the ammonia with the mixture. Upon shaking, a pink tinge is imparted to the foam.

This test appears very simple, and no one would suppose that any serious blunders would arise in the hands of competent men. We find, nevertheless, one of the greatest living authorities upon clinical diagnosis reporting it as valueless, and omitting all mention of ammonia in his description of the test. The same error occurred in the work of a very celebrated clinician, who found it in normal urines. Another elaborate report winds up with the reference to the yellow color of the ring. Another used a five-per-cent. solution of sodium nitrite, and could not get rid of the reaction. He found it in everything. Still another used sodium nitrate. His results were naturally deplorable, and he cruelly condemned the test. Such, sometimes, is the boasted accuracy of scientific medicine.

As I test this typhoid urine, you will notice that the color is not yellow, nor orange, but red. It must be red, or there is no reaction. Now, here is the urine of pneumonia and advanced tuberculosis. The color is orange. In the first specimen, shaking produces a pink foam; in the second, no pink is to be seen. The following rules are all important:

- 1. The urine must be fresh and filtered.
- 2. The urine must be acid.
- 3. The true color is red, and when the urine is shaken the foam should be slightly tinged with pink.
- 4. The test solution *C* is to be freshly prepared each day and accurately measured. A medicine dropper and a marked test tube will insure this.
- 5. The sodium-nitrite solution must be accurately made, and renewed at intervals of a week or ten days, and be not stronger than 0.5 per cent.
- 6. The color band should be held against a white background, the light falling upon it from behind the observer. It must not be held against the light.
- 7. The exact method of procedure must be conscientiously carried out.
- 8. The test is to be made during the height of infection.

The urines of three hundred and fifteen cases, comprising over fifty diseases, have been tested. No one of the three cases of supposed typhoid which failed to show the reaction was, in other respects, a typical case. In one the maximum temperature was only 100° F.; in another the spleen was unaffected; and in none of the three were there any rose spots. The reaction occurred in only two of sixteen cases of pulmonary tuberculosis, in one of which it was very faint. Both were cases in which the element of sepsis predominated. Septicæmia, if profound, would seem to show it, though, strangely enough, ulcerative endocarditis with markedly septic temperature curve did not show it.

The single case of pneumonia in which it occurred was an unusually rare and severe case of double pneumonia, with involvement of both apices, seen in consultation with Dr. H. P. Ritchie. Note that it did not occur in our malarias, in appendicitis, nor in miliary tuberculosis—a fact of the utmost importance in differential diagnosis. It should be stated, however, that these cases of malaria were of only moderate severity, being the usual imported variety met with in this region.

I shall also demonstrate to you the method proposed by Widal¹ to diagnose typhoid, by adding to a pure culture of Eberth's bacillus a drop of blood from a supposed typhoid. The method is simple and has so far proven to be reliable.

This patient is a convalescent, who, during his illness, presented a very typical group of symptoms. I take two cover slips and a glass slide, place a large drop of distilled water upon the slide, and stir in a bit of the pure culture taken with the usual precautions from this tube. I now draw a drop of blood from my patient, and, having sterilized my loop, take up a little of the blood and stir into the mixture of distilled water and typhoid bacilli, and drop on my cover glass. I now go through the same process with my own blood and a similar mixture placed upon another slide. We will leave them for a few minutes.

¹ Widal: La Presse Médicale, July 29, 1896. Dieulafoy: Journal des Praticiens, July 11, 1896. New York Medical Journal, August 3, 1896. Courmont, Achard, Widal, Hayem: La Semaine Médicale, July 29, 1896. Medical News, October 17, 1896.

and you will see that the typhoid blood has seriously interfered with the motility of the bacilli, which are for the most part grouped and show but little movement. The control slide will show the bacilli in rapid motion and not grouped. Widal recommends that the blood be allowed to clot and the serum used for the test, but for rapid clinical work the blood itself is more convenient and certainly proves satisfactory. The colon bacillus is said to react in the same way, and might, perhaps, be used if typhoid cultures were not at hand.

The following tests were made at the City Hospital, by Dr. H. P. Ritchie and myself, with the results as here stated:

Case 1.—W. J. M.—. Typhoid. Test of Widal made on twenty-fourth day after admission. Temperature nearly normal. Reaction present.

Case 2.—J. N.—. Typhoid. Test on fortieth day. Temperature normal. Reaction present.

Case 3.—F. D.—. Typhoid. Test on forty-sixth day. Temperature normal. Reaction marked.

Case 4.—A. G.—. Typhoid. Test on sixteenth day after admission. Reaction marked.

Case 5.—J. J.—. Typhoid (mild). Test on twenty-fourth day. Reaction present.

Case 6.—R. Y.—. Typhoid. Test on twenty-eighth day. Reaction marked.

Case 7.—Mrs. C.—. Typhoid. Test on thirtieth day. Reaction marked.

Case 8.—M. P.—. Typhoid (mild). Test on twentieth day. Reaction present.

Case 9.—Lizzie —. Typhoid. Test on sixtieth day. Reaction present.

Case 10.—M. G.—. Typhoid. Test on thirty-eighth day. Reaction marked.

Case 11.—L. F.—. Typhoid. Test on twenty-first day. Reaction marked.

Case 12.—D. D.—. Ulcerative endocarditis. No reaction.

Case 13.—Lama. Ulcerative endocarditis. No reaction.

Case 14.—G. T.—. Broncho-pneumonia. No reaction.

Case 15.—Mrs. H.—. Pyloric stenosis. No reaction.

Case 16.—Mrs. B.—. Lobar pneumonia. No reaction.

Case 17.—Mrs. S.—. Septicæmia (abortion). No reaction.

Case 18.—Diphtheria. No reaction.

Case 19.—Diphtheria. No reaction.

Case 20.—E. W.—. Gonorrhœal bubo with fever. No reaction.

Case 21.—Phthisis. No reaction.

Case 22.—Phthisis. No reaction.

Case 23.—Phthisis. No reaction.

Case 24.—Tuberculous pleurisy. No reaction.

Case 25.—Erysipelas. No reaction.

This would indicate that the method has value, though, of course, we must make many more tests before we can be entirely satisfied that the reaction is constant, and further determine the question as to its occurrence in other acute diseases. Widal states that it may be present on the fifth day, and is quite constant on the eighth or ninth.

I wish, in closing, to state what symptoms of typhoid appear to me necessary to a diagnosis, and to emphasize the importance of the two tests just described. The important symptoms are:

(a) An insidious onset.

(b) Continued fever.

(c) An enlarged and palpable spleen.

(d) The occurrence of a well-marked diazo reaction.

(e) Widal's test with the typhoid blood, if this preliminary report is verified by future work.

The occurrence of rose spots and the peculiar ochre stool are, of course, important, though less constant. Absence of leucocytosis is in favor of typhoid, and a marked leucocytosis during the course of typhoid indicates a complicating inflammation, such as pneumonia. Malaria may usually be differentiated by the finding of plasmodia in the blood of patients suffering from this disease.

The most important of these signs are the diazo reaction and Widal's test. Our tables show that if proper technique be observed, we have in the diazo reaction not a pathognomonic sign, but

(a) A constant sign.

(b) A very early sign.

When any sign is found in ninety-five per cent. of so large a number of cases as are here reported, it may certainly be called constant, and I, personally, believe that all cases of severe typhoid will show it if the test be made during the height of infection, *i.e.*, tenth to eighteenth day; and that when in a supposed typhoid the reaction is lacking we have positive proof that we are dealing with some other disease. The sign may occur before the end of the first week, having been observed upon the fourth day. The fact that it occurs occasionally in other diseases has led most of those who have reported upon the test to condemn it as valueless. This position is certainly illogical and untenable. We might as well deny the value of the physical signs of consolidation of lung tissue or albuminuria as a symptom, because they are common to many conditions; and the same argument applied to the classical signs of typhoid would leave us no symptomatology at all.

With regard to Widal's test, I can only say that if the comparatively limited number of cases reported can be taken as a fair indication, we have found something very nearly approaching the long-sought-for pathognomonic sign.

Lacking space for any extended discussion of the test at this time, I shall hope to report more fully at a later date. I am under great obligations to Drs. E. J. Batchelder, H. W. Knauff, and H. P. Ritchie, who have materially assisted me in making these tests, and venture to express the hope that this paper will serve in some slight degree to bring about the wider recognition and more general use, in this Northwest, of these clinical tests, which have to me proven both interesting and useful.

150 LOWRY ARCADE, October, 1896.

THE TREATMENT OF STRICTURE OF THE MALE URETHRA.¹

By RAMON GUITÉRAS, M.D.

PROFESSOR OF ANATOMY AND OPERATIVE SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL; CONSULTING SURGEON, FRENCH HOSPITAL; VISITING SURGEON, COLUMBUS HOSPITAL AND CITY HOSPITAL.

THE object of this paper is not to give a treatise on the treatment of stricture, with a review of the current literature, but to describe the methods that I am in the habit of pursuing in the cases which come under my care, and to mention a few of the various other methods now in vogue. The treatment of strictures depends entirely upon the varieties presenting themselves.

These are classified by different authors in a number of ways, as, for example, organic, inflammatory, spasmodic, traumatic, congenital, etc. It is my object in this paper, however, to simplify as much as possible, and I will therefore speak of them only as organic and functional.

By far the greatest number of strictures are organic, and under this head I include congenital, which are

¹ Read before the Medico-Surgical Society at September meeting.

narrows of the canal, usually at or near the meatus; traumatic, due generally to a blow on the perineum, by which the bulbo-membranous urethra is caught between the impinging body and the lower border of the subpubic ligament; and the so-called inflammatory strictures, due to acute urethritis and inflammations about organic strictures.

These vary in consistence, size, position, and resistance.

In consistence they vary from an induration and thickening of the mucous membrane, with connective-tissue proliferation occurring in its depths, to the formation of a dense mass of cicatricial tissue occupying the submucous region and extending into the meshes of the corpus spongiosum.

In size, they are spoken of as being of large calibre when they admit more than a 15 F. sound; of small calibre when they admit a smaller size, and impermeable when nothing can pass through them.

As to position observers differ, many believing them to be more frequent in the bulbo-membranous region. My own experience, however, leads me to think they most frequently occur in the pendulous portion. In the bulbo-membranous region, however, they are the most serious. In fact, the gravity of a stricture is in direct proportion to its distance from the meatus.

In resistance strictures of the urethra vary greatly, some of the soft and recent ones being very amenable to dilatation, while others are so hard or unyielding that not much headway can be made without resorting to the most radical measures. The most unyielding of those in my experience have been the congenital, the traumatic, and those of long standing.

Functional strictures are simply spasmodic, and will be considered later.

When a patient who has had frequent attacks of urethritis presents himself to me, with symptoms of a chronic urethral discharge (gleet), a feeling of pain or heaviness in the perineum or back, frequent desire to urinate, dribbling after urination, a stream twisted or small, or a condition of hypochondriasis or depression, I at once suspect stricture and advise an examination of his urethra.

Examination for Stricture.—At this examination I am in the habit of directing him to pass his urine in two glasses, which is then examined for threads and to observe the clearness of the two specimens, cloudiness in the first specimen indicating urethral discharge, in the second cystitis. I then direct him to lie at full length on the table, with his shoulders elevated, and wash out his urethra with warm boiled water. After this I insert the Otis bulbous sounds, usually commencing with a 15 F.

If this passes easily, I continue to increase the size, noticing the location of the strictures, if any be present. If the meatus is too small for a complete examination and the organ is a well developed one, it would seem probable that the average calibre of the canal is greater than that of the meatus, and therefore, to make a thorough exploration, the meatus should be cut.

Meatotomy.—In performing this operation, it is my custom to use a blunt-pointed bistoury or a blunt-pointed tenotomy knife, and to cut downward, endeavoring to enlarge the opening until it can admit a 30 French sound, or even one of larger size. The incision should be exactly in the median line toward the frænum. In this operation one must cut steadily and avoid a quick, sharp cut, which might prove to be too free, thus producing a condition of artificial balanitis hypospadias.

If the bleeding is slight, I at once make an examination of the anterior urethra, postponing that of the deep urethra until the next visit. The patient is directed to wear a plug of oakum or absorbent cotton for the next three days, inserting a fresh one after

each act of micturition, and is requested to return again at the expiration of that time. At the second visit, an examination of the entire urethra is made, as at the first visit in cases in which the meatus is of ordinary size.

If strictures of moderate calibre are found, gradual dilatation is attempted.

Gradual Dilatation.—For this purpose the best method that we have appears to me to be by means of the Oberlander dilator and sounds.

The Oberlander dilator affords the best-graded instrument of dilatation which we have at present. It is constructed after the model of the curved Otis urethrotome. It is inserted with a rubber covering, and is capable of dilating strictures both of the pendulous and bulbo-membranous portions of the canal. The dial at the handle end on the upper surface registers the amount of dilatation, each point corresponding to a millimetre. The dilatation is usually from one to three millimetres at each visit. It is well to alternate with sounds, the patient calling for treatment every second day.

During a course of dilatation in these cases the utmost care should be taken to have the bladder, the urethra, and the instruments as clean as possible. The instruments should be boiled in a soda solution before being used, and should be lubricated with borated glycerin before they are introduced.

The patient should be directed to take internally the so-called urinary antiseptics while under treatment, such as salol, boric acid, or oil of wintergreen, to abstain from liquor, and to avoid exposure to cold and wet. Tobacco is also bad, as it tends to produce general irritability and hyperæsthesia. Oil of eucalyptus in ten-minim doses is considered one of the best urinary antiseptics. If there is a spasm or congestion after the passage of sounds a hot sitz bath should be taken then, or just before retiring.

The patient should always urinate immediately before each treatment, after which his urethra should be washed out with boiled water. If moderate dilatation has been accomplished in this way, or the strictures are more than 18 F. and not much progress can be made by dilatation, I am inclined to cut them if they are situated anteriorly.

If they are deep, however, I should not recommend an operation until symptoms of an annoying character develop. In this latter class of cases, I should recommend the passing of sounds at intervals, to prevent any further contraction. It quite frequently happens that after cutting an anterior stricture the deep one can be dilated. The operations for internal and external urethrotomy will be considered later. If the introduction of sounds causes irritation, the French rubber or silk bougie will often irritate less and accomplish more.

Bougies may be disinfected by soaking them in a 1-1,000 bichloride solution.

If the strictures are small, that is, less than 15 F., more care is necessary. Strictures of this size are usually of some years' standing and are often very unyielding. All strictures will, however, yield somewhat to dilatation if it is properly performed. They are, of course, too small for dilatation with the Oberlander, which is equivalent to a 19 F. sound, and therefore must be treated with either sounds or bougies. Of these the latter are preferable, as they are much less liable to lacerate the tissues, and should always be used if the strictures are smaller than 10 F. By the passage of the bougies, the strictures can generally be stretched enough to admit a dilator or a urethrotome, when further treatment may be carried out as with strictures of a larger calibre.

In other cases strictures of this size are unyielding, and operative procedures have to be resorted to, either

an internal urethrotomy, with a Maisonneuve, or an external upon a Gouley tunnelled sound or catheter.

Instrumentation in irritable strictures, which usually occur in the nervous and hyperæsthetic, sometimes give rise to pain and spasms, followed later by chills and fever. The urethral fever in these cases is often obviated by irrigating the urethra with a hot bichloride solution before and after passing the sounds, or before cutting, if urethrotomy should be decided upon. This prevents the septic element present from causing urethral fever. Eucalyptus taken internally is a valuable agent in preventing chills in these cases. A great deal of time is saved, and suffering and distress are spared if an internal urethrotomy is performed in such conditions.

Continuous Dilatation.—We now come to a class of strictures nearly impermeable, in which all the skill and ingenuity of a surgeon is brought into play, as apparently nothing can be passed through them, and yet by a little careful manipulation the passage of an instrument may be effected. In these cases the urethra are distorted by strictures, and often by pockets and false passages as well. Here the smallest instruments are brought into play, namely, the filiform bougies. If one of these can be passed into the bladder, it should be left there during the night, as thus a certain amount of dilatation is accomplished by the continuous action of the bougie and the flowing of the urine beside it, and on the following day one or two more can usually be slipped in beside it, or perhaps a small French catheter may be introduced in its place. In either case, whatever is passed on the next day, whether it is one or two additional filiforms or a small French catheter, should be allowed to remain in for another twenty-four hours. By increasing the size of the catheter or the number of filiforms daily for a few days, a sufficient dilatation will be accomplished to allow the passage of small bougies and a continuation of the treatment by gradual dilatation.

The passage of a filiform bougie through the urethra is not always an easy thing. When it is found to be difficult, if a little warm sweet oil is first injected into the canal and held for a few minutes, the filiform can usually be worked through. In case it cannot be, it should be left in place and others slipped in beside it. When half a dozen or more of these are in the canal, they should be worked about gently for a few moments, when it will be found that one will slip by into the bladder. This should be allowed to remain in over night, as just referred to. If one cannot be made to pass through the stricture in this way, but engages, it should be allowed to remain in this position for the night, as on the following day it may possibly be worked into the bladder.

In other cases, in which a filiform cannot be passed and in which the stricture is considered impermeable, but in which the patient is able to pass his urine, I am in the habit of directing him to remain in bed for a few days in the dorsal decubitus, arising only to take hot sitz baths night and morning. During this time I give him a preparation of the acetate of potassium and sweet spirits of nitre three times a day. A few days of this treatment usually reduces the congestion of the urethra sufficiently to allow a filiform to be passed.

In all these cases of so-called impermeable strictures and strictures of small calibre in which a filiform can be passed through into the bladder, the pressure of the retained bougie and the urine passing along its sides will dilate it sufficiently to allow something larger to be introduced at the next visit. If, however, it seems advisable to operate at once, a Flührer's modified Maisonneuve urethrotome can be passed over it and the stricture cut if it is in the anterior urethra; or a Gouley tunnelled sound can be passed over it

into the bladder upon which an external perineal urethrotomy can be performed if it is in the deep urethra. I do not think that Flührer's modification of the Maisonneuve is so good as the original instrument which is attached to a guide. This guide is, however, the size of a No. 4 or No. 5 French bougie, and is therefore a little larger than a filiform over which a Flührer's modified instrument can be passed. A Maisonneuve urethrotome cuts up to 20 F., which is sufficient to allow gradual dilatation by sounds of a considerable size, or a further cutting operation by means of an Otis urethrotome, which cannot be introduced into a canal smaller than 18 F.

I may here say that I do not believe in a Maisonneuve urethrotome, as I think that it lacerates the tissues, and I feel that it cannot be used safely, excepting in connection with an external urethrotomy. Perhaps an ideal case for this double operation is when there are a number of very small resisting strictures along both the anterior and deep urethra.

To reconsider what has just been said, we may assume that all soft and yielding strictures, whether anterior or deep, large or small, should be dilated; resisting strictures of large size in the pendulous portion should be cut, while similar ones of the deep urethra should be kept open and observed carefully; resisting strictures of small calibre of the pendulous urethra should be cut by a Maisonneuve urethrotome, if very small, or by an Otis urethrotome if they can be dilated sufficiently to admit it, or by both; while resisting strictures of small calibre in the deep urethra should be treated by an external perineal urethrotomy. The so-called impermeable strictures should be opened sufficiently for operation by instruments on a guide, if possible; if not, by perineal section.

Internal Urethrotomy.—In all anterior urethrotomies, my preparation of the patient is the same. He is put on salol, ten grains, three times a day for three days before the operation, to be continued until three days after. A cathartic is given on the evening preceding the operation, and the bowel is washed out just before the patient is brought to the operating-room. When he is upon the table his urine is drawn by catheter and his bladder is washed out with a saturated solution of boric acid, about six ounces of which is allowed to remain in the bladder. A syringeful of a four-per-cent. cocaine solution is then injected into the urethra from a hand syringe holding about three drachms, and is held there for five minutes to allow perfect anæsthesia of the urethra to be produced. The choice of instruments now takes place. The two instruments of to-day are the Otis and the Maisonneuve urethrotomes. The numerous others which have been invented are now in disuse. As we have observed, the Maisonneuve is the smaller of the two, and is therefore used in the cases in which the Otis cannot be made to enter.

Operation by the Maisonneuve Urethrotome.—A Maisonneuve urethrotome is shaped like an ordinary small sound, with a groove running along the entire length of its concave aspect. In this groove a small wire shaft with a triangular blade on its end is inserted, which can be slid at will backward and forward in the groove. The instrument, which is of the size of an 8 or 9 F., is attached by a screw to a guide of the size of a 4 or 5 F. bougie.

The guide is pushed gently into the bladder, followed by the staff which is attached to it until its end has reached the prostatic urethra. The penis is then held steadily in the median line slightly on the stretch, while the urethrotome is carefully and firmly held in the urethra in such a way that the groove on the upper surface of the urethrotome corresponds exactly to the space between the two corpora cavernosa. Everything being in readiness, the blade is introduced

into the groove and is then pushed down through the strictures. The blade of the Maisonneuve is triangular, with a guard on the apex of the triangle, and a cutting edge in front and behind. The object of this guard on the apex of the cutting blade is to prevent the normal tissues along the canal from being cut, as it glides along the upper wall of the urethra and only stops when it comes in contact with the stricture through which the knife passes, when the guard again slides along the smooth urethra until another stricture is encountered. It is my opinion that the Maisonneuve is not a good cutting instrument, as it is difficult to keep sharp and the guard hinders the progress of the blade. It has frequently happened in my experience with this instrument that the force used in pushing the blade of the instrument has been sufficient to push the organ out of my grasp instead of sending the blade through the stricture. It is thus easy to see that the force used would be sufficient to lacerate and contuse the mucous membrane and soft tissues about a tough stricture. When there are one or two small strictures of the pendulous portion to be cut the Maisonneuve is of undoubted service, but when the strictures are in the bulbo-membranous region it is safer to associate this operation with an external urethrotomy. In cases of anterior strictures, after cutting them with the Maisonneuve, I frequently insert an Otis and cut to a larger size.

In almost every case anterior strictures can be dilated with patience and care to a size sufficient to allow the passage of the Otis urethrotome.

Operation by the Electrolyzer.—Professor Fort, of Paris, has recently devised a means of performing urethrotomy by an instrument known as the electrolyzer. This instrument is about the size of the Maisonneuve urethrotome and very similar to it in shape. It has a guide of about the same size as that of the Maisonneuve, and the staff to which it is attached also corresponds in shape and size. The blade of the electrolyzer corresponds to that of the Maisonneuve in shape, but it differs in material, as it is made of platinum instead of steel; and in edge, as it is dull on all sides, while that of the Maisonneuve is dull at the apex where the guard is situated and is sharp in front and behind. An electrolyzer, in fact, resembles in outline a Maisonneuve with the guide and staff joined and the blade pushed well down into its concavity. The blade of the electrolyzer is connected through the shaft and handle end of the instrument with the negative pole of a galvanic battery, while the positive pole is connected with an electrode, covered with chamois, which is placed over the pubis or on the adjoining thigh.

The guide is then pushed in until the platinum blade comes in contact with the stricture, against which it is gently pressed. The current then being turned on, the dull blade glides easily through the stricture, dissolving a furrow through it in the median line. The current is then discontinued and the instrument is withdrawn or pushed in until the next stricture is encountered, when the same process is again adopted. In this way, without using any force, the platinum blade gently slides through all the strictures present into the bladder. During the entire operation the blade remains perfectly cold, and very little pain is experienced, even if no cocaine is used. The strength of the current necessary successfully to operate on these strictures is from ten to twenty milliamperes, and the time required to go through a stricture is usually from thirty seconds to four minutes. The lumen of the strictured portion of the urethra is thus brought to the size of an 18 F. sound. Afterward the stricture can be still further enlarged by sounds or by a urethrotomy with the Otis urethrotome if the stricture is an anterior one.

This operation has been performed several times in this country by Dr. Fort and also by Dr. Chassaignac, of New Orleans. It has several advantages over the Maisonneuve, namely, it does not bruise and lacerate the tissues so much; it is less painful at the time and on urination afterward; there is almost no hemorrhage, and consequently very little danger of infection, as the blood-vessels in the urethra are not left open.

Operation by the Otis Urethrotome.—An Otis urethrotome consists of a shaft made of two pieces of steel, with a groove along its upper surface; a wire shaft with a small cutting blade on its end, which is pushed along the groove until the blade disappears from sight near the end of the shaft of the urethrotome; and a dial on the upper surface near the handle, on which the amount of dilatation is registered. The dilatation is accomplished in this way: A small wheel at the end of the handle is turned. This turning separates the two pieces of the shaft, thus dilating the urethra to a size corresponding to the circumference of the opened halves of the shaft, the amount of which dilatation is registered in millimetres on the dial of the instrument. There are two forms of the Otis urethrotome, the straight and the curved. The straight is of service only in cases of anterior strictures, while the curved one could be used in cases of deep strictures in the same way as the Maisonneuve, although I do not consider it safe unless combined with an external urethrotomy.

The steps of the operation are as follows: The point of the urethrotome is pushed about an inch beyond the stricture, when the screw at the handle end is turned until the degree determined upon as that of the average size of the urethra has been registered upon the dial of the instrument, when the knife is pulled up through the stricture and then pushed back again into place. The other strictures are then approached in the same way and severed. The canal is then tested with the sounds, to see if it admits with ease the size required. I do not believe in inserting the urethrotome into the penis at right angles to the body as far as it will go, then screwing it up to the highest point possible and pulling out the blade along its entire length, as I have frequently seen done by surgeons of good standing.

Otis determines the size of the urethra in two ways, first by his urethrometer, and second by measuring the circumference of the penis. His rule of comparison is as follows:

Circumference of penis	3	inches,	urethra	30	millimetres.
"	"	"	3 $\frac{1}{4}$	"	32
"	"	"	3 $\frac{1}{2}$	"	34
"	"	"	3 $\frac{3}{4}$	"	36
"	"	"	4	"	38
"	"	"	4 $\frac{1}{4}$	"	40

As each degree upon the dial of his urethrotome corresponds to one millimetre, it is easy to see how exactly he can make the size of his urethrotome correspond to that up to which he has determined to cut. These figures of Otis are the result of careful study and long observation, and yet I am afraid to be governed by them, although I do not doubt their accuracy.

The reason why I consider these figures difficult to be accepted as a standard are: 1st. Because in turning the screw of the urethrometer it is very difficult to tell when we have arrived at the exact size of the urethra or when we have it on the stretch. 2. Because the circumference of the organ varies so much when flaccid. This depends on the amount of blood in the organ at the time and is influenced by the temperature of the room, the feeling of fear or nervousness, and many other causes.

In my own practice when a patient's urethra will

admit a 32 F. with ease, it appears to me that he has a sufficiently good canal for all practical purposes, and cases of stricture of very large calibre seldom present themselves.

After-Treatment in Cases of Internal Urethrotomy.—In several cases that have come under my observation severe rigors and a rise of temperature to 103° or 104° F. have followed. These elevations of temperature usually began after the first urination. They are not nearly so frequent now, however, as they were formerly, and this improvement I attribute to my present system of urethral antiseptics already alluded to, namely, the administration of salol for some days before the operation and the injecting the bladder with a saturated solution of boric acid just before the urethrotomy, as the urine mixed with the boric-acid solution and influenced by the salol is much less irritating and more antiseptic.

After the operation sounds should be passed on the second day if there is no fever, but if fever is present this treatment should be postponed until it has subsided. I am in the habit of passing sounds every day for the first week, every other day for the second week, and every third day for the third week.

The patient should remain in bed for two days, or longer if necessary. The results of the operation in this country are very favorable and personally I have never had a fatal case. Other observers, however, claim a mortality of two per cent., while in England and on the continent as high as four per cent. is claimed.

Hemorrhage sometimes occurs after the operation, causing a great deal of alarm. It can be controlled by simply bandaging the penis. If it is very severe, a catheter may be introduced and pressure made by bandaging the organ, thus pressing the cut urethra against the catheter.

Fever, if it does occur, is benefited by quinine, grs. x., or Dover's powder, grs. x.

Gleets accompanying stricture usually disappear after a urethrotomy, as the source of irritation has been removed.

External Perineal Urethrotomy.—This operation is usually performed for strictures of the bulbo-membranous region which require operative interference. An internal urethrotomy with a Maisonneuve could be performed in these cases, but the drainage would not be so good and there would be more danger of infection. A perineal section might also be performed. The only real difference between a perineal urethrotomy and a perineal section, as they are understood to-day, is that the former is performed with the aid of a guide, and the latter without. You will frequently hear a surgeon say he is going to do a perineal section, but if you see the operation you will find that it is really an external urethrotomy, and not a Cock's operation.

The usual indication for an external urethrotomy is the existence in the deep urethra of a stricture of small calibre not amenable to dilatation. White, of Philadelphia, has enumerated these conditions very carefully, in Morrow's "System of Genito-Urinary Diseases," the following varieties of which I may here mention briefly: Tough, fibrous strictures which will not permit of dilatation; resilient strictures, which rapidly recontract after dilatation; hard, narrow strictures, associated with perineal indurations; strictures complicated with fistulæ, in which dilatation has failed; traumatic strictures, which are almost always dense; strictures with extravasation of urine behind them; strictures complicated by perineal abscesses; strictures associated with intense cystitis; strictures in which retention of urine is present.

The preparation of a patient for external urethrotomy is practically the same as for an internal. Have

the patient on salol, ten grains, three times a day for two days before the operation, and have the bowel well emptied before he is brought upon the operating-table. When he is upon the table, if the stricture is permeable, his urine should be drawn, and he should have eight ounces of boric acid left in his bladder. If it is not permeable to an instrument and he can urinate, he should be directed not to pass his urine for five hours before the operation, as it is much easier to perform a perineal urethrotomy when the bladder is full than when it is empty. Always pass the guide before placing the patient in a position for operation. The two best positions are the lithotomy and the Edebohls'. I generally use the latter, and find it perfectly satisfactory. Instruct the assistants carefully how to hold the thighs and be sure that they attend to the support of the limbs and not to other matters. Direct the assistant holding the guide to stand on the left of the patient near his waist, that he may control it in the median line in a steady manner. Do not have the buttocks and thighs so covered with towels that you cannot see whether the patient is in an even position or not, as it is most important to have him held squarely in an even position.

The Various Operations.—There are a number of methods of performing perineal urethrotomy which I will review hurriedly.

Boutonnière, that is, the simple opening of the urethra behind the stricture as a palliative measure, or for bladder drainage. It consists merely in passing a guide through the urethra into the bladder and cutting down on it through the perineum, after which, if for bladder drainage, a tube is introduced into the bladder by way of the perineal incision.

Syme's Operation.—In this method a staff can be pushed through the stricture upon which it can be cut. This staff is called a Syme's staff. It resembles in shape an ordinary sound with a generous curve, but with the peculiarity that the lowest third is much smaller than the remainder of the instrument. It has a groove running along the convex surface of the smaller part of the staff up on to the larger part. The junction of the smaller and larger parts form a shoulder, and it is this shoulder which comes up against the distal side of the stricture after the smaller part has passed through.

Steps: The patient is placed in the lithotomy position and the staff is introduced. An incision is then made in the median line of the perineum down on to the shoulder of the Syme's staff. The point of the knife enters into the groove above the shoulder and cuts down through the stricture in the groove toward the neck of the bladder. A director or Teale's gorget is then introduced along the staff into the bladder, after which the staff can be withdrawn. A catheter is passed into the bladder through the penis along the director. If the bladder is too irritable to retain the catheter, a tube should be passed into the bladder through the perineum and held by tapes.

Gouley's Operation.—In this method a Gouley's tunnelled sound or catheter is used. The Gouley tunnelled sound is an instrument shaped like any other sound, the latter half of it being grooved on its convex surface. At the end of the sound is a bridge about one-fourth of an inch long, extending over the concavity, thus making it round in circumference, with a passage for the transmission of the filiform bougie. It is thus easy to see how the tunnel or canal of the instrument can be slipped over the filiform and the instrument can then follow it down to the stricture.

A Gouley catheter is built with the same curve as the sound, with the difference that the concave side has a canal running along its entire extent, through which the fluid may escape from the bladder. The

handle end of the instrument is not solid, and therefore not so easy to steady as that of the sound.

The urethra is filled with olive oil, and a probe-pointed whalebone bougie is passed through the obstruction into the bladder. Gouley's grooved metallic catheter staff is then passed over the whalebone bougie until its point comes in contact with the stricture, when the patient is brought into the lithotomy position and the guide held in position by an assistant. The surgeon then makes an incision through the median line of the perineum and brings the urethra into view, which he incises upon the bridge of the catheter and a short distance along its groove. Sutures are then passed through each side of the incised urethra close to the stricture, which are held apart by assistants. The catheter is then withdrawn sufficiently to bring the filiform into view. The beaked bistoury is then introduced beside the filiform, and an incision is made well through the stricture, after which the guide is pushed through into the bladder, when the operation is complete.

Wheelhouse's Operation.—Lithotomy position. The Wheelhouse staff is then passed up the urethra with the groove away from the pubes until its end touches the stricture. A Wheelhouse staff is like a straight sound with a groove on one side, the other side being intact as far as the end, where it turns up in a little knob called a button.

Steps: This is held in position by an assistant while the surgeon makes an incision down on to the groove of the staff. The urethra being opened, its edges are grasped on either side by straight-bladed nibbed forceps and held apart. The staff is then drawn up and turned so that the button end catches the upper part of the urethral incision. The incision into the urethra is then held open from three different points, and the operator passes a grooved director through the stricture into the bladder. The director is then turned so that the groove is toward the surface of the perineum, and the stricture is divided along it to its full extent. A blunt-pointed bistoury is then run along the groove to complete the division of the tissues. After this a Teale's gorget is passed along the director into the bladder and a catheter is introduced through the urethra into the bladder, where it is fastened for drainage for a number of days.

Cock's Operation.—This consists in opening the urethra behind the obstruction at the apex of the prostate without the aid of a guide. It is spoken of as perineal section or external urethrotomy without a guide.

Steps: Lithotomy position. The operator's left forefinger is inserted into the rectum and its tip pressed against the apex of the prostate. The knife, having a double-edged blade, is then thrust into the perineum in the median line of the perineum and carried toward the tip of the forefinger at the apex of the prostate until it is felt to be close to it. The incision is at times made somewhat obliquely to be sure of cutting through the urethra. It is important that the knife should not at any time be withdrawn from the wound until the posterior urethra has been opened. The probe-pointed director is then passed through the incision into the bladder, and along this a perineal drainage tube, which is held in place by means of two tapes.

Observations on the Various External Urethrotomies.—It appears to me, after reviewing the various methods of performing external urethrotomy which I have just described, that each method has been formulated to fit some particular new instrument which the surgeon has designed. I consider the Gouley tunnelled sound or catheter by far the most ingenious and practical instrument which has been devised for

operative work in the deep urethra. Compared with the Syme's staff, a Gouley tunnelled sound No. 8 is smaller than any portion of it and far more practical. It is very convenient to know that a particular stricture of the deep urethra has the shoulder of the staff engaged in it; but if we have examined the urethra carefully, we know exactly where the stricture is, and it is as easy to cut through it in the groove of a Gouley as in that of a Syme. Again, suppose that there are one or two small anterior strictures present. In such a case, unless an anterior urethrotomy were first performed, the shoulder of the Syme's staff would stick in one of the anterior strictures, far away from the seat of operation.

Again, comparing the Gouley tunnelled catheter with the Wheelhouse staff; In the Wheelhouse operation the staff is passed down to the stricture. This could be done as well with the Gouley. An incision is made into the groove of the staff through the urethra and its edges are seized with straight-bladed nibbed forceps and held apart while the staff is turned and the button end is caught in the upper part of the incision. It appears to me that it is much easier to cut down into the groove of the Gouley sound, pass retraction sutures, and then turn the beak of the sound out through the perineal opening; while regarding the other steps of the operation, passing a grooved director through the stricture and cutting upon it, with the Gouley method there would already be a guide present in the filiform, along which the incision could be made; or if a grooved director could be inserted through the stricture, the Gouley sound could be pressed through, as they are of about the same size, the No. 8 Gouley being smaller than the average director, in which case the incision of the stricture could be made in the groove of the Gouley instrument. Another point which I should like to criticise is the method of preparing for drainage in the Syme and Wheelhouse operations, which is by a catheter through the urethra, as it appears to me that the use of the perineal tube is the preferable one.

Author's Method of Operating on the Urethra through the Perineum.—After the comparative study of the various methods of performing external perineal urethrotomy, I should like to outline the one which I am in the habit of teaching. I find that most men who are practising medicine do not know the difference between the methods here described, and have not the various instruments which characterize them. It is necessary, therefore, to recommend one instrument, if possible, as the most important one, and to show how it can be best used in all cases. The instrument that I recommend is the Gouley tunnelled sound. The only advantage that the catheter has is that the stylet can be withdrawn and one can tell whether or not he is in the bladder by the appearance of urine. The Gouley sound, on the other hand, is stronger, has a handle more like an ordinary sound, and can be held more steadily and firmly in place, and is therefore preferable.

In most cases of stricture of small calibre in the deep urethra not amenable to dilatation, the small sizes of the Gouley sound can be passed. The patient then having been prepared as already described, anesthetized, and the Gouley tunnelled sound passed, he is brought into the lithotomy or Edebohls' position. There should be four assistants, if possible, one at each corner of the table to support the legs, another standing at the waist of the patient to steady the sound, and another to pass instruments and sponge. If the instrument has passed through the stricture into the bladder, it is only necessary to cut down into the groove on the convex part of the instrument. The incision should be made exactly in the median line of the perineum from the base of the scrotum to within

half an inch of the anus; as the tissues retract and the superficial perineal fascia is cut through, the sound with its groove can be easily felt. Care must be now taken not to wound the bulb of the urethra, as its bleeding obscures the field of operation. This can be caught by a tenaculum and held up by an assistant. The point of the knife can now be pushed gently into the groove and a small incision made, after which it can follow the groove down into the prostatic urethra, the sound being taken by the operator and pushed along with it. The knife should then be withdrawn and the grooved director pushed along the sound into the bladder. The gush of urine along the director shows that its end is in the bladder. The forefinger should then be introduced along the director, when the characteristic feel of the neck of the bladder will be noted. If the opening is not large enough to admit the end of the finger, a scalpel should be run along the groove of the director, first above and then below, enlarging the opening sufficiently to admit the finger. The gorget should be introduced along the director, and a large rubber velvet-eyed catheter, with thick walls, from 17 to 19 English, should be inserted into the bladder along the hollow of the gorget. The gorget should then in turn be withdrawn and the drainage tube should be drawn down to the lowest point at which it will drain the bladder, and should be pinned by an ordinary safety pin to the skin of the perineum. A little iodoform gauze should be packed into the wound around the drainage tube, and the tube should be connected by a glass coupling with a larger rubber tube which passes down into the bottom of a wide-mouthed jar, about one-quarter full of carbolic-acid solution, on the floor by the bedside. In this way, siphon drainage is established.

If the Gouley sound cannot be introduced alone into the bladder, but a filiform may be made to enter, in almost every case the tunnelled sound can be forced along it into the bladder. I do not believe in forcing a sound ordinarily, but when it is my intention to cut into the area that has been forced and drain it almost immediately afterward, I do not think that a slight laceration will do any harm, and we are sure the sound has been forced in the right direction, as it has been pushed over a guide. When, however, the sound cannot be pushed over the guide without exerting a great deal of force, if the filiform is left in the urethra and continuous dilatation is resorted to for a few days, the Gouley sound can generally be made to pass. In either of the cases, the sound having been passed into the bladder, it can be cut down upon through the perineum in the manner just described. In case, however, that the tunnelled sound cannot be made to follow the guide into the bladder, the operation can be performed by passing it down to the distal end of the stricture, opening the urethra anterior to it through the perineum along the groove in the sound and then cutting through the stricture along the filiform with a beaked bistoury, as already described under the head of the Gouley operation.

If a filiform cannot be passed through the stricture, the tunnelled sound should be passed down to the distal end and an incision made down into its groove through the perineum. Traction sutures should then be passed through the walls of the urethra on either side and the beak of the sound should be turned and brought out through the opening in the perineum and held in the median line, thus keeping the urethra open from three points. A small silver grooved director should then be inserted into the stricture, which, if it passes, can be cut down on to. If this small director cannot be made to pass, a filiform may be tried. If nothing can be made to pass through, insert the left forefinger into the rectum, with its tip against the apex of the prostate, and make an incision toward it from the dis-

tal end of the stricture. If the point of the knife is inserted into the stricture from the opening just anterior, and a sharp, quick cut downward and outward made, it will often sever the stricture so that the sound may be slipped through. If it does not, however, the incision should be made steadily toward the apex of the prostate. After cutting a little way the prostatic urethra will be entered, and a little urine will be seen escaping. Pass a director up along this stream, and it will be found to enter the bladder. The opening can be enlarged in the manner already referred to, and the operation finished as in other cases of perineal operation. This last operation is really a perineal section. In these cases the exact position of the urethra must be known, and it is important to remember that the membranous urethra passes one inch below the symphysis and three-fourths of an inch above the perineal centre.

In all operations on the perineum, hot water is of the greatest value to stop the general oozing, and should be freely used. Unless the bulb or perineal arteries are cut into, there will not be much real hemorrhage. It is thus easy to see that it is not necessary to have many special instruments to do operative work on the deep urethra. A few filiforms and a Gouley sound are absolutely necessary, while a Teale's gorget, a Gouley's beaked bistoury, and a fine silver grooved director are luxuries which are much appreciated.

Perineal operations are at times very difficult. I have often spent an hour over a difficult case, and have at times been obliged to begin an operation on one day and finish it on the next. In cases in which considerable hacking has been done without opening the strictured urethra, and in which there is quite a profuse hemorrhage, I think that it is justifiable to open the bladder suprapubically and to pass an instrument through to the proximal end of the stricture, since with guides against both its distal and proximal ends it will be an easy matter to cut through it.

These perineal operations, although at times very difficult, are usually not dangerous, and the only fatal cases that I have ever seen were those in which there had been quite an extensive urinary infiltration existing for a few days and gangrene had already set in. Bryant estimates the mortality in external urethrotomy at five per cent.

After-Treatment.—The salol, ten grains, three times a day, should be continued for three days after the operation, and the patient should be kept upon a milk diet. The dressings should be changed on the following day and on every succeeding day. The bladder should be washed out twice a day with a boric-acid solution. Forty-eight hours after the operation the tube may be withdrawn, and the bladder, wound, and tube all thoroughly cleansed with the boric-acid solution, after which sounds should be passed through the urethra into the bladder. The tube is then reinserted and allowed to remain in place for two days more, when it is again withdrawn and sounds are passed as before. The perineal tube should be left in for from four to fourteen days (generally six). After the perineal tube has been discontinued, sounds should be passed every second day for three weeks, but if the deep urethra is much distorted a catheter may be passed through the penile urethra into the bladder and allowed to remain in for a few days longer.

If hemorrhage takes place after the operation, it can usually be controlled by packing gauze into the opening about the catheter. If this does not succeed, attach a piece of gauze to the tube in the manner known as a *cathétère en chemise*, and then pack the gauze with cotton within it into the wound.

The patient should remain in bed for two weeks after the operation, and after the tube is withdrawn

should always urinate with his legs pressed tightly together until the perineal wound has healed.

Functional Strictures (Spasmodic).—These are due to spasmodic contractions of the striped or unstriped muscular fibres. They are generally situated in the membranous urethra, as spasmodic contractions of the compressor urethræ muscle, in which case they closely resemble deep organic strictures. They are due to reflex and psychical causes, the former of which are by far the most frequent and important. The reflex causes are generally situated along the genito-urinary tract, and are usually anterior strictures, contracted meatus, localized areas of urethral inflammation, vesical calculus, retention of urine, excessive coitus, etc.; but they are sometimes situated about the lower end of the bowel, as in cases of hemorrhoids, fissures, and the like. Spasmodic strictures are sometimes so severe as to cause retention of urine.

The treatment in all these cases consists in determining what the source of the irritation is and treating it by some radical means.

It is quite common to find a urethra with anterior strictures of moderately large calibre and a deep one through which a very small bougie can be passed with difficulty, in which an external urethrotomy is contemplated, and in which after a division of the anterior strictures a sound of large size can be passed through the deep one.

Remarks.—On all occasions when the urethra is under treatment for stricture, whether by methods of dilatation or cutting, urinary antiseptics should be given until the treatment is at an end.

If the meatus is much smaller than the rest of the canal, meatotomy should always be performed at the start.

Dilatation is always to be preferred to cutting operations, if the strictures will yield to this measure.

In continuous dilatation in very small strictures we have a method which produces the most satisfactory results if used with patience and care, and it should always be tried in the beginning either to enlarge the urethra sufficiently for gradual dilatation or for the introduction of a good-sized guide if an operation is contemplated.

In performing gradual dilatation, an Oberlander dilator is the best instrument that we have, and I do not think that its use is sufficiently appreciated in this country.

The surgeon should never promise to cure a stricture by dilatation, as there is always a possibility of his failing, in which case a urethrotomy must be resorted to.

In cases in which a filiform has been passed through the urethra with difficulty, it is not advisable to pass a tunnelled sound over it unless it is to be followed by an operation, as the tissues are liable to be lacerated by such a procedure.

When an operation must be performed on an anterior urethra, if the stricture is very small a urethrotomy with a Maisonneuve urethrotome is usually advocated. This is a method that I am not particularly in favor of, for reasons already mentioned, and I believe that an operation by means of a Fort's electrolyzer in such cases will be found much safer and less harmful. It is argued that the formation of cicatricial tissue follows an operation by this instrument, but, as cicatricial tissue is present in the stricture before the operation, I do not see that the argument has any force. At any rate, the object will have been accomplished, that is, the urethra at the strictured portion will have been made to admit an 18 F. sound, whereas before the operation it could perhaps have admitted only a 4 or 5 F.

If the anterior stricture is larger than an 18 F. in size, I should recommend the Otis urethrotome as a

safe and useful cutting instrument, as the results of an internal urethrotomy by this means are usually very gratifying.

In operating by the perineum, a Cock's operation should be avoided, if possible. Regarding the various perineal urethrotomies that have been alluded to, I do not think that any one of the methods by the different instruments described will be found useful in all cases, and I believe that the general advice given by me in this article will be of great value, that is, of using the tunnelled sound or catheter as a guide. The other instruments are useful, and in the hands of a specialist may be employed in various cases, but for the general surgeon who is called upon to perform an operation of this nature the tunnelled sound and a few filiforms will be of the greatest value.

I do not believe that in the very small strictures of long standing in which a dense mass of cicatricial tissue is present any one operation will cure the case, and think that in such cases after an operation the urethra should be kept under constant observation for the remainder of the patient's life, to prevent a recurrence of the gradual chain of bladder and kidney complications which are apt to follow. One of the most important pieces of advice that I can give is never to perform a perineal section without a guide unless absolutely forced to do so; and when a guide is employed, the larger the better. It appears to me that the surgeons of to-day are too anxious to cut. There seems to be a certain fascination about doing a section. But we should not be governed by this, but should at all times perform the quickest, surest, and best operation for the patient, whether in a hospital or in private practice.

23 WEST FIFTY-THIRD STREET.

THE HIGHER AIMS OF DERMATOLOGY.*

BY A. R. ROBINSON, M.D.,

NEW YORK.

GENTLEMEN: My first duty after welcoming you to this meeting is a sad one. Since our last meeting this association has suffered the loss of one of the oldest, ablest, worthiest, most active, genial, and courteous of its members;² and, judging from report and conversation, each one of us, I am certain, regards and feels our general loss as a distinctly personal one also. To some of you he was an old and well-known and well-proven friend; to all of us he was an honored and admired colleague, whose absence from our meetings will be sadly felt. As your president I have asked one of his closest friends, Dr. Duhring, kindly to prepare such an obituary notice as could form a part of our proceedings and be incorporated in the printed transactions. It is for the association to decide what further action shall be taken concerning our late friend and colleague, Dr. Wigglesworth. Let us hope many meetings will be held before another such a loss occurs in our ranks.

Gentlemen, the honor you have conferred upon me, by electing me to the presidency of the American Dermatological Association, is, I assure you, fully appreciated by me; and it was my intention to give a token of that appreciation by carefully preparing, according to my ability, an address suitable for this occasion and worthy of your attention. With that object in view, I read, several weeks ago, all the addresses given before this association since its foundation, but found the ground had been so well covered by my predecessors that no untrodden, unworked area,

* President's address delivered at the annual meeting of the American Dermatological Association, held at Hot Springs, Va., September 8, 9, 10, 1896.

² Dr. Edward Wigglesworth.

inviting or requiring consideration, arose before my mental vision.

After further consideration, and especially after thinking over the brilliant address of our late lamented member, the idea was formed that to continue the historical description up to date of the struggle of dermatology for due recognition in America, as given by Dr. Wigglesworth: to describe its present position among the other branches of the medical tree; and also, peering into the future, to consider the lines of study and action most suitable for a proper increase and extension of our influence in territory rightfully belonging to us—territory we have not only discovered but in which we are the active workers, and have settled and cultivated almost everything that has been settled and cultivated—would be acceptable to you. I hope to make it clear, not to my colleagues, for you all know it already, but to the rest of the medical profession, that this territory is of much significance to the human race; that cutaneous diseases are much more numerous, complicated, and serious than is generally believed; that not a few of them are not alone annoying or humiliating, but dangerous to the life of the subjects of them; and that only those who are able to diagnose and understand their nature and course, as far as our present knowledge permits, should undertake their treatment.

At the present time dermatology as a specialty does not, in my opinion, hold the position it should in the eyes of the general profession, considering the magnitude of the subject and the importance of a knowledge of cutaneous diseases. There are reasons for this condition of sentiment, and I hold it possible for dermatologists to bring about a great change in this matter. One reason is the "dark-age" position of the medical schools toward the subject of diseases of the skin, as well as toward other important subjects—as diseases of the eye, etc. Almost every medical school acts on the absurd plan that internal medicine, obstetrics, and general surgery are the only subjects, from a clinical standpoint, worthy of serious consideration and study, and necessary for a student to know something about in order to obtain a diploma entitling the recipient to practise medicine and surgery in all its branches and certifying to his ability to do the same. It is necessary (sometimes) for graduation that the candidate should know the names and mutual relations of the deep muscles of the back; that he should be able to give the surgical anatomy of the parts concerned in the operation of œsophogotomy, and to describe the several steps of the operation; to give symptoms and pathology of Addison's disease, of Asiatic cholera, or of some disease limited to a foreign country. He is required to study diseases he will probably never be called upon to treat, and if he should would have plenty of time to read about—and yet he is not required to know the diagnosis and treatment of purulent ophthalmia, cutaneous epithelioma, or syphilis! Does it not seem strange that the plan of medical education has not yet reached a common-sense, economic basis? In no other branch of science is such a defective, absurd, and morally wrong method followed. If it be true that the diligent and bright student should have a degree at the end of four years of study in a medical college, a view with which I entirely disagree, his training should be so regulated as to give the best basis for independent study after graduation. As far as the practical subjects are concerned, he should be drilled in those diseases only with which he is most likely to be brought in contact, and particularly in those of such serious character as to demand active and correct treatment. He should be informed beforehand of the subject he is expected

thoroughly to study and will be examined in, instead of requiring him to grind into his inexperienced and confused head the contents of a large volume or of two volumes on internal medicine—an utter impossibility; there is even great probability that the author himself, if subjected to the usual "catch" examination, would not receive a fifty-per-cent. marking for his attempts to answer the questions. By such a curriculum he could study properly such subjects as auscultation and percussion, diseases of the heart, lungs, kidneys, digestive tract, etc., and establish a basis in that department upon which he could build after receiving his diploma. The same method in the selection of subjects would be proper as regards surgery and the other departments of medical science. No graduate in arts, not even the honor graduate, is expected to know all of mathematical subjects that is known; but his studies are so arranged that he can subsequently continue the study of his subjects without the aid of a personal teacher. So, also, the medical student who receives a degree entitling him to practise medicine and surgery in all its branches should pursue selected subjects and have such a basis of knowledge in all the branches that he can with advantage continue unaided to study for the rest of his professional life; at the same time his first patients in special departments would be likely to receive more or less correct treatment. If this result cannot be accomplished with four years' study, then no medical college has the moral right to graduate its students at the end of that period. It has no right to declare under seal a person to be fairly capable of treating serious diseases of common occurrence, unless he has been taught and has learned to recognize and treat with more or less skill such cases.

To return to the subject of dermatology: It is a glaring fact that, with the exceptions already noted, in no college in this country do the students devote the time they should to obtain any useful knowledge of the subject of skin diseases. It is true that many of the colleges have professors or lecturers of dermatology; but the classes are too large to be handled to advantage, the lectures are too few in number, and the students rarely devote any time to the study of the subject, as even a smattering knowledge of it is not necessary in order to obtain a diploma. The consequence of all this is that the young graduate does not know how to diagnose the most common skin disease, and, therefore, is unfit to treat it, and certainly is not justified in any sense in accepting a fee from a patient for treatment, especially when there are other physicians within easy reach who, from study and experience, can diagnose the disease and treat it according to recognized proper methods.

These remarks are meant to apply especially to physicians in cities, where specialists can be consulted, either at their private offices or at the clinics or dispensaries. If practising in the country, I think the physician should tell the patient that his knowledge of skin diseases is limited, but that he will treat the case, as he thinks he can benefit him, and certainly can do better for him than if he resorted to advertised "cure-all-skin-diseases" nostrums. Even in this case, if the physician cannot exclude in his diagnosis such diseases as epithelioma, lupus vulgaris, etc., he should write or send the patient to some specialist for assistance. If he writes, and the patient is not a pauper, but one from whom he receives money for his services, he should not forget to enclose a proper consultation fee. I mention this, as it is a notorious fact that physicians very rarely think of rewarding a specialist for advice obtained by letter; and this is most unfair, as the task of answering such letters usually consumes considerable time, and is, furthermore, a consultation, and should be regarded as such. I have no doubt you

¹ Harvard is an exception, and the University of Pennsylvania, I understand, intends to follow in Harvard's footsteps.

all, like myself, receive a great many such letters every year, and much time is taken up in considering and writing a suitable reply. This complaint is directed more to the older, so-called established physician, than to the one who has just hung out his shingle. Of course, if the case is one of charity, we are always willing to contribute to the relief of such sufferers, without money and without price.

I do not believe that dermatologists make known through the proper channels—the medical profession—our convictions upon this subject of the moral duty of the physician toward himself and his patients in the practice of medicine. A physician should appreciate the fact that, if he intends to practise the art in any special department in addition to internal medicine or surgery, he is not qualified to do so unless he has studied the special subject, under a capable teacher, a sufficient length of time to acquire a fair knowledge of it. That this knowledge is not obtained at the regular undergraduate schools, is easily demonstrated, as far as the subject of dermatology is concerned. Since the opening of the New York Polyclinic I have lectured to at least three thousand physicians, who have come from different parts of the country to take a post-graduate course. Of this number, not one per cent. were able to diagnose the different cases of eczema presented at the clinics, and such diseases as lupus vulgaris were an enigma. In England there is a special diploma in medicine and a special diploma in surgery. This, I believe, was a step in the right direction, and sufficient for the time when it was instituted. At the present day the subject of medicine is too large for the mental grasp of a single individual, especially if he has to earn his daily bread by the practice of his profession. The time has come, I believe, when colleges should separate, to a certain extent, the different well-recognized branches of medical science, and grant special diplomas or certificates to those who have given special attention to and shown special knowledge in a particular branch, in addition to the ordinary degree of doctor in medicine. Of course, a fair knowledge of general medicine and surgery should be required, just as the graduate in surgery in England must also pass an examination in internal medicine. As the country is greatly overstocked with physicians, necessitating considerable "hustling" with a large percentage of them in order to increase their incomes, and the colleges continue to manufacture them in increasing numbers each successive year, such a system would, in time, result in benefit to the afflicted, as they would probably learn to seek the advice of a physician according to the character of his extra diploma and the supposed nature of the disease. As a final result, owing to the increased attention given to special subjects, the poor and middle classes would probably cease flocking to dispensaries and clinics, as they could receive private treatment by a partial specialist for a fee within their means—and that, up to the present time, they cannot get, and so should not be blamed for seeking free advice at a clinic.

Until the above-sketched plan of teaching and graduating is followed, or dermatology accorded its proper place in medical schools, we must not without protest allow the recent graduate to imagine that he is justified in treating any skin disease except those he has learned to diagnose. By such action we might encourage him to pursue his studies further before commencing private practice, or combine both practice and post-graduate studies.

While we can quietly and honestly impress upon the recent graduate the necessity for further study, and the fact that he should regard the four years of under-graduate study as only preparatory to studies necessary to enable him to do justice to his patients, we must be more aggressive with the "old practition-

er," the "established" physician, especially in a city—he who grasps all but refuses to devote the time to such post-graduate instruction as would enable him to treat the ordinary run of office cases. I have always strongly advised the general practitioner in the country to take a six-weeks' course every second year, at one of our post-graduate schools, upon one or two special subjects each time. There is statistical proof that many physicians have followed this plan within the last few years, and they are a credit and a worthy example to the profession. They learn the difficulties of diagnosis, in skin diseases for instance, and to appreciate more fully the importance of the subject and the value of an expert opinion in many cases before resorting to that reputation agent, the knife. Post-graduate schools are the great teachers of the importance of the special departments in medicine. Under post-graduate instruction is included, of course, instruction from whatever source, whether in schools founded for that purpose, or in connection with an undergraduate school, or from a private teacher, such as our old friend, the "docent" in Vienna, or from medical books and journals. The "complete" specialist must draw from every source, and should not only study in America, but also in Europe; and the "would-be" dermatologist must remain long enough at the medical centres to learn the views of the different teachers, as well as see a large number of cases of skin diseases. In addition, he should not fail to devote for subsequent aid considerable attention to internal medicine and nerve diseases, even if he does not practise outside of pure dermatology.

The surgeon invades our territory almost as much as the general practitioner, and if he has not shown us as much consideration as we feel he should, it is, to a great extent, our own fault. We have not impressed him as much as we should with the real value of our opinion in consultation in a wide range of cases. He treats a good many diseases which we think belong more properly to dermatology, although the border line is often not well marked. Be that as it may, I think the surgeon should recognize the fact that unless he is thoroughly familiar with all the manifestations of syphilis, for instance, he should have a consultation with a dermatologist rather than with a surgeon, if he be in doubt as to whether a certain case be one of sarcoma, lupus, tuberculosis, or syphilis. We are all liable to make an incorrect diagnosis sometimes, but I have seen—we all have seen—a goodly number of unnecessary surgical operations and much mutilation produced in cases easily to be diagnosed by a skilled dermatologist. Most excellent and learned surgeons have performed serious operations with the view of removing a malignant growth, when iodide of potassium would have very quickly accomplished the same result. As the internal-medicine expert should be called in consultation by the surgeon in a suspected case of appendicitis, so the dermatologist should be consulted by him before operating upon a rectum for a supposed sarcoma, or removing a jaw for suspected cancer, or a testicle for supposed tuberculosis. A small lesion situated upon some other part of the body, a lesion to be diagnosed, perhaps, only by a skilled dermatologist, will often give a clew to a correct diagnosis of a tumor situated, say, in the jaw, tongue, or rectum. Who should be so capable of diagnosing a cutaneous epithelioma at its earliest stage, at a period when correct treatment offers such excellent results, as the physician familiar with all the forms of cutaneous disease? And who should be able to treat such a case more efficiently and with less resulting deformity than he? The dermatologist, with his knowledge of the anatomy and intimate structure of the skin, should usurp his real province in all cutaneous diseases, and obtain the legitimate results of

his special studies and knowledge therein. The general profession should learn, through our discussions and publications, that the study of cutaneous diseases is a large subject, and a comprehensive knowledge of it is obtained only after many years of diligent study and observation. Few physicians in a city think of invading the field of ophthalmology, and the same should be the case with our specialty, for it is an equally important one from every point of view. If we do justice to ourselves and our subject, the medical schools must and will, finally, give us rightful recognition, and the general physician and surgeon will cease thinking that any one can treat skin diseases and that a consultation with a dermatologist is only necessary "after all other means have failed."

By the term specialist, as used in this address, I mean a physician specially skilled in dermatology. A specialist—that is, one who devotes himself to the practice of only one subject—is not necessarily a specialist in the sense of the term as used by me, for such a one may, after all, not possess special knowledge of the subject. A physician, also, may be a learned specialist in more departments than one. That is not unusual, and even in widely separated subjects, such as dermatology and ophthalmology, or surgery. So, also, one may be an expert in the treatment of a limited number of diseases in a special department, without being a specialist in the whole subject; for instance, a surgeon may be an expert in abdominal surgery, and not in brain surgery or surgical diseases of the rectum.

It is, in reality, a question of brains, time, and opportunities; but there is a limit, and, as a rule, two special departments make the limit. And they should be somewhat related subjects, as internal medicine and dermatology, and not genito-urinary surgery and dermatology. In some places of study, one can see more dermatological cases in three months than in others in a year; and many physicians live a much longer medical life than others during the same number of years, by sticking closely to their studies and avoiding engagements, and limiting the hours devoted to sleep and meals to a physiological number. A great deal of time can be saved and utilized in this way, and if devoted to a second subject may lead to special knowledge of it. Personally I believe every physician should devote several years to post-graduate studies before commencing private practice on his own responsibility.

The time is long past when it was thought there were only three kinds of skin diseases—one sulphur would cure, another arsenic would cure, and a third the devil couldn't cure. The time should now be past when any physician is entitled to think he can treat any case of so-called eczema. The profession should learn that only a skilled expert can diagnose correctly the kind of eczematous inflammation present in a given case, and understand the cause and processes at work, and treat them intelligently and in a manner the patient has a right to expect. When all these things are learned—and we are the individuals who should teach them—then those afflicted with cutaneous disease, including syphilis, will receive proper treatment from skilful hands. Then we will see students anxious to attend colleges where dermatology can be learned; there will be special wards for cutaneous diseases in our public hospitals and private hospitals will be erected, such as now exist for other special branches, such as diseases of the eye; our not over-ethical nor over-scrupulous medical journals will not contain advertisements of some preparation warranted to cure all skin diseases, or be filled with formulæ for the treatment of eczema, pruritus, etc., for such advertisements on their very faces would bear the stamp of humbug

to the educated physician. To bring about this result, we must simply be properly aggressive in our writings toward notorious offenders, and by our studies and works show the great importance of a knowledge of our specialty for the relief of human suffering.

The above outspoken remarks are not intended to apply to all physicians, as they would not be true as regards the very considerable number of the profession who make a point of referring to some specialist all cases they do not feel fairly competent to treat. All I have said is intended to aid the advancement of medicine, both in its moral and scientific aspects.

I believe all publications representing original work, and equivalent to a contribution to existing knowledge, should be published only in a journal devoted to the specialty. The same is true of reports of meetings of dermatological societies and reports of unusual cases of skin disease. If this were done, it would, at a small expense, be possible for the dermatologist to keep track of the only literature upon the subject worth reading. Other articles, not representing contributions to existing knowledge, but intended to teach the general practitioner, should be printed in journals devoted to general medicine and not to dermatology. Such papers, when written, should be devoted to a discussion of diseases with which the general physician supposes himself to be capable of diagnosing and treating, as acne vulgaris, etc.; and even then the difficulties of diagnosis should be emphasized. Papers of this kind, or such as deal in a general manner with cutaneous diseases, may and should be written with the object of drawing attention to the knowledge and experience required for the proper recognition and treatment of these affections; and, as they can reach the general profession only through the columns of a general medical journal, that is the proper organ for their publication. At no time and on no occasion should a paper be read or published for the purpose of advertising the author, and yet I am afraid such things have occurred and will occur again. We should keep a lookout for such "dermatologists"—they may some day apply for admission to our association.

I believe it to be the duty of this association to guard the interests of dermatology in America and to maintain a membership herein. A membership should be the goal of every true dermatologist in this country, and when such a one has earned by his labors and character a fellowship with us he should be admitted, irrespective of personal feelings. We should watch the medical course of possible aspirants, read their articles, and observe if the quantity and quality are proportionate to the subject or subjects discussed. A scribbler who writes for notoriety and keeps the printing-machine busy is not likely to bring us much credit, and should not have a 16 to 1 chance for admission. I would suggest a very careful consideration of all candidates proposed for membership, and trust no one will propose a name merely because he was asked to do so or because he is a personal friend of its bearer. The more select the membership, the more honor to be admitted a member. I see danger ahead if much caution is not exercised.

I hope the innovation this year, of devoting considerable time to an exhibition of drawings, colored and uncolored photographs, instruments, microscopical sections, will be regarded favorably by the members. I am a warm believer in great mutual benefit from such exhibitions, and think that the reading of papers upon subjects specially adapted for general discussion and requiring only clinical observation, together with these exhibitions, should be the leading features of our annual meetings. Such an arrangement would make our meetings have more the character of clinical demonstrations than of didactic lectures, and more in-

accordance with modern ideas of teaching: for, after all is said, we meet not alone to enjoy each other's fellowship and guard the dignity of dermatology, but also to learn anything that is new and worthy of knowing.

THE EFFECT OF EARLY OPTIC ATROPHY UPON THE COURSE OF LOCOMOTOR ATAXIA.

BY PEARCE BAILEY, M.D.,

ASSISTANT IN NEUROLOGY, COLUMBIA COLLEGE; ATTENDING PHYSICIAN TO THE ALMSHOUSE AND WORKHOUSE HOSPITALS AND HOSPITAL FOR INCURABLES, NEW YORK CITY.

It has long been observed by neurologists and ophthalmologists that individuals who develop, without assignable cause, an atrophy of the optic nerves may, after a considerable period of time, begin to have lightning pains, or may become ataxic, or present other of the classical symptoms of locomotor ataxia. Although typical tabetic symptoms have been delayed for as long as nineteen years, the failure to discover any other cause for the optic atrophy and the frequency of occurrence of this symptom in tabes lend probability to the assumption that in such cases the atrophy was the first manifestation of the systemic degeneration, and that during the interval between the occurrence of atrophy and the beginning of the spinal symptoms the disease was quiescent.

The following case, which recently came to the Vanderbilt Clinic, has no symptoms of locomotor ataxia, except blindness and loss of knee jerk, although other tabetic symptoms will undoubtedly develop eventually: Man, aged thirty-six; syphilis denied. One year ago he became blind in the left eye and soon after in the right. Knee jerks absent; double optic atrophy; no pain; no Romberg symptom; no sensory changes; no crises; no oculo-motor paralyses.

The proportion of these "primary" optic atrophies which eventually develop tabes to those which do not is not accurately determined. Gowers states it to be about fifty per cent. The fact that optic atrophy may be an early symptom in general paralysis of the insane was illustrated by a case which recently came to my notice. There was nearly complete blindness, but the mental and physical symptoms of paresis, though unmistakable, were not far advanced.

Benedikt was the first to attribute to an initial optic atrophy a postponing influence upon the development of the other symptoms of locomotor ataxia; and he went further, and formulated the statement that in many cases of tabes in which atrophy of the optic nerves was an early symptom the character as well as the course of the disease would be changed. Symptoms sufficient for a recognition of the trouble might develop, but ataxia and pain would not occur. He also maintained that if the atrophy took place after the disease had become symptomatically characteristic the occurrence of blindness would be accompanied by an amelioration of the spinal symptoms. Déjerine indorses Benedikt's first proposition, but does not agree that optic atrophy, occurring after the disease is developed, will be followed by any improvement of the spinal symptoms. Since the appearance of these earlier articles, the subject has received attention from Berger, Walton, Martin, Pershing, Buzzard, and Déjerine. Martin's is the most valuable of these contributions, as it embodies the results of careful examination of twenty-one cases in which locomotor ataxia was surely present, and in which optic atrophy was the first (in six cases) or among the first symptoms. In three of these patients the pains did not appear until seventeen, eighteen, and nineteen years, respectively, after the blindness. In eleven cases the pains were diminished after atrophy occurred; ataxia was present

in six cases, but developed in one only, after the atrophy was established. But it will be seen from these studies that optic atrophy, as an early symptom, may be speedily followed by ataxia, and that the pains do not necessarily disappear when the blindness comes. Thus the position that initial optic atrophy will invariably retard the appearance of spinal symptoms is no longer tenable.

These results of Martin's accord in many ways with observations of my own; but as the subject, which is of considerable importance to neurologists, has received little attention, I have been led to record the cases of locomotor ataxia which are accessible to me, and most of which I have personally examined, in which optic-nerve atrophy was the initial or an early symptom. I am indebted to Professor Starr for his kindness in permitting me to utilize the records of the Vanderbilt Clinic for this purpose. Of the one hundred and twelve carefully recorded cases which have come to the clinic in the past few years, seven have given symptoms of optic atrophy as an early symptom. It is greatly to be regretted that in three of these an ophthalmoscopic examination was not made, but, as the examination of the pupillary reflexes necessitates close observation of the eye, I think it fair to assume that in these cases the blindness which involved both eyes was due neither to cataract nor to corneal opacities, of which no mention is made in the history, but in all probability to an atrophy of the optic nerves.

In addition to the seven clinic cases, five of the eighteen cases of tabes at present under my care at the Hospital for Incurables, give a history of early atrophy, which has been verified by ophthalmoscopic examination.

I have to thank Dr. Gomez for his kindness in undertaking the ophthalmoscopic examinations.

The cases are as follows:

CASE I.—Male, fifty-three years; has had syphilis. The first symptom was a failure of sight, which came on five years previously. There never were any pains. Knee jerks absent; inco-ordination; girdle sensation. Eyes: Pupils do not respond at all; totally blind in the left eye; can distinguish light only in the right.

CASE II.—Male, aged thirty-eight; syphilis denied. The first symptom was failure of sight, which came on two years previously. Never any pain or ataxia. Numbness of hands and feet; knee jerks absent. Eyes: Argyll-Robertson pupils; left eye totally blind; right eye very much impaired.

CASE III.—Male, forty-seven years; probably has had syphilis. The first symptom was failure of sight, which came on one year previously. Knee jerks absent; ataxia of arms and legs. Never any pain. Eyes: Advanced optic atrophy.

CASE IV.—Male, forty-five years; syphilis denied. The first symptom was dimness of sight, which came on three years previously. Ataxia began in third year of disease; there were very slight pains at first, none since. Knee jerks absent. Eyes: Right, pupil wider than the left; left, external strabismus, totally blind.

CASE V.—Male, aged forty-two; syphilis denied. The first symptom was dimness of vision. No pain; no inco-ordination. Knee jerks: Left, absent; right, present. Eyes: Argyll-Robertson pupil; double optic atrophy.

CASE VI.—S. D.—, female, aged fifty-five; syphilis denied. The first symptom, six years ago, was paræsthesia in legs and feet, followed by sharp shooting pains in the back and legs, which lasted one year. One year ago sight began to fail, and she became totally blind in six months. No ataxia; no Romberg symptom; no loss of sense of position; knee jerks absent; areas of cutaneous anæsthesia. No severe pain now, but paræsthesia in legs and back. Slight incontinence. Eyes: Pupils unequal; respond slightly

during efforts at accommodation, but not to light; almost totally blind; double optic-nerve atrophy; no oculo-motor palsies.

CASE VII.—G. K.—, aged forty-nine; syphilis denied. The first symptoms, seven years ago, were interference with gait and shooting pains in the thighs and legs. Six and one-half years ago eyesight began to fail in the left eye, and about one month later the right eye became affected; was totally blind in six months. At present, ataxia of legs and hands; cannot walk; loss of knee jerks; retention of urine. Pains less severe than before and trouble the patient very little. Eyes: Paralysis of the left internal rectus; pupils unequal; loss of pupillary reflexes; double optic-nerve atrophy.

CASE VIII.—A. M.—, aged fifty-six; syphilis uncertain. The first symptom, twenty-four years ago, was swelling of the right knee-joint, which was operated upon for "dropsy." This knee is now a typical Charcot joint. Sixteen years ago sight began to fail, and total blindness was established in one year. Could work very well until six or seven years ago, since which time ataxia in legs became so marked that walking was impossible. Never any pain, except local pain in the right knee-joint. The patient is now a perfect example of advanced locomotor ataxia—blind and bedridden, with retention of urine, loss of all reflexes, and areas of cutaneous anæsthesia. Eyes: Totally blind; pupillary reflexes, absent; bilateral third-nerve paresis, with double external strabismus and atrophy of both optic nerves.

CASE IX.—W. W.—, aged fifty-five; syphilis thirty-six years ago. The first symptom, three or four years ago, was inco-ordination of legs. One year ago he began to lose sight, and now is totally blind. Never any pain. Gait very ataxic. Loss of sense of position; hands not involved. Knee jerks absent; sphincter control retained; no changes in sensation; Romberg symptom. Eyes: No pupillary reactions; totally blind; double optic atrophy; no oculo-motor palsies.

But no rule is without its exception, and that an initial optic atrophy may very speedily be followed by other characteristic and serious symptoms of locomotor ataxia is positively proved by the three cases which follow:

CASE X.—W. F.—, aged fifty-five; syphilis probable. The first symptoms, in 1891, were sharp shooting pains in the back and legs and difficulty in walking. About one year later, began to lose sight; the left eye was first affected, and was totally blind in one year. Pains increased in severity with the occurrence of blindness. Now very ataxic; cannot walk. Pains not very severe. Eyes: No pupillary response; double optic-nerve atrophy; bilateral third-nerve paresis, with double external strabismus.

CASE XI.—Male, forty-nine years; has had syphilis. The first symptom, occurring three years previously, was dimness of vision. This was soon followed by sharp shooting pains and ataxia. Knee jerks absent. Eyes: Argyll-Robertson pupil; beginning optic atrophy.

CASE XII.—Male, aged thirty-two; has had syphilis. Symptoms, consisting of dimness of vision, pains, and ataxia, came on simultaneously one year previously. Knee jerk absent. Eyes: Optic atrophy.

A summary of these twelve cases shows that in nine the early development of optic atrophy had an apparent inhibitory influence upon the evolution of the disease, especially as regards pain, which either developed not at all, or was slight, or became less severe when the atrophy began. Ataxia failed to develop in three of these nine, but was present in the rest, and in some was very marked. When pain and ataxia both were absent, there were, in addition to the optic atrophy, sufficient symptoms to justify the diagnosis of tabes.

In four of the cases cited there were present oculo-motor palsies, affecting chiefly the third pair.

The last three cases of the series demonstrate very positively that locomotor ataxia may develop in its characteristic form in spite of optic atrophy as the initial symptom.

It is unquestionable that in some but by no means all cases of tabes early optic atrophy exercises an apparently inhibitory influence upon the evolution of the disease. Why this should be so it is impossible to conjecture, and we are obliged to be content with the ability to hold out to patients in whom optic atrophy is an early symptom the hope that the disease will pursue a mild course in other directions. It is possible that more extensive statistics, based upon the systematic observation of patients who develop primary optic atrophies, will alter our present views on this subject. Widely different results have been obtained by different investigators in regard to the symptomatology and etiology of this sensory systemic disease.

As an example of the latter fact may be cited the assertion, made by high authorities, that aortic insufficiency, directly dependent upon the syphilitic or tabetic process, is the commonest complication of the disease. Some investigations of my own tend to contradict this opinion; and in three hundred cases of Erb's, reported by Leimbach, in which the heart was carefully examined, only three presented any evidences of aortic leakage.

Again, Erb's statistics show that optic atrophy occurs in 6.75 per cent. of the cases, while Déjerine says that of one hundred tabetic patients under his care eighteen were completely blind from an early atrophy of the optic nerves.

Thus more extended attention than the influence of the optic-nerve atrophy has obtained will be necessary before it can be definitely determined just how far and how frequently the disease may be modified by the occurrence of any initial individual symptom. There is at present a man, aged thirty-five years, syphilitic, under my observation, who for two years has had retention combined with occasional incontinence of urine. He has the Argyll-Robertson pupil and no knee jerks, and there is no discoverable local cause for the urinary symptoms. The man, in my opinion, has had locomotor ataxia for two years, yet he never has had either pain or ataxia. It would not be justifiable to infer that the bladder trouble had caused a delay in the evolution of other symptoms. So it may be with any individual initial symptom. And with early optic atrophy we would be on the safe side if we limited ourselves to stating that, from the present knowledge of the subject, in a considerable proportion of the cases of locomotor ataxia in which atrophy of the optic nerves is an initial or early manifestation some of the spinal symptoms may be late in appearance or may not develop at all. So that the only justifiable conclusions from present data are that:

1. In about seventy-five per cent. of the cases of tabes in which optic atrophy is an early symptom some of the other tabetic symptoms may be late in appearing or may not develop at all. This is especially the case in respect to the lightning pains and the inco-ordination of movement. The loss of knee jerk in such cases is very constant.

2. The most distressing symptoms may develop simultaneously with or immediately succeed the blindness.

3. The association with the optic atrophy of oculo-motor palsies is without prognostic significance.

4. The subject will receive its best elucidation by the observation, over long periods of time, of patients with "primary optic atrophy."

Progress of Medical Science.

Magnan's Sign in Chronic Cocainism.—Dr. Ribakoff (*Gaz. d. Osp. e d. Clin.*, August 4th) has had occasion to observe a couple of cases of severe chronic cocainism, in which Magnan's sign was the predominant symptom. This is a hallucination of the cutaneous sensibility, characterized by the sensation of a spheric foreign body under the skin, varying in size from a grain to a nut. This sensation is peculiar to this intoxication, and its differential value should be more generally recognized.

Chlorosis no Contraindication for Marriage.—Dr. Grosset (*Thèse de Paris*, 1896) discusses this subject, and concludes as follows: 1. The physical and spiritual excitement which marriage offers a chlorotic girl can have only a favorable effect upon her disease. 2. The sterility of chlorosis is only a temporary one in most cases, the rare instances of infantile genitals being excepted. 3. Chlorosis does not predispose to abortion. 4. The children of a chlorotic woman are likely to be chlorotic, but they seem to show little tendency to become tuberculous.

Etiology of Peritonsillar Abscess.—Dr. Logueki ("Beiträge zur Aetiol.," etc., *Arch. f. Laryn. u. Rhin.*, Bd. IV., Heft 2) says that abscess in this region presents itself usually under two distinct clinical forms. In the first the pus collection is situated between the gland and the anterior pillar, which is decidedly bulged forward. There is likewise prominence of the vault of the palate and considerable œdema of the uvula. In the second the abscess is located between the tonsil and the posterior pillar. In this variety the affection lasts longer and presents more pronounced symptoms than in the first variety. The author has examined eleven cases from a bacteriologic standpoint. In a recently opened abscess about the tonsil streptococci are especially found; at a later period streptococci and staphylococci; in a still later period only staphylococci. Now it is well known that all these micro-organisms are found in crypts of the tonsil even in healthy persons. If an acute amygdalitis comes on, this always occasions an adhesion between the surface of the tonsil and the pillars of the fauces: the contents of the crypt, not finding any external exit, set up an irritation of the peritonsillar tissue and determine in it an inflammation and an infection by the above-mentioned microbes, which suddenly acquire virulent properties.

Venereal Bubo.—In an article on their etiology and treatment, Dr. Perry, of the Marine Hospital service concludes as follows (*The American Journal of the Medical Sciences*, November, 1896): 1. That buboes are probably caused by the absorption of chemical poisons, the result of the action of the micro-organisms in the chancroid, and not to the entrance of the micro-organisms themselves into the lymphatics. 2. That the benzoate of mercury yields such satisfactory results that it should be employed in the treatment of

non-suppurating buboes, and excision reserved for those cases in which benzoate has failed. 3. The injection of iodoform ointment should be used in the treatment of all freely suppurating buboes, since statistics show that it yields much more satisfactory results than the other methods of treatment applicable to this variety. 4. Incision and curettage should be used in a few cases in which the skin has been destroyed and the ulcer presents an unhealthy granulating surface. 5. Excision should be reserved for cases that have not yielded to other treatment, and for those in which there are several foci of suppuration.

Results of Hydatids.—Dr. Frank (*American Journal of the Medical Sciences*, October, 1896) writes that hydatids of the liver may cause no trouble whatever or the following results may transpire: 1. By pressure interfering with the functions of some organs of the body, and by attaining a large size causing ascites and dropsy. 2. Forming adhesions with the diaphragm and ulcerating through, either into the pleura, causing pleuritis; or further ulceration may take place in the lung, and the contents, coming originally from the liver, may by this channel be expectorated and lead to a spontaneous cure. 3. A fistulous opening may be formed into the lumen of the bowel and lead to a cure. 4. If they open into the stomach and the fluids and cysts be vomited, a cure is the result. 5. If a simple cyst ruptures into the kidney or bladder, a spontaneous cure is possible. 6. If they empty into the pericardium, the peritoneal cavity, bile ducts, or gall bladder, the result is disastrous. 7. Cases are on record in which hydatids have invaded the trachea and produced death by suffocation. 8. Nature's best cure, without any surgical aid, is the formation of adhesions to the parietes. Cases are on record which have emptied themselves externally, but this favorable result is not often met with. 9. Finally, a calcareous degeneration may take place within the cyst, and thus lead to a very satisfactory termination.

The Cause of Sudden Death after Antitoxin Injections.—Drs. A. Seibert and F. Schwyzer (*Medical Journal*, May 30th) published the following conclusions: 1. Antitoxic serum does not seem to be capable of causing threatening symptoms and speedy death, even when brought quickly into the blood current in very large doses. 2. The carbolic acid used in preserving the antidiphtheritic serum must be in such a weak solution as to be entirely unable to cause the characteristic carbolic convulsions produced in every one of our second series of experiments. The absence of these convulsions in patients in the cases of sudden death, the entirely different group of symptoms reported in them, and the fact that guinea-pigs and rabbits will survive even very large and concentrated doses of carbolic acid injected into a vein, lead us to discard the possibility of this drug having caused the reported deaths. 3. Even very small quantities of air will cause severe disturbances and ultimate cessation of breathing in every animal experimented upon. These disturbances are entirely analogous to the symptoms reported as preceding the sudden deaths after antitoxin injections. Air is found alongside of the fluid in every syringe used for hypodermic injections, and being pressed under the skin with the fluid may readily come in contact with a punctured cutaneous vein and so may enter the blood-vessel and the right heart, even before the serum has been absorbed. In view of these facts and of our experiments, we here express our firm opinion that the sudden deaths reported after antitoxin injections were caused by injected air and not by the antidiphtheritic serum.

THE TREATMENT OF PERNICIOUS ANÆMIA.

OUR notions concerning the nature of pernicious anæmia have undergone various modifications since its recognition by Addison in 1855, and by him designated idiopathic, and its subsequent description by Biermer, in 1868, as an independent affection. A final decision cannot yet be given as to whether the disorder is dependent principally upon excessive blood destruction or upon deficient blood production, but the statement can be safely made that the affection is no longer looked upon as primary or idiopathic, and doubt may exist in some cases as to its progressive and pernicious character, in the sense in which it has been customary to employ these terms.

A growing experience has taught that profound and fatal anæmia may result from a variety of causes, sometimes perfectly obvious, but at other times so obscure as to escape detection at the hands of the keenest clinical observer. Sufficient evidence has accumulated to justify the conclusion that in a not inconsiderable proportion of cases the blood depravity results through the gastro-intestinal tract, perhaps in consequence of poisonous products there generated, or by infection, or from the presence of parasites of other character. These advances in our knowledge of the etiology of the disease have not been without their influence upon a selection of the means employed in its treatment. Thus, whenever a source of hemorrhage or other wasting discharge can be discovered, the first essential step is to secure its control. When animal parasites are found to be present in the intestinal tract, their extrusion must be effected by appropriate means. When it is suspected that the condition arises in consequence of intoxication, resulting from some failure in the normal digestive and assimilative processes, measures calculated to aid gastro-intestinal digestion and disinfection will be indicated; if the intoxication be dependent upon the retention of metabolic products intended for excretion, laxatives—and especially calomel and salines—may be used with advantage.

Upon the assumption that the excessive hæmolysis is supposed to take place in pernicious anæmia as a result of the presence of toxic matters in the gastro-intestinal tract, Gibson¹ was led to use two-grain

pills of beta-naphthol, given twice or thrice daily, in the treatment of a case of that disorder, with the happiest results. Acting upon the same thought and adopting a suggestion of Fraser,¹ Dieballa² employed successfully salol in a case of similar kind, in which the usual remedial agents had been previously employed without avail. The patient was a laborer, fifty years old, who suffered greatly from weakness, and presented a yellowish discoloration of the skin and conjunctivæ, and pallor of the lips and mucous membranes, with a reduction of the red blood corpuscles to 1,120,000 per cubic millimetre, of the white to 2,600, and of the hæmoglobin to 43 per cent. At the age of thirty-one he had had a like attack, from which he recovered in the course of six months, and again at the age of forty-five. The red blood corpuscles varied greatly in size and shape, and some were nucleated. Of the colorless corpuscles, 55 per cent. were polymorphous neutrophile, 21 per cent. lymphocytes, 13 per cent. large mononuclear cells, 8.5 per cent. transitional forms, and 2.5 per cent. eosinophile cells. After arsenic, bone marrow, iron, inhalations of oxygen, and quinine, singly and in combination, had been employed for more than four months without appreciable benefit, salol was given in doses of fifteen grains five times a day. Unpleasant symptoms arising, the frequency of administration was reduced to three times a day. The treatment was continued thus for three months, at the end of which time the red corpuscles had increased in number to 4,200,000 per cubic millimetre, the colorless corpuscles to 7,000, and the hæmoglobin to 60 per cent., while a gain in weight of thirty pounds had been made. Of the colorless corpuscles, the polynuclear neutrophile were increased to 68 per cent., and the large mononuclear and transitional forms to 8 per cent., the others undergoing practically no change. The presence of eosinophile cells in about normal proportion was looked upon as indicative of maintained functional activity of the bone marrow in the process of hæmogenesis, and to this extent of favorable prognostic omen.

In cases in which the blood-forming organs are believed to be at fault, bone marrow may serve a useful purpose. The influence which this substance is capable of exerting is still undecided, but in a disease like pernicious anæmia, in which no measure can be expected to act with certainty for good, the patient should be given the advantage of every doubt, and no remedy should be neglected which may even doubtfully render a service. In the way of agents that aid in blood making, the first place must be given to arsenic, given in doses as large as the patient will bear and for a long period of time. Iron is not capable of the same good, but may find a useful place in the treatment. Inhalations of oxygen have at time proved a valuable therapeutic adjunct.

It goes without saying that the diet should always be the most nutritious possible, special care being observed to maintain digestive integrity and activity, while no general hygienic precaution should be neglected. Moderate and gentle exercise in the open

air, within the limits of fatigue, and exposure to sunshine, should be judiciously indulged in. Symptomatic indications must be met as they arise. Strychnine in moderate doses will almost always serve a useful purpose.

In attempting to reach a decision as to the efficacy of any plan pursued in the treatment of pernicious anæmia, it is to be borne in mind that periods of transitory improvement, of varying duration, are often a part of the natural course of the disease, so that too much importance must not be attached to the favorable results that may follow the special line of medication employed. Even if such improvement continue for a long time, the conclusion must not be too hastily reached that the disease is cured.

THE SIGNS OF LONGEVITY.

EVERY ONE is interested in the question of long life as applied to himself, and all facts bearing on it are noted with becoming feelings of self-congratulation or otherwise. It is the staying power that is in demand, backed by an inherited and reserved vitality of resistance against the usual evils to which all flesh and other perishable things are subject. The law of heredity, which our life insurance companies understand so well, is at the bottom of all calculations as to whether a particular man or woman is wound up for seventy years or will run down at twenty or forty years.

Aside from this testimony, there are certain physical qualities which have great weight in determining the result of the struggle against a conspiring environment. An oak has one configuration, and a cedar, pine, or mullein stalk another. It is the proper recognition of such distinctions that aids physicians in their prognosis and turns the balance against apparently desperate chances.

At a recent meeting of the Academy of Science, Mr. F. W. Warner, in speaking upon the subject of biometry, offered some very interesting data, which are in the main true.

"Every person," said he, "carries about with him the physical indications of his longevity. A long-lived person may be distinguished from a short-lived person at sight. In many instances a physician may look at the hand of a patient and tell whether he will live or die.

"In the vegetable as well as in the animal kingdom, each life takes its characteristics from the life from which it sprung. Among these inherited characteristics we find the capacity for continuing its life for a given length of time. This capacity for living we call the inherent or potential longevity.

"Under favorable conditions and environment, the individual should live out the potential longevity. With unfavorable conditions this longevity may be greatly decreased, but with a favorable environment the longevity of the person, the family, or the race may be increased."

Herein are presented the two leading considerations, always present and always interdependent—the

inherited potentiality and the reactionary influences of environment.

"The primary conditions of longevity," he continues, "are that the heart, lungs, and digestive organs, as well as the brain, should be large. If these organs are large, the trunk will be long and the limbs comparatively short. The person will appear tall in sitting and short in standing. The hand will have a long and somewhat heavy palm and short fingers. The brain will be deeply seated, as shown by the orifice of the ear being low. The blue hazel or brown hazel eye, as showing an intermission of temperament, is a favorable indication. The nostrils being large, open, and free indicates large lungs. A pinched and half-closed nostril indicates small or weak lungs."

These are general points of distinction from those of short-lived tendencies, but, of course, subject to the usual individual exceptions. Still, it is well acknowledged that the characteristics noted are expressions of inherent potentiality, which have been proven on the basis of abundant statistical evidence.

Again, he says truly:

"In the case of persons who have short-lived parentage on one side and long-lived on the other side, the question becomes more involved. It is shown in grafting and hybridizing that nature makes a supreme effort to pass the period of the shorter longevity and extend the life to the greater longevity. Any one who understands these weak and dangerous periods of life is forewarned and forearmed. It has been observed that the children of long-lived parents mature much later and are usually backward in their studies."

Such observations are of the highest importance, especially to the physician, and it is on this ground we commend them to his thoughtful consideration.

CHARCOAL AS A SURGICAL DRESSING.

KIKUZI, a Japanese army surgeon, as our readers already know, has introduced, with great success, charcoal, freshly prepared by burning rice straw, as a dressing on the battlefield and in military hospitals. A qualitative analysis shows the presence of potassium, sodium, aluminium, magnesium, lime, iron, chlorine, sulphur, phosphorus, silicates, and organic substance. Its absorbent qualities are but slightly inferior to that of gauze, and it makes even pressure. Dr. Matignon, an attaché of the French legation in China, has been most favorably impressed with this dressing, and gives, in *La Médecine Moderne*, May 6, 1896, the following *résumé* of its advantages:

"1. Its elasticity and its absorbent powers are equal to those of gauze.

"2. It is found everywhere, and can be obtained quickly in large quantities.

"3. Its price is minimum, being a twentieth part of that of gauze.

"4. It may be employed at once, its disinfection resulting from its preparation.

"5. It is not necessary to transport it."

In this connection we would refer to an article upon the uses of charcoal as a dressing in military surgery,

based upon an experience in the Franco-Prussian war. Dr. Samuel Sherwell, of Brooklyn, published in the *New York Medical Journal and Obstetrical Review* for October, 1882, a paper which he had written in 1876, just after the battle of Plevna, and which he read in the surgical section of the International Medical Congress in London, in 1881.

As surgeon in the Anglo-American ambulance, the writer saw considerable field-hospital practice at Sedan, Orleans, and other places, and was only too familiar with the ravages of septicæmia and pyæmia after amputation and important operations. In his article, which is entitled "A Ready and Convenient Antiseptic Dressing for Amputations and Other Open Wounds in Field Hospitals," he says: "Among almost all continental nations charcoal is largely used and everywhere available or easily obtained. I would suggest, then, after operation, the instant envelopment of the wounds, particularly those of the limbs, and more especially, as I think, those of the lower limbs, in a sack or bag (a common small pillow slip would serve) of charcoal finely pulverized, a fair excess of this to be used so as to shield and envelop the tissues, the charcoal to be either directly laid on the wound or mediately, a fold of gauze being applied next the surface; this not to be removed for days at a time, except under pressing necessity, and then preferably by a jet of water from some clean source."

It should be a source of gratification to Dr. Sherwell to know that, after all these years of Listerism and antiseptis and aseptic treatment, which can never be properly carried out in a busy field of carnage, his excellent and original suggestion has been put into practical use on a large scale, and with such favorable results.

News of the Week.

Illness of Sir William MacCormack.—Sir William MacCormack is very ill with pneumonia following influenza. His numerous friends are very anxious.

Surgeon in Ordinary to the Lord Lieutenant.—Mr. Thompson, president of the Royal College of Surgeons in Ireland, is the new surgeon in ordinary to the lord lieutenant.

The Widow as Partner.—The tribunal of the Seine has just handed down a decision of interest to French relicts of medical men, who may wish to dispose of their husbands' clientèle or to enter into copartnership (professional) with another physician who succeeds to the practice. The court holds that the doctor's knowledge and experience cannot be made the object of a contract, and a copartnership between the widow and a practitioner of the art of her defunct husband is void.

Rabies.—The city of Lyons, France, continues to give a large percentage of this affection, ninety persons having been bitten during the past year. There have been observed one hundred and three dogs, ten cats, and one horse showing manifestations of the distemper.

Obituary Notes.—DR. JOHN RUSSELL McCLURG died at West Chester, Pa., on November 3d, at the age of seventy-six years. He was graduated from Jefferson Medical College, and in 1864 was commissioned major and surgeon, United States volunteers, retiring at the close of the war with the brevet rank of colonel.

Vital Statistics of Philadelphia.—For the week ending October 31st there occurred in the city of Philadelphia 362 deaths—114 in children under five years of age. The largest number of deaths from any one disease resulted from pulmonary tuberculosis, 44; the next largest number from pneumonia, 33; and next, diseases of the heart, 22. There were reported during the week new cases of diphtheria, 59; of typhoid fever, 38; and of scarlet fever, 20.

The New York Obstetrical Society.—At the annual meeting of the New York Obstetrical Society, held October 20, 1896, the following officers were elected: Dr. Robert A. Murray, *President*; Dr. C. A. Von Ramdohr, *First Vice-President*; Dr. George W. Jarman, *Second Vice-President*; Dr. Arthur M. Jacobus, *Recording Secretary*; Dr. Le Roy Brown, *Assistant Recording Secretary*; Dr. H. J. Boldt, *Corresponding Secretary*; Dr. J. Lee Morrill, *Treasurer*; Dr. G. C. Freeborn, *Pathologist*.

A Novel Enterprise.—The announcement is made that articles of incorporation have been filed in the Camden County (N. J.) clerk's office by the Pennsylvania Medical and Burial Company, whose avowed objects are the entering into contracts with parties for the purpose of providing them with funeral and mourning supplies, drugs, medicines, and medical services. It would seem that the enterprising incorporators of this novel commercial scheme have reversed the order in which it would naturally be supposed their services might be useful, as one would scarcely have need for medical attendance after having been provided with funeral and mourning supplies.

College of Physicians of Philadelphia.—At a stated meeting of the College of Physicians of Philadelphia, on November 4th, Dr. Guy Hinsdale presented a communication entitled "Case of Foreign Body in the Larynx; Death from Suffocation: Exhibition of Specimen." Dr. A. A. Eshner read a paper entitled "A Graphic Study of Tremor." Dr. Frederick A. Packard read a paper entitled "Movable Liver, with Report of a Case." Dr. John Ashhurst, Jr., read a notice of the late Dr. W. S. W. Ruschenberger. It is announced that the Mütter course of lectures for 1896 will be delivered in the Mütter Museum of the college, by Dr. Oscar H. Allis, on November 18th, 20th, 24th, 27th, 30th; December 4th, 7th, 8th, 14th, and 16th, at 8 P.M. The subject of these lectures will be "Luxations; the Traumatisms Present in the Major Articulations."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending November 7, 1896: October 31st.—Medical Inspector J. L. Neilson detached from the *Maine*, November 10th, and placed on waiting orders; Surgeon L. G.

Heneberger ordered to the *Maine*, November 10th; D. N. Carpenter and F. L. Pleadwell appointed assistant surgeons from October 24th. November 2d.—Surgeon G. P. Lumsden detached from the *Yorktown*, ordered home, and granted three months' leave; Passed Assistant Surgeon J. E. Page detached from the *Boston* and ordered to the *Yorktown*; Passed Assistant Surgeon G. Rothganger detached from the *Oregon* and ordered to the *Patterson*; Passed Assistant Surgeon R. M. Kennedy detached from the *Patterson*, ordered home, and granted three months' leave; Assistant Surgeon R. S. Blakeman detached from the *Vermont*, November 12th, and ordered to the *Boston*, per steamer of November 21st; Assistant Surgeon W. M. Wheeler detached from the *Franklin*, November 12th, and ordered to the naval hospital, Mare Island; Assistant Surgeon A. Farenholt detached from the Mare Island naval hospital and ordered to the *Oregon*; Assistant Surgeon S. B. Palmer detached from the naval laboratory, New York, and ordered to the *Vermont*. November 5th.—Assistant Surgeons D. N. Carpenter and F. L. Pleadwell ordered to the naval laboratory and department of instruction, New York.

Killed by His Patient.—Dr. J. S. Wintermute, of Tacamah, Wash., was shot and killed November 11th by a patient whom he was treating for melancholia.

Tuxedo Quarantined.—An epidemic of diphtheria of virulent type has recently occurred at Sloatsburg, Rockland County, N. Y., in which out of fifteen cases there occurred five deaths. For some time Tuxedo was quarantined against Sloatsburgers.

Department of Charities.—A contract has been given out for uniforms for all employees of the department and they are now having their measure taken. Physicians, we understand, are exempt from the workings of the rule.

Bellevue Hospital Dispensary has been renovated in several important particulars. Wooden floors have been wholly done away with and replaced by asphalt with automatic central drainage. The whole interior has been repainted.

Medical Examination by Civil Service.—The New York City civil service commission will hold the following examinations at its office, in the new criminal court building (corner of Franklin and Centre streets) at 10 A.M. on the dates given. Applicants must be citizens of the United States, residents of the State of New York, eighteen years of age and over. Applications may be obtained from S. William Briscoe, secretary, new criminal court building, New York City. November 24th, assistant bacteriologist, health department. Candidates must hold degree of M.D. and possess knowledge of general bacteriology. Salary, \$1,200 per annum. November 24th, assistant bacteriologist, health department (temporary). Candidates must hold degree of M.D., and possess knowledge of general bacteriology. Salary, \$600 per annum. Medical chief of staff, department of public charities. Candidates must hold degree of M.D. and have had experience in hospital organization and management. Salary, \$3,000 per annum.

Marine Hospital Service.—A competitive examination will be held in Washington on February 3, 1897, for the position of assistant surgeon in the United States Marine Hospital service. After four years of service a second examination is held for promotion to the grade of passed assistant surgeon. The salary of assistant surgeon is \$1,600, quarters, light, fuel. That of passed assistant surgeon \$1,800, and that of surgeon \$2,500. Information can be obtained from the surgeon-general of the Marine Hospital service.

Cleveland Medical Society.—It appears that an Ohio man was elected as a member of the judicial council of the American Medical Association at its last meeting who was objected to by the Ohio member of the nominating committee. In his official capacity the gentleman elected seems to have prevented the recognition of delegates from the Cleveland Medical Society and thus returned the compliment. Now the members of the Cleveland Medical Society have agreed among themselves to keep away from the next meeting of the American Association. It is said that the Ohio State Society approves of the Cleveland Society's action.

Contract Practice.—Resolutions have been signed by nine-tenths of the Santa Clara, Cal., physicians pledging themselves not to enter into any agreement or contract to render medical or surgical service at reduced rates to any association or organization.

A Hospital Reform Association, having for its object the correction of abuses which exist in the outpatient departments, has been organized in London. While wishing the association all success, we would state that an attempt has been made in this direction here, and unless London hospital managers and physicians differ greatly from our own, little or nothing will be accomplished. There are a few things in the world which seem beyond reformation, and the dispensary physician who once acquires a taste for large classes of well-to-do patients is one of them, and another is the "professor" who boasts that his interests have nothing in common with those of the young and struggling practitioner, and that abundant material must be provided for his clinics, no matter from what source the patients are drawn or who is injured.

London, too, has her noises of unnecessary nature of which to complain, but there they do something at least looking to their abatement. The county council have just resolved "that the local government and taxation committee should further consider the matter and report with a view to the mitigation or suppression of such street noises as constitute a public nuisance." Will our honorable board of aldermen allow the London gentlemen to outdo it?

Errata.—In Dr. Craig's article on the "Plasmodium of Malaria," published in the issue of November 7th, the authorities quoted as "Doch" and "Dambewsky" should read Dock and Danilewsky. In Dr. Louis Fischer's remarks on "Weaning of Infants," p. 612, the amount of salt used in the cow's milk should be from ten to fifteen grains, instead of ten-fifteenths of a grain, as printed.

Philadelphia Neurological Society.—At the opening meeting of the Philadelphia Neurological Society on October 26th Drs. De Forest Willard and William G. Spiller presented a communication entitled "Concussion of the Spinal Cord (Railway Spine)."

Northern Medical Association of Philadelphia.

At a meeting of the Northern Medical Association of Philadelphia, on October 23d, Dr. Samuel Wolfe read a paper on "Puerperal Convulsions." The association will shortly celebrate the fiftieth anniversary of its organization. It is thus a little older than the American Medical Association and by several years the senior of the Philadelphia County Medical Society.

Philadelphia County Medical Society.—At a meeting of the Philadelphia County Medical Society on October 28th Dr. Joseph Price read a paper entitled "Surgery for Typhoid Perforation," in which he related three cases of intestinal perforation, probably of typhoid origin, in which recovery followed operation. Dr. J. T. Rugh read a paper entitled "Profound Toxic Effects from Drinking Large Amounts of Strong Coffee." Dr. John B. Roberts read a paper entitled "The Perfect Surgical Needle; with Remarks on Common Defects in Needles." The needle recommended was the ordinary glovers' needle properly polished and sharpened.

Additional Laboratory of Bacteriology at the University of Pennsylvania.—A laboratory of bacteriology has been established at the University of Pennsylvania in connection with the courses in veterinary medicine, to be under the supervision of the State live-stock sanitary board and in direct charge of Dr. M. P. Ravenel, instructor in bacteriology in the medical department of the university. Special attention will be given to the study and investigation of the diseases of poultry and cattle. Arrangements have also been made for the preparation of tuberculin for employment in the treatment of tuberculosis in cattle. This laboratory work is independent of the course in bacteriology already offered to students in the medical department of the university.

Medical Students at Vienna.—During the last summer semester there were 2,228 students of medicine at the University of Vienna, 110 fewer than there were the corresponding semester of 1895. According to the university calendar, recently issued, there will be held during the present winter 271 courses by 29 ordinary professors, 36 extraordinary professors, and 94 *Privatdozenten* and assistants. The number of courses in the various subjects is as follows: history of medicine, 2; anatomy, 8; physiology, 13; pathology, 16; pharmacology, 6; medicine, 63; surgery, 47; otology, 13; ophthalmology, 28; midwifery and gynecology, 29; syphilis, 17; mental pathology, 8; public health, 10; chemistry, 9; and veterinary medicine, 2.

Moral Turpitude in a Physician.—The medical board of Oregon was recently requested to revoke the license of a physician for getting drunk and using forcible language. The board agreed, however, with the counsel of the accused that getting drunk was only

a violation of a city ordinance, and even when frequently repeated did not involve any inherent baseness of character. It was established that a physician may get drunk and indulge in loud language occasionally without his conduct being held to indicate moral turpitude.

Hygeia Medical College of Cincinnati has had its diplomas refused by the Ohio State board.

Dr. Black on English Hypocrisy.—Dr. D. Campbell Black, of Glasgow, who must know whereof he speaks, writes to *The Medical Press* that "our moral censors of the British Medical Association, who object so much to advertising, take good care that their lucubrations at the annual meetings are reported in as many 'lay' papers as possible; and if this did not happen, the association would not long be favored with the exalted light of their countenances, and the British Medical Association itself would collapse (no great loss!) in twenty-four hours."

Non-Toxic Properties of Aluminium.—Recently two healthy and robust physicians, aged twenty-six and thirty-five, were selected by the imperial German health bureau to undergo an interesting experiment to ascertain whether aluminium is poisonous or not. These two gentlemen, in order to test the non-poisonous properties of aluminium, volunteered to swallow, every morning for one month, fifteen grains of aluminium tartrate with their lunch. At the end of the trial neither of them had lost flesh or appetite nor experienced the slightest discomfort during the entire period of their metallic lunch. It was found that the metal is not adapted, however, to contain for a long period brandy, whiskey, or wine. After a time these liquids turn turbid, and, although perfectly harmless, are not inviting, to say the least, although for two or three days' journey they are not appreciably acted on when carried in aluminium flasks.—*College and Clinical Record*.

The Rush Monument Fund.—Dr. Albert L. Gihon, who will deserve a monument himself for his indefatigable advocacy of every good cause which he takes up, has issued another appeal for subscriptions to the Rush monument fund. He calls attention to the fact that the homœopathic physicians of the country have raised \$75,000 for a monument to Hahnemann, a foreigner, while less than \$4,000 has been subscribed for a monument to the American patriot, Benjamin Rush. The navy department has already generously designated a commanding site in the park fronting the United States Naval Museum of Hygiene, where it will be one of the most conspicuous features of the national capital, but there is as yet nothing to place on this site. The American Medical Association will meet next year in Philadelphia, and it would be a graceful and grateful act on the part of the physicians of that city to raise among themselves the modest sum necessary to honor the man who brought so great honor to their city. That would no doubt stimulate others to give, and then there would be a monument to the great man of which all physicians and all Americans could justly be proud.

Cremation of Paupers.—A petition is in circulation in Washington asking that a crematory be substituted for the Potter's Field.

The American Laryngological, Rhinological, and Otological Society will hold its next meeting in New Orleans, March 3 and 4, 1897, this being in the carnival season.

Sir Andrew Clark's house, which is in reality somewhat of a mansion, in Cavendish Square, vacant since the death of its illustrious occupant, has now been leased to a manufacturing dental firm, and will be used in part for a post-graduate dental school.

Intellectually Enfranchised, the woman physician of England now shows her gratitude to her professional brothers, according to *The Medical Press and Circular*, October 21st, by opening an obstetrical dispensary, at which for the sum of five shillings confinements are undertaken.

Surgeon to the Queen.—Succeeding the late Sir John Erichsen, Mr. Bryant, ex-president of the Royal College of Surgeons, has been appointed surgeon-extraordinary to Queen Victoria. The appointment seems to have given general satisfaction in English professional circles. Can there be anything in the name which is attractive to English-speaking crowned heads?

The International Congress of Criminal Anthropology, which held its fourth session in Geneva on August 25th to 29th, will meet again at The Hague in 1901. The most practical outcome of the Geneva congress was the unanimous adoption of a resolution calling for legislation in all countries restricting the sale of alcoholic liquors, and declaring it to be the business of the congress to further such restrictive legislation of a stringent kind.

San Francisco is to have a college of physicians and surgeons. Articles of incorporation were filed in June last. S. M. Mouser is president and S. O. L. Potter secretary. The Pacific coast is fast supplying facilities for medical instruction. San Francisco already has the University, the Cooper Medical College, and the Polyclinic. Los Angeles has two schools and Portland, Ore., two.

Boston Public Institutions.—Mayor Quincy has dismissed Dr. A. B. Heath from the position of commissioner of public institutions after asking for his resignation, which Dr. Heath declined to hand in. The charge against the commissioner, who was appointed by Mayor Curtis to succeed Dr. Jenks, is that the expenditures have exceeded those of his predecessor by some \$140,000 per annum, leaving at the present time a deficit in the treasury. Dr. Heath has many friends in New York who will regret to learn that, however much his free use of funds has been pleasing to the patients and paupers under his care, it has not had the same effect upon the tax-paying public whom the mayor represents. Boston has had the reputation of caring for the city's poor and needy in a handsome manner, but it evidently does not like to foot the bill.

Clinical Department.

REPORT OF A CASE OF NASAL POLYPUS IN A FEMALE INFANT FOUR WEEKS OLD.¹

By ADOLPH RUPP, M.D.,

NEW YORK,

FORMERLY PHYSICIAN TO THE NORTHERN DISPENSARY AND FORMERLY AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY.

CASES of nasal polypi in infants and young children are so rarely observed by both pediatricists and laryngorhinologists as to make the following observation almost unique. Considering the frequency with which catarrh of the nose is met with in children, it is remarkable how rarely neoplasms are observed before the age of puberty. Thus, Moritz Schmidt, in his ample experience, saw and operated upon only one case, the child being a girl six months old. Schmidt and other specialists quote Cardonne, who saw a polypus in the nose of a child two days old. Bosworth states that Krakauer removed twelve polypi from the right nasal fossa of an infant four and one-half months old. My neighbor, Dr. Traugott Roediger, told me he has seen one case in his extensive general practice. This child, when two weeks old, had the polypus removed by Dr. Simrock, of this city.

My own case is a girl baby, N—, four weeks old. I was consulted because since its birth nursing had become gradually more difficult, and the snuffling breathing had also become gradually more marked. This breathing difficulty had been attributed by the midwife and parents to a slight "cold in the head," until the father thought he discovered the real cause, in "something which flapped up and down" in the left nasal fossa. Examining the infant's nose, I found a pinkish pedunculated polypus, large enough almost to occlude the left nasal air passage in the vestibule of the nose. Its consistency was neither soft nor hard, but friable. The attachment of the little tumor was high up, possibly on the upper portion of the middle turbinate. There was only slight nasal catarrh present, but in no sense was it obstructive. The rest of the nasal passages of both fossæ were clear. There was a slight conjunctivitis of the left eye, which may have some pathological interest but was clinically insignificant. Neither of the parents have catarrhal affections, and from neither could a syphilitic history be obtained, nor were there any signs of syphilis about the infant.

Part of the little tumor was removed with a wire snare (cold), and the remainder by means of a blunt ring curette (Buck's). Very little hemorrhage ensued. The operative results were all that could be desired—the child was able to breathe and nurse satisfactorily and with comfort, and slept better than it had before the removal of the tumor.

406 WEST THIRTY-FOURTH STREET.

ABSENCE OF LEFT KIDNEY

By J. H. SMITH, M.D.,

PLATTSBURG, N. Y.

THE article "Congenital Absence of Kidney," on page 550 of the *MEDICAL RECORD* of October 17th, brings to mind a case of the same kind in my practice: A. M—, male, an inmate of Clinton Prison, aged thirty-three, French Canadian, died in the prison hospital on April 24, 1881, of diabetes mellitus. Post-mortem examination showed an entire absence of the left kidney. The right kidney was enlarged, weighing a little more than seven and one-half ounces.

¹ Reported October 25, 1896, at a meeting of the laryngological section of the New York Academy of Medicine.

A COMPLICATED CASE OF BICHLORIDE POISONING.

BY WILLIAM EDGAR DARNALL, M.D.,

ATLANTIC CITY, N. J.

MRS. A—, primipara, consulted me a few days before her labor, complaining of dysentery. Her husband being sick, she had not taken proper care of herself; the gravid uterus, by pressure on the rectum, had therefore set up irritation. Little could be expected from treatment under such circumstances until the child was born. Two or three days later came the call for confinement. The process was uneventful; the labor was a little slow on account of its being the first child. The exciting cause of the dysentery being removed, rapid improvement took place for a day or two. The labor had been conducted with every care, and the uterus thoroughly emptied of its contents. No alarm was felt, therefore, for the mother's safety.

On the morning of the third day after labor, however, I found the patient restless, with chilly sensations, etc.; lochia slightly diminished and foul; a temperature of 102° F.; pulse, 110; and her expression anxious. The only discoverable source of infection was that she must have carried the poison from the rectum to the vagina by carelessness during her frequent stools. A half-gallon of 1 in 40 carbolic-acid solution, with iodoform suspended, was promptly injected into the uterine cavity by means of a fountain syringe. The temperature at once fell to normal.

About 10:30 P.M. the same day, I received an urgent call to the house, the messenger stating that the patient had been poisoned by taking the wrong medicine. On my arrival I found she had been given by mistake a bichloride tablet of one and three-fourth grains, which had been left with careful directions for bathing the parts. Fortunately she discovered, as soon as she swallowed it, that it was not one of the morphine tablets which she was taking for after-pains and called her mother's attention to the fact. Mustard and other household emetics were given as soon as they could be gotten ready, and vigorous vomiting was produced before my arrival. The whites of eggs and milk were then ordered. Her excitement quieted, and I left her fairly comfortable.

Next morning her temperature was 100° F., and for seven days it dodged about from 99° to 102.5° F., being unaffected by intra-uterine treatment. The patient, meanwhile, became worse daily. She had ingested enough of the bichloride to set up a severe gastro-enteritis and relight the old flame at the lower end of the alimentary canal. The most distressing feature, perhaps, was the violent paroxysms of griping abdominal pain, which constantly occurred two or three times an hour. These dated from the poisoning, and continued throughout the sickness. All the analgesics available were tried in turn, but after a few doses the effects of each wore off and they became useless. Morphine did not give any relief. Turpentine stupes were applied to the abdomen. Hoffman's anodyne gave the stimulation the weakened body needed, and kept the cramps in check longer than the others; but it did not wholly meet the emergency. The inflammatory condition seemed to extend from one end of the alimentary canal to the other. Large doses of bismuth with powdered acacia were administered every four hours, with good effect. The diet was restricted to milk and albumin water. On the ninth day the temperature remained at normal, and the bowel symptoms were mitigated a little. The patient was in a precarious condition, at times almost collapsed. Hot bottles and judicious stimulation were applied. The following day she was a little brighter. Mild astringents were ordered as soon as the acute

stages of inflammation were passed. From this time on she gained strength, her acute symptoms gradually subsided, and her recovery took place uneventfully.

Here was a case of acute dysentery complicating labor, associated with septic infection and poisoning with bichloride of mercury. Had emesis been delayed till I arrived, I feel sure the patient would have succumbed. The case was critical enough as it was. The continued abnormal temperature, in my opinion, was kept up more by reason of the intestinal inflammation than from septic processes in the uterus, for it must be borne in mind that it often takes very little to throw a puerperal woman into a fever, when there is no sign of any septic process present. This view is strengthened by the fact that the mild infection present just before the poisoning occurred seems to have been completely removed by the intra-uterine douches, and that after the poisoning intra-uterine treatment had no effect whatever upon the temperature.

PLASTIC OPERATION FOR MALFORMATION OF THE NOSE CAUSED BY SYPHILIS, WITH ILLUSTRATION.¹

BY F. L. FORKER, M.D.,

BINGHAMTON, N. Y.

THE case which I present is one made interesting principally by the transforming effects of plastic surgery. Plastic surgery was originally restricted to the repair of the nose, but during the present century has busied itself in different ways with the emendation of various organs, and has thus greatly enriched the domain of general surgery. It has been a field of conquests, and the perfection to which it has attained constitutes some of the proudest triumphs of the human mind in modern times. I will first give you a brief description of the case and then show you the result. H. Y—, aged twenty-two years, came under my care at the City Hospital, May 13, 1896, and gave the following history: Family history good; personal health good until fourteen years of age, when ulcers began to appear in the mouth, nose, and throat. The end of the nose became very red and painful, and at the end of two weeks the tissues began to break down, the process continuing until the nasal septum and floor of the nasal cavities, including the central portion of the superior maxilla with the incisor teeth were carried away. The nose continued for some time afterward to diminish gradually in size; after being treated for some time this ulcerating process discontinued, and she enjoyed comparatively good health until January, 1894, when her right leg began to ulcerate, and in spite of treatment the process had extended at the end of one year entirely around the limb and destroyed three-fourths of the integument below the knee, in places laying the bone bare. All I am able to learn in regard to the treatment received is that she was in the care of a regular physician, who advised her to enter the hospital and have her leg amputated, since it was entirely useless. She accordingly entered the hospital, but the surgeon-in-charge did not deem amputation necessary, so after three months' treatment she was discharged improved. After leaving the hospital the ulcer again extended, and she returned in May of the present year for further treatment. On admission her general condition was very poor, the extensive ulceration had exhausted her strength to a marked degree, digestion was disturbed, severe pain was felt in the left iliac region, and a large gangrenous ulcer extended over nearly one-half the surface of the right limb below the knee. The external nasal tissues were too small

¹ Read at the annual meeting of Broome County Medical Society, October 6, 1896.

to cover the nasal cavities, being only three-fourths of an inch in length and much distorted, the nasal septum being absent, as were also a portion of the superior maxilla, and four incisor teeth, leaving an opening between the nasal cavities and the mouth about one inch square. The uvula and palate on the right side were closely adherent to the posterior wall of the pharynx. As a result of these deformities, she had a very marked nasal voice and her sense of smell was almost entirely destroyed. Treatment consisted of rest in bed, milk diet, tonics, and potassium iodide. The latter was begun in dose of five grains, t.i.d., and gradually increased to fifteen grains. The ulcer was first thoroughly cauterized with nitrate of silver, and then antiseptic dressings were applied daily for one month, at which time Thiersch's operation of skin-grafting was done with very gratifying results, and two months from the patient's admission to hospital the ulcer was entirely healed.

The deformity in this case had not only destroyed the normal functions of this important organ, but had rendered the patient so repulsive in appearance that she was unable to earn a livelihood; accordingly a successful repair of this deformity was a very important matter to her. After consulting with various members of the hospital staff, and receiving practically no encouragement, I performed the following operation, after the usual preliminaries were attended to. The first step consisted in detaching the nose at its root and sides by two incisions, and folding it down over the upper lip one inch; the second step consisted in dissecting up two triangular flaps, one from each cheek, and turning them around to fill in space created by the first step. These flaps were composed of integument and cellular tissue about one-quarter of an inch in thickness, and were left attached at the angle of the space by a pedicle about one-fourth inch in diameter. The third step consisted in suturing the flaps in their new position and bringing together the borders of the space left in the cheeks by means of silk and worm-gut sutures. Iodoform along the line of suture constituted the only dressing applied. Primary union followed throughout and the sutures were removed on the second day.

Considering the diseased constitution of my patient, it was a question what would happen to the cellular tissue covering the under surface of the flaps which was left uncovered, but by the aid of a solution of peroxide of hydrogen used daily a form of mucous membrane gradually crept out from the border, and at the end of two weeks this exposed surface was entirely covered over.

The adhesions of the uvula and soft palate were separated at a second operation, by means of a knife constructed for the purpose.

I next took my patient to a dentist and had a plate constructed to fill in the cleft in the superior maxilla and to restore the lost teeth.

And now as a result of three months' treatment I am able to report the following condition: First, a gain of integument and healthy tissue over the right leg of about ten inches square; second, a gain in weight of twenty pounds; third, a gain in voice production from a marked nasal to an almost natural tone; fourth, a gain in sense of smell which is quite marked, and fifth, a gain in length of nose of one inch, which, taken together with changes produced in my patient's cheeks by removal of flaps therefrom, amounts to little less than a complete transformation in her appearance.

In Memory of Pasteur.—The municipality of Paris has changed the name of the Boulevard de Vaugirard to that of Boulevard Pasteur.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 5, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Wesley M. Carpenter Lecture—The Etiology and Classification of Infectious Diseases.—DR. GEORGE M. STERNBERG, U. S. A., delivered the lecture. What he should present was not claimed to be new. Etiological studies had always possessed special attraction for him, and he thought a general view of the etiology and classification of infectious diseases might not be out of place on the present occasion. By infectious diseases were meant those which resulted from the introduction into the body of some disease-producing agent, and he thought we were justified in saying that an essential condition of infection was that the disease-producing agent must be capable of reproduction in the body of the infected individual; in other words, that it was a living organism. It was indifferent whether it was large or small; whether it belonged to the animal or to the vegetable kingdom; whether it was located in the skin, as in scabies, or in the blood, as in relapsing fever. The introduction and multiplication of the infecting agent constituted infection.

We were now including among infectious diseases many diseases which a few years ago were not recognized as being due to infection—for example, tetanus, pneumonia. The number was constantly being increased. It was true, we might have inflammation independent of infection, as a gastritis from the introduction of a chemical poison, or in a wound from mechanical cause; but this form of irritation did not give rise to suppurative inflammation. It was only a potent predisposing factor, inasmuch as the injured tissues were thereby rendered liable to infection. The stone in the bladder and the surgeon's instrument did not produce cystitis, but the bacteria which caused cystitis would be impotent without such predisposing cause, *i.e.*, injury. The difference between infectious and non-infectious inflammatory irritation from mechanical cause was well illustrated by some experiments which he had made in 1884. Under antiseptic precautions he introduced finely broken sterilized glass into the abdomen of rabbits, without producing fatal peritonitis. The inflammation which occurred was of a conservative kind, walling in the powdered glass and forming nodules of various sizes. The animals remained in good health, and even gained in weight until killed. Similar results were obtained from introducing sterilized bodies into other tissues. But let the foreign body carry bacteria, and we would find a localized septic process established, if not infection of the blood and pyæmia.

In many diseases the infectious agent was constantly present, awaiting an opportunity to enter the tissues or the circulation through a broken mucous membrane or skin. No doubt this was true of croupous pneumonia and associated diseases. But other conditions besides a wound for their entrance might be necessary to favor production of the disease by the germs. One of the objects of the address was to call attention to these other factors. Among them was natural susceptibility to the disease, which might be increased by depressing agents, such as alcoholism and unsanitary surroundings. Local congestion from "taking cold" was a frequent factor in diphtheria, tonsillitis, pneumonia, etc. It had been demonstrated that a person might carry the bacilli of diphtheria in the throat without developing diphtheria. The same was true of cholera germs. Further, the germs might be pres-

ent and cause a mild attack of diphtheria or cholera, which might not be recognized from the clinical symptoms alone, as these might seem those of a simple tonsillitis or a simple intestinal catarrh. Thus it became apparent that a diagnosis based upon symptomatology alone was not always reliable. Sometimes the most prominent symptom depended upon a mixed infection, and not upon the specific germ of the disease. The laity and some physicians committed the error frequently of attributing the infectious disease to the exciting factor, as cold or injury, instead of to the infecting germ. The prevalence of certain infectious diseases at certain seasons was to be accounted for by the favorable atmospheric conditions for the development of the infecting germs, or by the depression of the patient's system and confinement within doors.

Regarding influenza, Dr. Sternberg was surprised that so few physicians recognized its distinctly infectious nature, and that its germ had been discovered (in 1892). The impression which many had expressed, even of comparatively recent years, that it was wafted long distances—say across a continent or ocean—by the air, was quite without foundation. The author mentioned only one disease whose infectious agent was carried to any considerable distance—malaria. But even in this instance, it was only in the neighborhood of the marsh whence the wind came. Doubt was expressed whether true malaria was conveyed through water or mosquitoes. There were questions of uncertainty in all reported cases. Many of them were cases of typhoid or some form of infectious fever different from typical malaria. The plasmodium of malaria was frequently reported as present when it was not, as there were other conditions of the blood which resembled it more or less. Continued absence of the malarial parasite from the blood and failure to respond to quinine was pretty positive evidence that the case was not one of malaria.

Classification of Infectious Diseases.—Dr. Sternberg said, regarding the classification of infectious diseases, that any attempt in this direction, based on present knowledge, must be more or less incomplete and provisional. One classification might be as follows, based on the channel of contagion: (a) Traumatic infections; (b) infection by contact or direct contagion; (c) infection through ingesta; (d) infection through the respiratory tract. Another classification might be based on the nature of the infectious agent: 1, Diseases due to infection by vegetable parasites, of which there were several subdivisions; 2, diseases due to animal parasites, of which there were several subdivisions. Further, a classification might be made which was based on the special tissues involved, as the blood, the skin, mucous membranes, serous membranes, glands, lungs.

The academy extended to Dr. Sternberg a vote of thanks for his instructive address.

The Physical and Schott Treatment of Chronic Cardiac Disease.—DR. H. NEWTON HEINEMAN read this paper. Contrary to the opinion which he had expressed in a paper read before the academy seven years ago, he now believed the physical and Schott treatment of chronic heart disease gave the best results. This conclusion was based on observation and experience with the method, as carried out at Bad Nauheim and elsewhere in Europe. The waters at Bad Nauheim were chalybeate, but also contained a high percentage of chloride of sodium, calcium chloride, etc., and were strongly impregnated with carbonic acid gas. The temperature was from 83° to 93° F. in the baths, which were taken either in the sprudel bath (*Sprudelstrom*) or after more or less of the gas had escaped, as it did when the water was allowed to stand in the open tub. The longest stay in the bath did not exceed twenty minutes. It should be followed

by an hour's rest. The author pointed out the different effect of these baths and fresh-water baths. The benefit did not come from absorption, for it had long since been shown that there was practically no absorption in baths. The effect of the bath on the heart had been shown by physical signs and by the x-ray. After the treatment had been started, a diminution in the dilated heart could be observed after the individual bath, and a progressive diminution was demonstrable. In addition to the bath, resistance movements were practised. These were made slowly and without special exertion, each successive movement bringing into exercise a different set of muscles. While these were being carried out, the pulse, respirations, and *alæ nasi* should be watched. Five to ten minutes was long enough for exercise at the commencement, but the time should be extended gradually to thirty minutes; and when a second *séance* was held the same day it should be only for twenty minutes. Always go slowly. The reduction in the size of the dilated heart might be observed in one or both ventricles, one or both auricles, and diminution in different directions. The gain was lost in a degree by the following day, but gradually one succeeded in attaining that size of the heart which gave the most perfect muscular accommodation. While he was at Bad Nauheim the majority of patients received only the bath and exercises, yet in general practice one should omit no means by which the patient might be benefited. Diet should be regulated. In explaining the benefit derived from the bath, Dr. Heineman laid most stress on the surface influence. There were a few cases of cardiac disease in which the treatment was contraindicated. Among them were complications by pulmonary infarction, excessive debility, advanced arterial sclerosis, aneurism of the aorta, acute and chronic Bright's. Some of these only required special precautions. The treatment was of most benefit in cases of irritable heart independent of changes; cases of relative inefficiency; in that large group, cardiac valvular lesions; and in angina pectoris. During the past year he had followed one hundred and twenty cases at Bad Nauheim. Of these, considerably more than half had come the second year, and many had returned yearly for three or more years. By such cases the permanency of the improvement had been established beyond doubt.

Gymnastics and Fatty Heart.—DR. A. JACOBI thought it worth while to mention the fact that neither the author nor the doctors at Bad Nauheim regarded the baths as a cure for all heart diseases. Regarding gymnastics, he thought they would be of special benefit when the muscle of the heart was defective. The exercise should be frequently repeated and not too violent. There were cases of fatty degeneration of the heart and of over-fat. It was in the latter that gymnastics were specially beneficial. But there was nothing more dangerous than to try to reduce the overgrown heart too rapidly.

DR. WILLIAM H. THOMSON said his experience had been limited entirely to gymnastic exercises in this treatment, but he now proposed to extend it to the baths. From exercises he had seen striking results. He would attach a good deal of importance to the reflex dilatation of the small arteries, which were contracted reflexly as well as narrowed by arterial change, especially in Bright's. This opening of the small blood-vessels by the bath went far toward relieving the heart.

DR. JACOB TESCHNER read the histories of three cases, in which there was marked improvement of the pulse and diminution in the size of the dilated heart dependent upon valvular lesion, following gymnastic exercises, prescribed more particularly for rotary lateral spinal curvature, in the manner which he had described on former occasions. These exercises were

pushed more rapidly than those recommended by the author, but they were not violent.

DR. F. W. JACKSON expressed surprise that more attention had not been directed to the method in America. He asked Dr. Heineman whether the effect upon the heart could be accepted as permanent, or whether it was only temporary compensation, which was likely to be lost, at least if the patient did not continue his visits to the bath. He thought the method could be adopted with advantage at bath springs in this country.

DR. HEINEMAN said the patients came back to the baths to retain, not to regain. After practising the treatment a while, cardiac tonics which had lost their power could again be used with effect. He agreed with Dr. Thomson that the influence upon the capillary circulation was an enormous factor in relieving the heart. He again impressed the necessity for not hurrying; otherwise, harm would be done in nine cases out of ten.

Semicentennial of the Academy.—THE PRESIDENT, in accordance with a resolution recommended from the council, appointed several committees on the approaching semicentennial of the academy.

SECTION ON NEUROLOGY.

Stated Meeting, October 30, 1896.

PEARCE BAILEY, M.D., CHAIRMAN.

The Relation of Toxic Agents in the Production of Nervous and Mental Diseases.—DR. IRA VAN GIESON read parts of several papers on this subject which he had prepared for another audience but had not presented. The following were the subjects of the several chapters: 1. The homology of the structure of the nervous system with that of the general viscera and tissues of the body. 2. The homology of the diseases of the nervous system with those of the simpler organs of the body, as the kidney or liver. 3. The significance, reasons, and explanation of the fundamental pathological processes, such as degeneration, necrosis, and inflammation. 4. Separation of the toxic diseases. 5. Acute degeneration of the nervous system. 6. Resitution or destruction of ganglion cells after acute degeneration. 7. Acute degeneration of the nervous system from auto-intoxication. 8. From extrinsic poisons. 9. Acute exudative inflammation of the nervous system. 10. Sequelæ of acute exudative inflammation of the nervous system. 11. The occurrence of acute bacterial toxæmias of the nervous system apparently independently of somatic disease, and on the distribution and selective action of poisons on the several departments of the nervous system. 12. Acute parenchymatous degeneration and exudative inflammation of the spinal cord. 13. Acute toxic lesions of the pia mater and the relations of the pia mater to the central nervous system in the toxic diseases. 14. Chronic degeneration of the nervous system. 15. Several examples of that, mainly the systemic diseases of the spinal cord, such as locomotor ataxia and others of the so-called system diseases of the cord.

Our knowledge of the effects of toxic agents upon the nervous system, he said, was much more limited than with relation to other parts of the body. The nervous system had been looked upon as something apart from the rest of the body, as if it were not subjected to similar pathological processes. During the past fifty years it had been studied in a topographic sense. Furthermore, formerly it was thought that as long as the ganglion cell was not blotted out changes were likely to be overlooked, whereas now it was known that the ganglion cell itself might remain and yet show change more or less destructive.

The laws of pathological processes were few, were

uniform and unavoidable. Nor did the brain escape them. They were not modified greatly in the nervous system, although the clinical results were much more complex on account of the varied functions of the nervous system and the intricacy of its anatomy. Neurologists had plunged into the study of the nervous system without the preparation which came from studying similar processes as they occurred in simpler organs in which they could be understood more readily and their significance interpreted. All sorts of clinical names had been given to nervous symptoms which were in reality due to but a few basic changes in the nervous tissue, similar to what was often seen in other structures of the body. The majority, if not nearly all, of the diseases of the nervous system were dependent upon or secondary to diseases of the general body, and these were usually due to or associated with poisoning from intrinsic or extrinsic toxic agents—bacteria and their poisons, auto-intoxication, alcohol, etc.

After pointing out the homology of the structure of the kidney and nervous system, each containing parenchyma and stroma, the author mentioned the several lesions of the kidney and their analogous conditions in the nervous system. For instance, acute parenchymatous nephritis, so often present in connection with infectious and contagious diseases, had exactly its counterpart in the brain—a fact of great importance but very little recognized. When the poison producing the lesion was not too voluminous or intense, the cerebral as well as the renal tissue returned to its normal state and the symptoms disappeared. Acute and chronic diffuse nephritis, in which both the parenchyma and stroma of the kidney were involved, were exemplified in the nervous system by some form of general paresis. Even the pia could be stripped off, carrying with it some of the cortex in some cases of general paresis, just as the capsule of the kidney could be stripped off in the similar condition in that organ. Chronic interstitial inflammation in the kidney also had its analogy in the brain. The early stages were difficult to identify. It was seen in certain epilepsies. Lesions corresponding to all of these were seen in the brain, and were caused largely by the same things which produced the lesions in the kidneys.

The author then passed to the etiology, and referred as a most valuable article upon the subject to one entitled "Immunity and Cure," by Dr. F. Stanley Abbot. As already suggested, the chief cause was poisons, and among these were bacteria, and especially their secretions. At this point Dr. Van Gieson dwelt upon the manner in which the bacteria gained entrance to the body and the way in which the latter tried to cast them out or to counteract their injurious influences. There was an effort to limit them to the point of entrance and also to neutralize their toxic agents. The degenerative processes themselves were conservative, but of course at great cost to the tissues. In disease, therefore, there were two factors, one pertaining to the invader or the bacteria, the other to the host. The bacteria varied in virulence and kind; number was important; and there was the question of mixed infection. Therefore this side of the equation was a very variable one. The same was true of the other side, the bodily resisting forces. In some persons they were generally powerful, in others slight; in some organs strong, in others weak; and varied at different times as well as in different individuals of the same and different races and according to the kind of bacteria which were the invaders, etc. In tuberculosis and pneumonia the variation of these factors was not so great but that they produced a pretty constant result, whereas in typhoid it might vary greatly. In typhoid with brain symptoms we might assume that the bacterial forces were powerful or the bodily forces weak. The lesions themselves varied to a certain

extent both in degree and locality, but of the symptoms it could be said that they were kaleidoscopic, so great might be the variations.

Acute degeneration of the nervous system had its homologue in acute parenchymatous nephritis, acute degeneration of the liver or of other organs, and was seen in a great variety of acute infectious diseases, the eruptive fevers, sunstroke, auto-intoxications, cachexia from removal of the thyroid, eclampsia, poisoning by alcohol and phosphorus or other drugs. All of these things, if the poison were not too intense, acted in the same way, causing acute degeneration of the nervous system. The chromophyllic plaque within the cell disintegrated in greater or less degree, and the cell might even be destroyed. This disintegration of the plaques might be in itself conservative, having an antagonistic effect upon the poison or uniting with it and producing an inert compound. When the dividing line existed between destruction of the cell and the stage at which it could be restored, he had considered in a separate chapter on the restitution of the cell after degeneration. In one case of autopsy after typhoid fever he had found nearly universal breaking up of the chromophyllic plaques, yet the woman had had no more delirium nor cerebral symptoms than the ordinary case of typhoid fever, which would seem to show that such an amount of change in the nerve cells was not uncommon in this disease and restoration might still be possible. In fact, it seemed remarkable to what an extent the brain cells could recover after acute degeneration, just as happened with the kidney cells. In alcoholism this was also seen, but it was evident that alcoholic poisoning could not continue indefinitely without irremediable destruction of the brain cells.

Acute exudative inflammation of the nervous system was generally misunderstood. It had been thought to be an individual disease of the nervous system called multiple sclerosis, the basic change and its cause having been overlooked. It was a question of intensity or amount of the poison, for the greater the intensity or volume the greater was the effort of nature to protect herself. This was accomplished by throwing out an exudate, and this in multiple sclerosis resulted in patches of sclerotic tissue. Landry's paralysis was explained in a similar way.

Dr. Van Gieson thought the freedom of the terminal circulation of the given portion of the nervous system had much to do with its power to resist bacteria and poisons. The pia mater was a network of blood-vessels, and in that portion of the cortex where the circulation was freest the power of resistance and restitution was greatest. Tuberculosis affected the base more than the vertex.

DR. FREDERIC PETERSON opened the discussion. He thought there was, besides pathological evidence, also much clinical evidence in favor of the facts presented. Regarding insanity, the more we studied it clinically the more circumscribed became the class of cases which we had heretofore looked upon as without special cause. He mentioned some cases in which the evident cause was either intrinsic or extrinsic poison. In one of them autopsy showed renal disease as the source of the poisoning; in another there was poisoning from bisulphide of carbon. Both patients were maniacal; one became comatose.

DR. P. M. WISE, state commissioner in lunacy, thought no one who had observed psychoses in hospitals for the insane and the effect of treatment could have reached any other conclusion than that a large proportion of cases of insanity were of toxic origin. He thought disease of the kidneys was the source of the poisoning in a large number. There were insomnia and mental depression, which might go farther.

One of his assistants had found in some cases of periodic insanity a relation between the attacks and the quantity and quality of the urine. Acting on this information he had sometimes been able to abort a threatened outbreak of the mental symptoms by stimulating kidney elimination.

DR. GEORGE BIGGS emphasized the importance of a knowledge of general pathology in studying the diseases of the nervous system. The theory of the toxic origin of most nervous diseases impressed him as a very plausible one. It was certainly sufficient to explain a large number of them.

DR. E. D. FISHER remarked that the author had mapped out an immense scheme, one which would, as suggested, permit of a great deal of amplification. He regarded the paper as the most suggestive one that had been read on any similar topic for a long time. Regarding the etiology of nervous diseases or symptoms, Dr. Fisher thought the infectious diseases produced only very slight nervous symptoms usually, and the toxic influence on the nervous structures could not be great. He thought the cerebral symptoms corresponded more closely to the rise of temperature. As to extrinsic poisons, alcohol produced immediate effects, it was true, but these passed off, and then we could observe no change in the cell. In chronic alcoholism there was another factor to be considered. It was the change in the arteries, not the direct effect upon the nerve cells, which was the striking feature. Cell degeneration here was not due directly to the alcohol, but to diminished circulation through arterial degeneration. While the paper was a most interesting one, he thought it laid too much stress upon toxic agents in the etiology of diseases of the nervous system.

DR. GRANGER said that fifteen years ago the alienist considered scarcely anything but brain diseases and what he could find in the brain itself. Pathology from a broader view had then hardly been considered. We were now largely engaged in unlearning what we had learned fifteen years ago. The study of the diseases of the nervous system had been much broadened. Dr. Granger referred to several cases of acute mania in certain fevers, particularly typhoid, and attributed it to poison acting on the nervous structures, as suggested in the paper.

DR. BERNARD SACHS remarked that Dr. Van Gieson had given a great deal for one evening, yet he had, no doubt, withheld more than he had had time to read. Dr. Sachs had no criticisms to offer, but thought there was a possibility of going to an extreme in generalizing. Regarding toxic agents, it seemed the author did not believe so much in differentiating between the bacteria. It was possible to go too far in this direction and cast aside valuable work done by bacteriological investigators.

DR. EWING was surprised to hear the author state so definitely the changes which took place in the nerve cells in toxic conditions. In the course of his study he had been unable to make positive statements. The subject was still a very complex one.

DR. M. PUTNAM JACOBI mentioned some attempts which had been made to show the association of certain forms of mental disturbance with given kinds of bacterial or toxic poisoning, or certain diseases or disturbances of the general system. In this connection influenza was mentioned, and dilatation of the stomach, in which stomach irrigation relieved attacks of mental depression. She also mentioned a case of muttering delirium in typhoid succeeded by systematized delirium, and was unable to draw the line between the influence of the typhoid poison and of prior alcoholism in producing the mental symptoms. Féré had claimed to observe a diminution of urine preceding epileptic attacks, pointing to an accumulation of

toxic principles in the tissues before the attack and elimination afterward.

DR. HERTER thought progress was going to be along the line mapped out by Dr. Van Gieson. In his opinion the author had been sufficiently cautious in his statements. He could not agree with Dr. Fisher in his exceptions. In studying the influence of the urine, too much attention had been given its clinical aspect and its influence on lower animals.

DR. BAILEY said the presumptive clinical evidence of intoxication as the causative factor in nervous and mental diseases was very strong, yet absolute microscopic and chemical proof was far from being complete.

DR. VAN GIESON made some concluding remarks, and was requested by the section to present the rest of his paper at some early meeting.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 14, 1896.

JOHN SLADE ELV, M.D., PRESIDENT.

Malformation of the Genital Organs; Probably a Case of True Hermaphroditism.—DR. CARL BECK, present by invitation, presented specimens taken from an individual, twenty-one years of age, upon whom he had performed laparotomy last June. The patient died of pneumonia sixteen days later. One specimen showed a well-developed penis, with the exception of the urethra, in the place of which was a slight depression. There was an infundibulum, very closely resembling the introitus vaginae. The membrane covering this was easily broken through, and disclosed a vagina and an infantile uterus. The patient stated that he had been regarded as a girl up to his seventeenth year, and that he had had sexual connection from the fifteenth year. He then assumed the male attire. There had been no menstruation, according to the history. At the time of the operation, which was done for the removal of two pelvic tumors, it was found that the removal of the larger growth was very difficult on account of extensive adhesions. The two tumors filled up the small pelvis, the larger one reaching up as high as the umbilicus. The pedicle of each tumor was rather thick, and was attached to the peritoneum about half an inch laterally from the symphysis and about one-fourth of an inch below the os pubis. Dr. Beck said that he had a distinct impression that on the right side an ovary could be felt, but, just as he was endeavoring to examine into this point more carefully, the patient's respiration suddenly ceased, and this abruptly terminated the examination and also the operation. Unfortunately, the autopsy had been performed in his absence, and many interesting points had been consequently overlooked. The pathologist, Dr. Brooks, reported that the tumor consisted of mixed elements, making it impossible to classify it. The bulk of the growth was composed of embryonic tissue, and the tumor apparently belonged to the teratomata. He had shown these tumors to several eminent medical gentlemen, and none of these had cared to express any distinct opinion on the question of whether these growths were testicles or ovaries. No seminal vesicles had been found. Dr. Torek had informed him that this patient had been admitted to the Skin and Cancer Hospital last year, and had been treated by Dr. Fox for syphilis.

Discussion.—THE PRESIDENT said that the decision as to the actual sex in this case depended upon whether these tumors were ovaries or testicles, or whether one was an ovary and the other a testicle.

Such cases had been reported. An examination of the specimen seemed to him to indicate that the case was one of pseudo-hermaphroditism of the male type, with failure of union of the lateral halves of the body at the time of the completion of the external genitals, and with the persistence of the remnants of the Müllerian duct, which ordinarily becomes atrophied in man, but which in the female is developed into the uterus and Fallopian tubes. In a number of cases of masculine pseudo-hermaphroditism, uteri of about this size had been described as a result of the persistence of a portion of the Müllerian ducts. In a case like this, in which positive evidence was lacking, the fact that the definite function of the male had been performed should have considerable weight in reaching a decision. Certainly, the penis in this case bore a much closer resemblance to the true penis than to a hypertrophied clitoris, although Ziegler pictures a hypertrophied clitoris which very closely resembles the organ found in this specimen.

DR. H. J. GARRIGUES, present by invitation, said that in order to understand these cases of hermaphroditism, whether true or false, we must go back to the history of development. Before the tenth week we could not distinguish the sex at all. It should be remembered that the development takes place from three different localities, viz.: (1) For the outer part the starting-point is the genital tubercle and genital fold. (2) Inside of that are the Müllerian and Wolffian ducts. The former develops into the Fallopian tube and uterus in the female; the other duct becomes the vas deferens in the male, and is often found as a remnant in women. (3) The sexual glands are developed from the epithelium covering the Wolffian body. Bearing these facts in mind, he said, it was evident that any one of these three parts could assume the type of the opposite sex. In spurious hermaphroditism, there is only one sex, and there is an opposition between the outer part and the inner part. In true hermaphroditism, there must be at least one testicle and one ovary. A microscopical examination was necessary to prove a case one of true hermaphroditism. So far as he knew, there was only one reported case of true hermaphroditism—i.e., one in which there had been a microscopical examination to confirm the diagnosis. This was the case of a little child, who lived only one month. In this case there were two testicles and two ovaries, and the nature of all of these organs was demonstrated by microscopical examination. There was no difficulty, he said, in understanding how one sexual gland might take the male type, and the other the female type; nor in understanding how the glands might both belong to one sex, and the external genitals to the other. But how could there be both ovaries and testicles? The explanation probably was to be found in the different origin of the stroma of the testicle and the ovary. According to Waldeyer, the seminal canals of the testicle were formed by invagination from the Wolffian ducts, while the follicles in the ovaries were formed from the germ epithelium.

Dr. Garrigues said that he had seen the two tumors in the case under discussion, just after their removal from the patient, and hence while in the fresh state. They had appeared to him to be sarcomata. He had also had the opportunity of examining the patient while alive, and had in this way been able to diagnose an entirely normal virginal uterus. A certain journal had made the statement that these cases were quite common, but this seemed to him a gross exaggeration. During twenty-five years he had made a considerable number of examinations, and he had never seen a specimen as well developed as this one. He had measured the uterus in this case, and had found it two and one-fourth inches deep. On the left side was an entirely normal ovarian ligament, one

and one-fourth inches long, which had been abruptly cut off. The same was true of the broad ligament on that side. On the other side the post-mortem knife had left only short tabs to indicate the site of these parts. In his own mind he felt sure that this was a case of true hermaphroditism, and hence he regretted exceedingly that a minute examination had not been made. He knew of an individual, now alive, who not only menstruated, but possessed semen. The left side of this individual looked like a male, and the other side like a female.

DR. J. F. ERDMANN, present by invitation, said that he had also seen the specimen. He could not add materially to the report of this case, but desired to refer to an interesting clinical history recently sent to him, which bore on the subject under discussion. The patient was about twenty-five years of age, and had all the appearance of a female as regards the mammary development, and all the appearance of a true hermaphrodite as regards the development of the genitals. In the labia majora on both sides were what appeared to be testicles, and there was also a vagina. The patient would not submit to an examination with the finger or with a sound. He stated that he had had sexual connection after the manner of the male sex. Recently a specimen had been shown in the genito-urinary section of the academy which was really an example of the false type of hermaphroditism.

DR. BECK, in closing, said that he personally had very little doubt that this case was one of true hermaphroditism. It was not certain that there had not been menstruation in this case, for the patient might have had it and denied the fact. The fact that this patient had had a chancre—the initial lesion of syphilis—on the male organ would also be in favor of the opinion that this organ was a true penis.

Congenital Occlusion of the Bowel.—DR. THOMAS S. SOUTHWORTH presented a specimen. The child was one of twins, and died when five days old. The other twin died after two hours and a quarter, and the autopsy showed congenital pulmonary atelectasis. In the child about to be presented there had been no asphyxia at birth. On the first day a little mucus had been passed from the bowel, and the infant also vomited. On the third day, there having been no further discharge from the bowel, castor oil was given, without effect. On the fourth day there was a little vomiting, but there was no faecal odor to it. The little finger was passed a short distance into the rectum and a catheter was also introduced in the same way. The only result of this examination was the discharge of a long string of mucus. Just before death, on the fifth day, there was faecal vomiting. Post-mortem examination showed the lungs fairly well aerated and the heart normal. The stomach was distended with gas, and its greater curvature was turned upward by the distended intestine. The peritoneum contained from four to six drachms of bloody fluid and a few stringy clots. The small intestine protruded from the abdomen on making the first incision. The small intestine and the vessels of the mesentery were injected. The intestine was distended with a yellowish faecal matter. The lower part of the ileum was green and contained meconium. The diameter of the gut at the point of greatest distention was about three-fourths of an inch. In the ileum, and about two inches above the caecum, the bowel was filled with a rather firm mass of faecal matter and mucus. Below this, the ileum was contracted and nearly empty. A probe could be easily passed through the ileo-caecal valve. The caecum was exceedingly small and the appendix was normal. The colon varied from one-eighth to three-eighths of an inch in diameter. The rectum was a little larger and admitted the little finger up to the first joint. It was connected to the sacrum, and appeared to have been

torn from its attachments. This probably accounted for the bloody fluid found in the abdomen.

The speaker said that cases of congenital occlusion were rare. It had been stated that only two cases had been found in the Vienna Hospital in over one hundred thousand children. There might be: (1) An abnormally short or double bowel; (2) a double caecum and appendix; (3) abnormal positions, due to unusual length of mesentery, to hernia through the diaphragm, or to transposition of the viscera; (4) congenital absence of portions of the gut, a condition generally met with in poorly-developed and acephalic monsters; (5) the stenosis might exist in the form of one or more rings. Atresia was only a more advanced condition. The most frequent sites were the beginning of the rectum, the end of the rectum, at the duodenum, and at the lower end of the ileum. Occlusion might also occur from anomalies connected with the omphalo-mesenteric duct. The persistence at the umbilicus of a portion of this duct might give rise to "mucous polyp of the umbilicus," or it might result in a blind pouch, extending out of the ileum. Sometimes there was only a cord, extending from the ileum to the umbilicus.

The etiology was briefly summarized as follows: (1) The duct may be occluded by a fold or diaphragm of mucous membrane, a condition which is most common in the duodenum or jejunum; (2) such malformations are ascribed to arrested foetal development, or to accidents in development; (3) the occlusion may be due to foetal peritonitis; (4) it may arise from changes in the peritoneum in early foetal life, resulting in adhesions or constricting bands; (5) there may be obstruction at the junction of the ileum and omphalo-mesenteric duct, due to an excessive twisting of the umbilical cord—an increase of the normal condition at this point. If the twist extends to the intestine itself, atresia occurs. In the case just presented, the stenosis was about two inches above the ileo-caecal valve, and there was very imperfect development of the entire large intestine.

A New Morphological Element in the Cones of the Retina—"The Kuttarasome Body."—DR. IRA VAN GIESON said that the cones of the retina had been studied only as regards their shape and form. Max Schultze, in 1869, had so well described the cones, not only in the retina of the human subject, but in some of the lower animals, that very little had been added to our knowledge for about twenty years afterward. Then the connection of these cones with the central organs and with the ganglion cells of the retina was perfected. The cytology of the cone up to the present time had been almost entirely neglected. It had been his fortune to secure the retinae from criminals executed at Sing Sing, and hence it had been possible to obtain them in a very fresh condition. They had then been stained by Nissl's method, and examined according to the most recent and approved methods. Unless done in this way, the object to be described could not be seen. A striking body had been found just at the neck of the cone. It was composed of a series of parallel bars, and presented a gridiron appearance. These bars had lateral anastomoses, and at the top joined in a semicircular manner. For this reason he had given this body the name of the "kuttarasome body." This body was to be taken as the analogue of the chromophyllic granules in the ganglion cells. He would also call attention to the fact that the material composing this body extended up into the cone itself in the form of lines.

A Case of Fissure of the Abdomen, Pubic Region, and Genitalia was described by DR. J. S. ELY, by means of diagrams and photographs. The appearance of the child was that of one in good health. It was the third child, two previous children being healthy. There was an indefinite history of an at-

tempt at early abortion, followed by slight hemorrhage. The labor occurred on June 26, 1892, and the presentation was R. O. A. The umbilical cord was so short as to cause some delay in the labor. The child died about twelve hours after birth. At the autopsy the development was noted to be that of a child at full term. There was talipes varus of both feet, and the abdominal wall and genitals were malformed. From about three centimetres below the xyphoid cartilage down to the usual situation of the symphysis pubis was a large gash, measuring eight centimetres from above downward and seven centimetres laterally, and having an elliptical shape. In the edge of this defect in the abdominal parietes a membranous pouch protruded forward. In this pouch a large part of the liver and small intestine could be seen and felt. From about the centre the umbilical cord originated and was of normal diameter. The development of the genitals was exceedingly abnormal. A small wart-like prominence was seen in the median line, about five millimetres in both diameters, and of a bluish-red color. Just external to this was a slit-like opening, about six millimetres in length, from which meconium could be forced by pressure on the gut through the thin-walled omphalocele. At the same time meconium passed in small quantity from a small opening just above the wart-like mass. In each groin was a reddish mass, about two centimetres long and one centimetre at the broadest part. The lower part of this mass was composed chiefly of a thin reddish membrane. Toward its inner border was a small round opening, through which a probe passed into a larger cavity. Above and externally this mass in the groin was made up of denser tissue. Below this mass was a slender protrusion, one centimetre long, and somewhat resembling in appearance the labium minus. Below this was a rounded prominence, covered with tissue-like skin, and resembling slightly the labium majus. Below this was a small depression. On opening the abdomen by a median incision, the upper and anterior portion of the liver was found loosely adherent to the sac of the omphalocele. There was no evidence of a urachus. The liver was rather large, somewhat irregularly lobulated, and situated on the right side of the abdomen. The spleen was somewhat enlarged; it was situated normally, and its structure was also normal. The stomach had the usual situation, size, and shape. The small intestine was normal in size and attachments, but at the lower extremity of the ileum it was adherent to the anterior abdominal wall at a point corresponding to the small median opening already described. A probe passed from this opening into the lower portion of the ileum. The ileum also communicated by an opening in its right wall with the caput coli. This last was of normal size, and to it was attached the vermiform appendix. It was, however, almost spherical, and formed a sac about two centimetres in diameter. It represented all that there was of a large intestine. This cloaca-like pouch was closely attached to the posterior abdominal wall by a very slight mesentery. The ureter passed almost straight downward and communicated with the pyriform bodies extending upward from the prominences in the groin. These pyriform bodies were alike on the two sides. Each was about four centimetres long, broad below, and circular throughout in cross-section. The lower portion was soft and hollow, and was lined by a somewhat wrinkled mucous membrane. The upper three-fourths of the body were hard, but contained a very small cavity and resembled the uterus. It communicated below with the vagina by a well-marked cervix. From the upper and outer side of this uterine mass a tortuous Fallopian tube ran upward to the vertebral column. It had a distinct fimbriated extremity. Each pyriform body represented

a hymen, uterus, tube, and ovary, and the ureter on each side opened into the vagina on the corresponding side. The pelvis was rudimentary and defective in form. The ischium was represented only by a small knob. The ilium was well formed.

Dr. Ely then presented three specimens showing deficiency of the anterior abdominal wall. He said that when there was absence of bladder and of the pubic bones there was apt to be complete fissure of the genitalia, the ducts developing on their respective sides but never fusing.

Discussion.—DR. C. N. DOWD said that it was noticeable that almost all of these deformities were due to a failure of one of the ordinary processes. In one of the specimens there were various amniotic bands and adhesions. It would seem quite possible that many of these deformities were due to such bands. We could not but grant their existence; and, having done this, many malformations could be explained by such mechanical obstruction to growth. He had found that there were very few cloven feet on record—one such had been shown in the specimens just exhibited. In all the reported cases there had been a failure of development in the middle of the feet. It was easy to understand how such a cleft might result from amniotic bands. In all the cases he had been able to study there had been an absence of one or more of the bones of the tarsus.

DR. W. B. NOYES said that, in contradistinction to a purely local cause, such as amniotic bands, he would call attention to a series of cases in which the monstrosities occurred in families showing a distinctly hereditary element. For instance, certain families were known to have cretins, associated with deaf-mutism, or with supernumerary digits, or something of the kind. Unless this could be explained as a coincidence, it was difficult to understand its occurrence on the theory of a purely local cause.

DR. DOWD said that it could not be denied that there was a hereditary element, particularly in regard to the occurrence of supernumerary parts. The mechanical explanation, however, applied to a certain number of the cases of failure of development.

DR. GEORGE P. BIGGS thought that a band of sufficient size to produce such marked disturbances of development ought to be represented by some remnant. This would indicate that there must be something more than the bands to explain the condition.

DR. DOWD replied that if the arrest of development occurred at a very early period of development, it would not be necessary to suppose the existence of very large amniotic bands.

DR. ELY said that there could be no question that amniotic bands had much to do with the occurrence of certain very marked malformations; nevertheless, the theory did not seem necessary to explain the failure of union of the two lateral halves of the body, or such phenomena as cleft hands or cleft feet. It was well known that the respective halves of the hands depended for their development upon the respective sides of the forearm. If, for example, the thumb were absent, the radius would be frequently found to be absent. It seemed quite possible to suppose that some maldevelopment—such as an interference with the nutrition of the cells which usually united the two lateral portions in the median line—might result in this class of malformations. It was now known that certain malformations could be produced by irritation of the embryo. The cytologists were able to state, very early in the development, the exact part which would result in the formation of the respective systems or divisions of the body. It was evident, therefore, that certain cells were set apart for the formation of certain definite parts of the body.

The society then went into executive session.

Reviews and Notices.

MINOR SURGERY AND BANDAGING: Including the Treatment of Fractures, Dislocations, the Ligation of Arteries, Amputations, Excisions and Resections, Operations upon Nerves and Tendons, Tracheotomy, Intubation of the Larynx, etc. By HENRY R. WHARTON, M.D., Demonstrator of Surgery in the University of Pennsylvania, Surgeon to the Presbyterian Hospital, etc. Third Edition, thoroughly Revised and Enlarged, with 475 Illustrations. Philadelphia and New York: Lea Brothers & Co. 1896.

THE title page tells what the book contains, or almost all. The ground of minor surgery is well covered, and as there are five hundred and seventy-nine text pages it will be seen that they are quite well covered, too—with pictures. Most of them are very good, especially those illustrating bandaging, which are reproductions of photographs, several somewhat suggestive of the "living pictures." The chapters on antiseptic and aseptic wound treatment have been thoroughly revised, and some additions have elsewhere been made.

We bespeak for the work a continuance of the favor with which it was originally received.

A MANUAL OF OBSTETRICS. By W. A. NEWMAN DORLAND, A.M., M.D., Assistant Demonstrator of Obstetrics, University of Pennsylvania, Instructor in Gynecology in the Philadelphia Polyclinic, etc. With 163 Illustrations in the Text and 6 Full-Page Plates. Philadelphia: W. B. Saunders, 925 Walnut Street. 1896.

THIS work is constructed upon a combined clinical, physiologic, and pathologic basis. A normal labor in a normal woman is taken as the representative of physiologic obstetrics. In the second part the pathological deviations from this natural state are taken up and discussed in the same order, beginning with ovarian development and ending with the pathology of the puerperium. Following this is a chapter upon the pathology of the new-born, covering the accidents from asphyxia neonatorum to umbilical hernia.

The manual is illustrated in a practical and instructive way. The general style of the publisher's part is that of the "Saunders' New Aid Series."

It is a work worth having by all engaged in learning, teaching, or practising obstetrics. A system of paragraphing, numbering, and cross-reference makes the efficiency of the work more pronounced.

A MANUAL OF PHARMACOLOGY AND THERAPEUTICS. By WILLIAM MURRELL, M.D., F.R.C.P., Physician to and Lecturer on Pharmacology and Therapeutics at the Westminster Hospital, Late Examiner in Materia Medica and Pharmacy to the Conjoint Board of the Royal College of Surgeons of England and the Royal College of Physicians of London. Revised by FREDERICK A. CASTLE, M.D., Member of the Committee for Revision and Publication of the Pharmacopœia of the United States of America, Late Lecturer on Pharmacology at Bellevue Hospital Medical College, Physician to the Presbyterian Hospital; Editor of "New Remedies," etc. New York: William Wood and Company. 1896.

THIS is an abstract of the lectures on pharmacology delivered by the author before the students at the Westminster Hospital, and especially designed for the purposes of students preparing for examination. Still, the therapeutic part has been written in such a way as to make the work most available for the requirements of practitioners of medicine, and with this view a large number of modern prescriptions has been incorporated in the text, and in a separate appendix the introduction covers one hundred and forty-three pages and embraces a large variety of subjects, including climate, baths, serums, alkaloids, ptomaines, the art of prescribing, etc. An excellent feature, in connection with the index, is the addition of the customary maximum single dose for adults, placed opposite each drug intended for internal use. The work of the reviser has been carried out with a full realization of the requirements of the American student and reader, and all points interesting the English purchaser of the work alone have been omitted. In compensation much of interest and importance has been added, and this matter is enclosed in brackets to indicate its source. The work upon both sides appears to have been done with the utmost painstaking care,

and the experience and reputation of the American reviser in such matters are a warrant that accuracy may be depended upon.

There would seem to exist a field of usefulness for just such a work, since pharmacology is attaining from year to year greater importance in the college course, and the branch is keeping well up with advances in other lines.

A TEXT-BOOK OF DISEASES OF THE NOSE AND THROAT. By FRANCKE HUNTINGTON BOSWORTH, A.M., M.D. Profusely Illustrated with nearly 200 Engravings and 7 Full-Page Chromolithographic Plates. New York: William Wood and Company. 1896.

THIS work, unlike the rather voluminous one recently issued by the same author, is better adapted for the practical use of both practitioner and student. It is in reality a condensation of the two volumes into one, leaving out such portions as were mainly intended for reference. Only a few immaterial changes appear to have been made in the condensing process, which was accomplished, as the author states, mainly through the efforts of Dr. A. R. Schroeder. The number of chapters escaped by one reaching the hundred mark, making eight hundred and twenty-one pages, including seven colored plates inserted after the index. The chapters are divided into six sections: (1) "Diseases of the Nasal Passages." (2) "Diseases of the Naso-Pharynx." (3) "External Surgery of the Nose." (4) "Diseases of the Fauces." (5) "Diseases of the Larynx." (6) "External Surgery of the Throat." The list of illustrations covers a wide range of subjects, whose description is thus rendered much clearer. The wide experience of the author as practitioner in this department and as teacher of this special branch has well qualified him for the task which has been accomplished. Not only have the usual affections which are so common in this climate been almost exhaustively dwelt upon, but all the serious operations which the surgeon is called upon to perform in this region of the body have been described and depicted. The original work having been reviewed at some length, it need now only be said that the reducer of those two volumes has acquitted himself in a most satisfactory manner and presented a book well worthy of the extensive and important subject.

A MANUAL OF CLINICAL DIAGNOSIS by Means of Microscopic and Chemical Methods. For Students, Hospital Physicians, and Practitioners. By CHARLES E. SIMON, M.D., Late Assistant Resident Physician, Johns Hopkins Hospital, Baltimore. With 132 Illustrations on Wood and 10 Colored Plates. Philadelphia and New York: Lea Brothers & Co. 1896.

THIS is a work which enters into a comparatively new field, and one which we must admit has been too much neglected both in America and in Europe. To be sure, the schools are taking up laboratory methods of examination more and more each year, but the older generation of physicians has not realized the importance of securing competent assistants to do such work for it when too busy to devote the requisite time to it. The student and the diagnostician will alike find here pointed out the way through clinical chemistry and clinical microscopy to the attainment of definite results. The arrangement is such that one who has had no special training in these branches can follow out the scheme of work in examinations of blood, secretions of the mouth, the stomach contents, feces, nasal secretions, sputum, vaginal discharges, milk, etc. The normal secretions of the part are described and afterward the pathological, and finally the technique of examination. Naturally the chapter on the urine is the most important, in point of number of pages devoted to it, which extend from page 239 to page 460. There are a number of instructive colored plates, some of which, as well as many of the wood cuts, are taken from von Jaksch's work.

Malakine has been found by Merkel to possess marked influence over rheumatism in those cases in which salicylate of sodium remained without effect. In three cases Korotky and Oussoff secured, by its employment in doses of from two to three grains daily, a lowering of temperature and suppression of pains without any of the discomforts which the salicylate may occasion.—*Meditz. Obos*, No. 2, 1896.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

JUBILEE OF THE PATHOLOGICAL SOCIETY—A GLASGOW INSTITUTE FOR PATHOLOGY—THE HARVEIAN ORATION—GUILD OF ST. LUKE—DOCTORS AT ST. PAUL'S CATHEDRAL—THE ARMY DEADLOCK—SIR W. MACCORMACK—WATER SUPPLY—ENTRIES AT THE SCHOOLS.

LONDON, October 23, 1896.

THE Pathological Society, on Tuesday, celebrated its jubilee by an address from the president, Mr. Butlin, and an exhibition of a series of specimens which have no little historical interest. Mr. Butlin spoke of the great influence the society has exerted in promoting the study of morbid anatomy and pathology. The society held its first meeting on October 20, 1846, when a number of specimens were contributed by the members. Indeed, the exhibition of specimens, drawings, casts, or models of morbid parts was the first object of the society, and has held a foremost place through the half-century of its existence. The forty-six volumes of Transactions are a kind of record of the progress of pathology, and of immense use in the study; but I doubt not the influence of the meetings has been far more widespread. Mr. Butlin anticipates that the records of the society are likely to be of value for the next fifty years, and he spoke from his experience as to their use in collecting cases of morbid growths for analysis—an experience common to all searchers and writers for the last thirty years. Still, I think, as I have said, that the influence of the meetings has been more useful in promoting a wider interest in the subject.

Nevertheless, Mr. Butlin was constrained to express apprehension that the society may have passed its zenith and is in the stage of decadence, although there are some seven hundred members on its list. From some points of view this is undoubtedly the case, and to assist in its rejuvenescence I would suggest that an effort should be made to make the meetings more interesting to those who cannot attend regularly. In this view it is doubtful whether set discussions, in which a few experts are engaged to state their views, are really attractive. Such debates can be read in the journals. That which can only be obtained at the meetings is a sight of the specimens and the remarks, which often shed fresh light on them from different points of views.

After reviewing the history of the society for the last fifty years, the president expressed a hope that the work should go on for an equal period, and he suggested that departments of applied pathology, established at our hospitals, would be a good plan for maintaining the proper relations between purely scientific work and the practice of medicine and surgery.

Sir R. Quain, one of the five surviving original members, moved the vote of thanks to the president, which was seconded by Dr. Wilks, who mentioned that the idea of the society was due to Dr. Bentley, of Guys, at whose house the first meeting was held.

The exhibits were confined to specimens of morbid anatomy, which illustrated subjects of general pathological interest—the restriction being due to want of space. A catalogue was ready. Among them were Paget's specimens of osteitis deformans; Wilks' specimens demonstrating the fact of visceral syphilis; Addison's specimens of suprarenal capsules, from which he made his discovery; and others of similar historical interest.

While pathology has been to the front in London, it has also attracted attention in Glasgow, where a Path-

ological Institute, in a suitable building erected at a cost of £15,000, has just been opened. Professor Gairdner gave an inaugural address on the occasion. No one is more capable of showing the place of pathology in the science of medicine, and this, of course, he did in the felicitous manner that charms his hearers whenever he is the speaker.

On Monday the Harveian oration was delivered by Dr. J. F. Payne, before the College of Physicians. The chief point in his discourse was the relation of Harvey to his predecessors, and especially to Galen, the final representative of the great Greek school. Dr. Payne argued that it was that school which put into shape, but could not solve, the problem which remained insoluble until the appearance of Harvey. His genius was able to solve it. But it may be said that he was influenced in no small degree by his two preceding generations. In fact, Linacre and Caius may be said to represent two successive stages in the movement which was preliminary and essential to the work of Harvey, and of which his discovery was the culmination. The period of the renaissance was that of the revival of Greek learning, and Linacre's object was to make the works of Aristotle and Galen accessible to all by translation and the earnest study of all. Modern science, the orator argued, grew out of Greek learning, and it was only a speculation as to how otherwise it could have arisen. The student of to-day, who goes to his anatomical work with his text-book and dissecting-case in his hand, should be thankful that in the fifteenth century they began to read Greek manuscripts. The moral drawn by the orator was that we cannot ignore the instruments of the past, and that is a growing truth of which the lovers of Greek learning scarcely need a reminder.

On Thursday St. Paul's Cathedral was the scene of an interesting ceremony, promoted by the guild of St. Luke. This guild is an association of doctors who are churchmen—and one may say high churchmen, for it is in that party the guild originates and on its lines it is carried on. But all practitioners and even students were invited to the service at St. Paul's, and doubtless many of the throng who attended neither knew nor cared what party organized the ceremony. It was the thirty-second anniversary of the Guild of St. Luke (patron saint of doctors, as "the beloved physician"), and that association initiated the ceremony, which was announced to be analogous to that among lawyers when Her Majesty's judges annually attend St. Paul's in state, though I fail to see how a private association is analogous to Her Majesty's judges, or can give state to a ceremony of the kind named. However this may be, the guild satisfied the lord mayor and sheriffs, who attended in state and so gave civic pomp to the occasion. It had been requested that graduates should appear in the gowns and hoods of their academic degrees, and, as many complied with the request, the scene under the great dome was unusually brilliant, and must have given great satisfaction to the organizers and all who take delight in robes and ornaments. The Bishop of Stepney preached the sermon, in the place which was to have been occupied by the late archbishop. He referred to the training of young medical men, which he had observed at Cambridge, and did not wonder that some for a time became materialists, as they found no part of nature that might not fully occupy the highest intellects. But that phase must not continue, and, though he was quite certain that religion could not do without science, he also was profoundly convinced that science could not do without religion. In the harmony of the two and the perfection of each is the healing of this world and the building up of the next. After praising the work the guild is doing in this direction, the bishop spoke of the deceased archbishop, whose vacant pulpit re-

minded them of that "marvellous voice—once heard, never forgotten—which would have said things that not all the anxieties of professional life would be able to remove from your minds." He asked if they needed a more speaking message of the poor, feeble thing materialism is, when they met such a blow as his death. In such cases consolation, strength, hope, has to be sought outside any particle of matter. It is in the world of spirit you are plunged. Then he dwelt on how the late prelate would have rejoiced to see the enormous and brilliant assembly that thronged the great cathedral—"such a gathering as I have never seen in this place, under circumstances that make the occasion absolutely and entirely unique."

The deadlock in the army medical service seems, at length, likely to rouse public attention. The *Court Circular* protests against the attempt now being made to conceal the dearth of officers by overworking those who remain, to an extent likely to lead to an ignominious breakdown. The *Circular* says that "rather than admit a deficiency in the medical staff, the department, where possible, is doubling the duties of medical officers." This new departure, adds the journal quoted, "at best can only serve a temporary purpose, and sooner or later the weakness of the staff will have to be officially acknowledged." The sooner the better, for the public is determined to maintain the army and navy in an efficient state, and should these forces have to be employed and the wounded lack medical aid a stern retribution would overtake those responsible.

The service papers cannot ignore the state of affairs. In one of them a correspondent, over the signature "Common-Sense," makes suggestions which should, perhaps, have been sent to a comic paper. However, whether intended as a joke or not, their appearance in a service paper shows the folly of the officials and the prejudices of the so-called combatants. "Common-Sense" says he would abolish the director-general and his staff of doctors, and put the medical staff under the adjutant-general, who could have a civilian doctor on his staff to advise him on professional matters. Exactly! Give your pretentious "combatants" every possible post, and for the sake of doing so make the mere doctors civil servants. Then, when army surgeons were wanted for the grasping combatants, who had driven them from the service, what an outcry would be raised on behalf of the wounded, who could send for "civilian doctors" only.

I am glad to report that Sir William MacCormack is much better, and it is hoped he will soon enter the convalescent stage.

The London water supply is now impugned on the ground of quality, and recent analyses are far from reassuring.

The entries at the London schools are much below the number expected, and the lamentations of the teachers are loud. The provincial schools have kept up their average.

Nymphomania.—Search carefully for local causes, such as may occasion pruritus vulvæ—vaginitis, vegetations, vulvitis, eczema, syphilis, herpes. Investigate, especially, as to diabetes. Where nervous disorders are suspected, bromides in medium dose are indicated. When associated with opium, they combat in an effective manner the exaltation of the venereal appetite. Camphor may be added, and when insomnia coexists chloral is to be given at night. Local applications are useful. Cocaine in lotion or ointment has the preference. Hydrotherapy is indicated in all cases. When scientific douchings are not possible, applications of cold water to the vertebral column at bedtime are beneficial.—LUTAUD.

"THE APPENDICITIS CONTROVERSY"—AN UNFAIR CRITICISM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Having read with no little astonishment Dr. Halton's communication and severe arraignment of some gentlemen who treated a case according to modern methods, I shall feel grateful for space in your valuable journal for a few remarks in reference to certain statements it contains.

Usually those opinions concerning this very important and dangerous disease which have the greatest weight come from men who are able to substantiate their statements with an experience in a fair number of cases. Still greater weight should be accorded the opinion of the physician or surgeon who has treated a number of cases by both plans, thereby enabling him to speak intelligently, drawing his conclusions from clinical experience and actual observation. I regret that I am not personally acquainted with Dr. Halton, and that I am unable to find his name in the green book as being a member of any of the scientific bodies formed for the purpose of discussing just such questions. While operation has saved a large proportion of patients in appendicitis, he says it has also killed not a few of them, a very bold statement, which no attempt is made to substantiate by recorded experience. Bad judgment in the selection of cases to be operated upon is mentioned, but he does not tell us what cases we should operate upon and those which should be treated otherwise. He does not tell us who it is that belittles the physician and elevates the surgeon. Dr. Halton criticises the work of thousands of students of surgery and medicine throughout the civilized world who advocate in the strongest possible terms operative procedure in appendicitis. He also deems himself competent to criticise the judgment of these same men in their selection of cases to be operated upon, when he must know, even if he has had but a limited experience, that no living man can foretell the final result of any given (well-marked) case of appendicitis. Physicians and surgeons, in the early operative days, receded from position to position in their honest endeavors to stay the ravages of this destructive disease and to lessen its mortality, until they betook themselves to storming the citadel by early operation, which is at the present day advocated by the majority of both physicians and surgeons.

In reference to the case related by Dr. Halton, according to his own statement, we find a boy sick with appendicitis for at least three days and perhaps longer, without medical attendance of any kind whatever, notwithstanding the fact that he himself was the family physician. A neighboring physician was called and recognized the disease at once; but just what the conditions were that this physician found, whether the boy wore the facial expression which at all times bespeaks very great suffering, whether he had a glazed and dry tongue, a rapid pulse, a high temperature, a swollen and tympanitic abdomen, whether he had a well-marked tumor in his right iliac fossa, Dr. Halton fails to tell us. Perhaps he is to be excused for not informing us of these points, not having been there. We understand from the criticism that the boy had pain, vomited, went to bed; got up and walked around (a very dangerous thing, by the way, to do in appendicitis). The patient's condition, it is stated, finally became alarming and the neighboring physician was sent for. The latter seems to have been prompt in applying the best possible remedy in a very much neglected case, namely, operation.

We are not told whether catarrhal appendicitis is more or less fatal than other forms of the disease, but the simple statement is made that he was told the boy had a catarrhal condition.

Dr. Halton states that when he saw the boy the latter was dying (by the way he lived for several days after this), but he learned that the attending physician expressed a hopeful opinion; he does not state whether the attending physician or surgeon qualified this statement. He concludes that here was a healthy boy suffering with appendicitis (I presume he means that here was a boy sick with appendicitis whose previous health was good) starting slowly for the grave from the moment of operation. Being entirely unacquainted with the facts in the case, how could he say that the patient did not start in this direction from the beginning of his attack? He does not explain what the pathological conditions were in this case. He thinks it would be reasonable to infer that the wrong time was chosen for operation. Here is the only point on which I can possibly agree with the writer. The proper time was within the first twelve to sixteen hours of the attack. He further thinks that by waiting twenty-four hours longer the tendency to general peritonitis might have been reduced by warm applications and the administration of opium. If the appendix was necrotic and its mucous lining had sloughed, warm applications would do no good, and as for opium, this drug has long since been condemned in the treatment of appendicitis because it masks the symptoms. Dr. Halton thinks that the physician's powers of observation are very different from those of the surgeon, forgetting that many surgeons have spent years in the practice of medicine before devoting themselves to the practice of surgery.

To make it clear that Dr. Halton does not voice the sentiments of physicians generally, at least in the city of Brooklyn, I will relate two cases now under my care:

CASE I.—Immediate operation advised by two eminent physicians after seeing the patient for the first time. Mr. G——, native, aged forty-five years; married; residence, Vanderbilt Avenue, Brooklyn. October 3, 1896, complained of pain in the stomach; the following day of pain lower down on right side. October 5th and 6th somewhat better. October 7th, compelled to take to his bed. October 8th, went to business. October 9th, was again compelled to go to bed. October 10th, morning, called his family physician, who is visiting physician to St. Mary's General Hospital, Dr. George R. Kuhn, who diagnosed appendicitis and suggested operation as being the proper remedy. Dr. Kuhn asked me to see the patient with him in order to settle this question. I saw the patient at 11:30 A.M. of the same day and had but to confirm Dr. Kuhn's diagnosis and proposed plan of treatment at 3 P.M. Dr. Kuhn and Professor McCorkle of the Long Island College Hospital saw the patient together, both concurring in the diagnosis and advising immediate operation. At no time was the temperature by the mouth above 99° F. or by the rectum above 100.6° F. per rectum.

The patient was sent into my service at St. Mary's Hospital the same evening, and at 10 P.M. was operated upon. The appendix was found curled upon itself and partially embedded in a firm coating of inflammatory tissue, with its lower end adherent to the omentum. This was separated from the appendix and about two inches of it cut away after being firmly tied with catgut. The serous covering was stripped down to the base of the appendix, which was then cut off and the stump inverted. The serous covering was drawn over it by Lembert sutures. The appendix was perforated about half an inch from its apex, its mucous membrane having entirely sloughed; its muscular wall was necrotic for about three-fourths of its length, its mesocæcum partially gangrenous. At the point of perforation there was a small abscess cavity containing perhaps two ounces of foul-smelling pus. The part of this abscess wall which pointed toward the base of the appendix was very thin. Internally to this the

general peritoneal cavity was unprotected, so that in time this thin wall must have given way, flooding the general peritoneal cavity with pus. October 21st the patient is still in the hospital but practically well. What would have been his fate had Dr. Halton's methods been carried out, I leave the reader to surmise.

CASE II.—Dr. I. Fuchs after early consultation advises early operation. Miss G. S——, native, aged fourteen years; residence, Madison Street, Brooklyn. October 5, 1896, in the evening, patient complained of pain in the abdomen. October 6th, used some home remedies. October 7th, sent for Dr. I. Fuchs, visiting physician to St. Catherine's Hospital. Dr. Fuchs took almost immediate steps to have his patient operated upon, thereby saving her life, as the following pathological conditions will show: She was sent into my service at St. Catherine's Hospital on Monday, October 8th, and operated upon at once (2 A.M.). The enlarged and inflamed appendix was removed and found to contain four large fecal concretions, some little distance apart, filling almost the entire canal. The meso-appendix and the base of the appendix were partially gangrenous, necrosis extending well upon the cæcal wall. The general peritoneal cavity was not protected. There are other interesting and instructive points in connection with this case which I will not bring out here.

I quote these cases to show that the eminent physicians interested in them are at variance with Dr. Halton in his plan of treatment, namely, warm applications, opium, and waiting, and in each case they followed the course pursued by the physician whom Dr. Halton criticises.

That some patients get comparatively well without operation no one denies, but usually improvement commences in such cases within from twelve to sixteen hours from the onset. On the contrary, if the symptoms become aggravated after this time or if the disease persists in spite of palliative measures (opium excluded), it becomes an operative case, and the physician or surgeon who hesitates to advise operation robs his patient of one of the best means known to science at the present day of saving life in this dreaded disease.

JAMES C. KENNEDY, M.D.,
Visiting Surgeon to St. Mary's and St. Catherine's Hospitals, Brooklyn, N. Y.

The Absence of Gonococci in Gleet.—Dr. Taylor, in his recent work on "Venereal Disease," believes that after gleet has lasted for some months the gonococci are in all probability absent. Dr. Pilcher, in reviewing the work, remarks that this is a comforting doctrine, but if true the exception must be very frequent, as is shown by the experience of numerous unfortunate young women, who, upon marriage, find that the mucous membrane of the vagina and uterus is a most favorable culture ground for the gonococci that still persist in the urethras of the husbands.

Dislocations of the Hips.—Dr. Oscar H. Allis, in a monograph relating to the difficulties encountered in the reduction of dislocations of the hip, discusses the following points: 1. The capsule is the most important agent against traumatic dislocations of the femur. 2. For the laceration of the capsule and dislodgment of the head of the femur, the femur is employed as a lever. 3. Every lever has a fulcrum: the fulcrum required in dislocations of the femur are bony and ligamentous. 4. Dislocation by thrust, if possible, is infrequent. 5. Reduction by circumduction is the simplest, the most brilliant, and the most hazardous of all modes of replacement. 6. Method suggested for reduction of dislocation of the head of the femur when associated with fracture of the shaft.

Surgical Suggestions.

Pyelitis in Infancy.—Dr. Wolfstein (*Archives of Pediatrics*, xiii., No. 5) names the following causes: 1. The lithæmic state, especially any irritation of the kidney by uric acid, in form of crystals or calculi, or strong acidity. 2. Tuberculosis. 3. Retention of urine with ammoniacal decomposition, causing an ascending pyelitis. 4. Irritation by such drugs as turpentine, carbolic acid, and salicylic acid. 5. Vulvovaginitis, cystitis. 6. Infectious diseases. 7. Septic catheterization. 8. Idiopathic pyelitis from chilling or wetting.

Menorrhagia in Virgins.—Dr. Laroyenne (*Lyon Médicale*) distinguishes the majority of cases of profuse menstruation in young girls which require no local treatment from a minority in which the use of the curette is advisable. If, after long attention to hygiene and a course of suitable tonics, menorrhagia persists, interrupted by occasional amenorrhœa, granular or fungous endometritis probably exists. This disease is yet more safely diagnosed when the patient has been perfectly healthy and quite free from anæmia before profuse menorrhagia appeared, and equally free from evidence of diseased appendages after the local symptoms became marked. It is right after dilatation to use the curette when the excessive menstruation causes debility. A single application of cotton wool, soaked in equal parts of water and chloride of zinc, made immediately after the scraping, is sufficient. Repeated cauterizations may readily cause atresia.

Surgical Treatment of Focal Epilepsy.—Drs. Sachs and Gerster (*American Journal of the Medical Sciences*, October, 1896), after a discussion of this subject, summarize as follows: 1. Surgical interference is advisable in those case of partial epilepsy in which not more than one year, or at the utmost two years, have elapsed since the traumatic injury or the beginning of the disease which has given rise to the convulsive seizures. 2. In cases of depression or other injury of the skull, surgical interference is warranted, even though a number of years have elapsed; but the prospect of recovery is brighter the shorter the period of time since the injury. 3. Simple trephining may prove sufficient in a number of cases, and particularly in those in which there is an injury to the skull, or in which a cystic condition is the main cause of the epilepsy. 4. Excision of cortical tissue is advisable if the epilepsy has lasted but a short time, and if the symptoms point to a strictly circumscribed focus of disease. 5. Since such cortical lesions are often of a microscopical character, excision should be practised even if the tissue appears to be perfectly normal at the time of operation; but the greatest caution should be exercised in order to make sure that the proper area is removed. 6. Surgical interference for the cure of epilepsy associated with infantile cerebral palsies may be attempted, particularly if too long an interval has not elapsed since the beginning of the palsy. 7. In cases of epilepsy of long standing, in which there is in all probability a widespread degeneration of the association fibres, every surgical procedure is useless.

Transperitoneal Treatment of Artificial Anus.—Dr. Gangolphe (*Revue de Chirurgie*) advises opening the peritoneum at once in operating for artificial anus, instead of having recourse to the enterotome of Dupuytren. He claims that it has the following advantages: 1. It is rapid; the surgeon is not delayed by fear of wounding any important organs or tissues. 2. It is sure; the finger introduced into the abdominal cavity explores the parts in the neighborhood of the opening; it also guides the scissors in loosening the

intestines at a distance from it. 3. It permits the withdrawal of the infected intestines outside the abdomen, where they can be protected with gauze while being operated upon; the chances of infection are diminished, while manipulations are facilitated. 4. It is possible in all cases, while operation by other methods is not always possible.

A New Traumaticine.—Treat an aqueous solution of soap with a solution of alum. A magma forms which can be pressed out and which is a fatty-acid salt of alumen. This magma is dissolved in ether while it is still moist. The solution thus obtained can be medicated with chrysarobin, etc., for the treatment of psoriasis.—DUCOMMUN.

Foreign Bodies Swallowed by Children.—*The American Medical and Surgical Bulletin* in an article on this subject says that pins, safety pins, pebbles, jackstones, etc., swallowed by children need occasion no alarm, as they will all pass through without harming the child. The greatest danger is from the castor oil with which the child is usually dosed in such cases; it is better to leave the bowels at rest and give gruel, crackers, baked potatoes, milk, anything which will constipate the child and make a pultaceous mass in which the foreign bodies will be embedded and carried through. When foreign bodies stick in the throat and the child is unable to swallow, it should receive an emetic, or the coin catcher should be introduced. This is a basket-like affair easily used. In one case both a one-cent and a two-cent piece were removed at the same time by this instrument.

Surgery of the Kidney.—Dr. Holmes (*Journal of the American Medical Association*, September 5, 1896) makes the following summary: 1. Tuberculosis of the kidney is a relatively common disease. 2. It usually begins in the kidney itself, descends through the ureter to the bladder, and ascends to the opposite kidney. 3. It is, therefore, for a long time a unilateral disease. 4. It is a progressive and destructive disease, not subject to improvement through medication, offering an unfavorable prognosis as to life and comfort, and subject to extension downward by the urinary tract and outward through the perirenal lymphatics. 5. Diagnosis can be made through the symptoms of cystitis with low temperature, rapid pulse, and dilatation of the heart; the detection of tubercle bacilli in the urine; tuberculosis of the bladder about the orifice of the ureter of the diseased kidney; pus or blood with tubercle bacilli and diminished normal constituents in the urine from the diseased kidney; normal urine in increased quantity from the opposite kidney; sometimes tenderness, pain, and tumor *in situ* of diseased kidney and ureter. 6. The indications in case of an absolute diagnosis of tuberculosis of one kidney and healthy opposite kidney are immediate removal of the diseased kidney and its ureter; in case of disease in both kidneys, no operation should be performed. 7. The competency of the healthy kidney should be proved by repeated catheterization of the ureters before nephrectomy and the removal of all toxic elements from the blood should be secured by a liquid diet, irrigation of the colon, and hydration of the whole system for some days before the removal of the kidney. 8. Lumbar extraperitoneal nephrectomy is the safer operation. 9. In women the removal of the ureter should be completed through the vagina. 10. Any remaining tuberculosis of the bladder should be treated locally by curetting or cauterization. 11. Catheterization of the ureter is not a dangerous procedure, and it may easily be accomplished in women with the simple cystoscope of Simon, Pawlik, or Kelley, and in men with the more complicated instrument of Casper.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 7, 1896:

	Cases.	Deaths.
Tuberculosis.....	102	97
Typhoid fever.....	21	4
Scarlet fever.....	77	1
Cerebro-spinal meningitis.....	0	0
Measles.....	57	2
Diphtheria.....	210	24
Small-pox.....	0	0

The Diagnosis of Typhoid Fever.—Facilities for the new diagnosis of typhoid fever are now offered to the physicians of New York, as will be seen by the following:

“NEW YORK, November 6, 1896.

“Hon. Charles G. Wilson, President, Health Department, City of New York.

“DEAR SIR: I desire to direct the attention of the board to a new laboratory method for the diagnosis of typhoid fever, which, judging from the data available at the present time, promises to be of very considerable practical value in the diagnosis of early or ill-defined cases of this disease.

“The investigations of Pfeiffer and Widal have shown that the blood of persons suffering from typhoid fever, when mixed with active cultures of the typhoid bacillus, has the power of arresting the active movement of these organisms, and of producing peculiar and characteristic clumping of the bacilli. It has been shown that this reaction occurs frequently very early in the course of the disease; that it is found throughout its course, during convalescence, and often for a considerable period after complete recovery. It does not occur with other organisms than the typhoid bacillus, and it does not occur with cultures of the typhoid bacillus when the blood of persons suffering with other diseases is employed. As has been shown by Widal and Johnson, this reaction occurs as well with specimens of dried blood as with fresh blood, and thus can be employed practically in municipal laboratories for the diagnosis of this disease. Observations on this matter, which have been in progress in the laboratories of this department for some time past, have thus far confirmed the conclusions of previous investigators.

“In order that more numerous data shall be at the command of this department, and that physicians of New York may at the earliest moment have facilities for testing the reliability of the observations thus far made, I would respectfully recommend that arrangements be made to place facilities for such examination at the command of all physicians in this city—it being distinctly understood that this action of the department is for the purpose of gaining information on this important subject, and at the same time of placing at the command of physicians opportunities for observing the results. If the data already obtained are entirely confirmed by subsequent observations, this method will undoubtedly prove of great service in the diagnosis of early and obscure cases of typhoid fever.

“Should this action be determined upon, circulars of information as to the method of collecting blood and slides for this purpose may be left at the depots already established for the collection of diphtheria

culture tubes and the distribution of diphtheria antitoxin.

“Respectfully submitted,

“HERMANN M. BIGGS,

“Pathologist and Director of the Bacteriological Laboratory.”

The following resolution was adopted by the board of health of the health department, at a meeting held on November 6, 1896:

“Resolved, That the recommendations of the director of the bacteriological laboratories of this department, contained in the communication dated November 6th, be and are hereby approved, and that he is hereby authorized to place facilities at the command of physicians of this city for the diagnosis of cases of typhoid fever, in accordance with the method prescribed in said communication.”

Circulars of information regarding the method employed, and slides for collection of blood, may now be obtained at the various pharmacies where diphtheria culture tubes are kept. Physicians desiring to make use of this method in the diagnosis of early or obscure cases of typhoid fever can secure these, and, after collection of blood as described, may leave the slides, with the data relating to the case, at the various depots. They will be collected each day, examined the following day, and the report of the result forwarded to the physician.

Boiled Milk requires much more digestive effort than does the unboiled material, as in the latter case the serum albumin and nucleated cells, it is said, are absorbed directly by osmosis without any chemical change. Milk may be pasteurized (warmed to 160° F.) without interfering with its digestibility by coagulation of the cell and serum albumin.—*Atlantic Medical Weekly*.

Grape Growers in the neighborhood of the lakes have allowed their crops to be fed to hogs and to rot on the vines this season, because the appendicitis craze has injured the business. We therefore see the luscious but inoffensive grape, that graces the table and brings to pass so many delights, banished to the domain of the pigsty. Could there be a sadder commentary on ignorance in these panic days of dislocated wit and judgment, when so many people are suffering for the want of wholesome food?—Dr. Rosse, *Maryland Medical Journal*, October.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE SPHERE OF THE PHYSICIAN AND THE HOSPITAL.¹

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

MR. PRESIDENT, GENTLEMEN OF THE BOARD OF TRUSTEES, LADIES, AND GENTLEMEN: When Professor Chandler asked me to give the annual address before St. Luke's Hospital, I was much at a loss to select a proper theme for such an occasion. The distinguished gentlemen who have been with you in previous years have ably treated the topics that would naturally suggest themselves at such a time. Hence, much that I can say will doubtless be but a repetition of what has been already well said. The fact, however, that the medical profession is beginning to assert itself not only in questions relating to its own interests, but in the larger problems of the day, tempts me to offer a few random thoughts upon the calling of the physician and the work of the hospital in their relation to the community at large. I can heartily agree with Dr. Andrew Smith's address before you last year, in which he deprecated the extreme tendency toward specialism that has manifested itself in the profession in recent years. That this tendency, unless checked in some proper degree, will work an injury to the profession itself, as well as to the public at large, is equally clear to my mind. Upon the physician himself the exclusive working upon single lines cannot but have a narrowing effect, unless offset by a large general experience previously spent in the practice of medicine in all its branches. It is too much the fashion for young graduates in medicine to start at once upon the exclusive practice of a specialty, in the operation of which they soon gain great manual dexterity. But this skill, as just suggested, is of the hand rather than of the head. As we inspect the ingenious and too often complicated contrivances for repairing and removing the organs of the body, we are reminded more of the mechanic than of the physician. In direct ratio to the celerity with which the parts of our economy can be removed, there seems to be a weakening of the judgment that will tell us not only when they should be removed, but whether it is necessary to remove them at all. This extreme specialism cannot but be injurious to the public at large, which is now beginning to trust the various organs of their body to as many different healers, and this again suggests the idea of the machine and the mechanical repairer. The common argument that the field of medicine is now so broad as to prevent any one from attempting to occupy it all is only a half-truth. While much advanced work is being done by special investigators, any positive results that they may gain can usually be absorbed by the mass of the profession for the benefit of their patients. It is well to bear in mind that the margin between what is known and necessary for the good of the patient, and needless theorizing and differentiation, is often a pretty wide one. The post-graduate

schools of medicine that in the last decade have sprung up all over the country cannot but have a beneficial effect in acquainting the every-day practitioner with the advances in all lines that can directly benefit his patients. It has often seemed to me that, as far as our patients are concerned, we need in medicine less science and more philosophy. A man who has an average development on all lines will often give safer advice than the extreme specialist, even in his own department. It is not here contended that every physician should not pursue some special line of research. Indeed, this is highly desirable; but both the science and art of medicine will be benefited if such researches can be made by men of broad equipment and experience, who will see facts in their proper relations, and who will thus be less liable to be carried away by undue theorizing. The general practitioner is not yet in his decadence. He has a future of more importance than acting as a sort of intelligence office, to dole out his patients to the proper specialist. The specialists themselves will become more important as they grow less differential, less verbose, and develop out of a solid foundation of knowledge and experience with the whole art of medicine.

A hopeful sign in the physician's sphere of work is the lessening tendency of detaching himself from participation in the broad movements of modern life. To many of the questionings of the day he can throw as much if not more help than most classes in the community. The medical profession affords opportunity for broad and candid judgment upon many problems of life, as it touches humanity in close and many-sided relations, dealing with all classes, drawing experience from the poorest in swarming dispensaries and hospitals, as well as from the better favored in homes of ease. The pure philanthropist is often apt to consider a subject in an unreal, hypothetical sort of way, that may be out of touch with the actual life of the world. The physician, if any one, sees the world as it is—not as it should be, nor as many suppose it to be. Of the many panaceas that are offered for social as well as individual ills, very few are based upon a correct appreciation and knowledge of the operation of natural law.

It may be that physiology will be able to afford the best preliminary solution of some of the problems of sociology. Attempted social relief that is not based upon essential causes cannot be permanently successful. Social reformation that is not in harmony with the underlying laws of nature will always be a failure. It must follow in the lines indicated by a logical study of the sciences of biology, of physiology, and even of pathology. Social law must conform to natural law. All artificial adjustments only complicate existing troubles, in leaving untouched the underlying causes of these troubles. Economic laws are often, at bottom, the outcome of physiological laws and conditions. Assuredly, laws of nature are fundamental, and must largely underlie even economic laws; the latter may be modified but are not necessarily altered by artificial social relations. Here, then, is briefly traced the line in which the physician's knowledge and experience can throw some helpful side-light upon many of the questions of the day. By recognizing and enter-

¹ Annual address delivered at St. Luke's Hospital, South Bethlehem, Pa., on St. Luke's Day.

ing into this larger sphere the profession can take its true commanding position in the community at large.

In like manner should the work of the hospital be planned to meet the widest requirements of the community and the profession. A hospital may be rightly considered as a place to study the nature and course of disease and the most approved methods of cure. Many other interesting questions, however, confront one in such a service. What have been the life conditions of the patients before entrance that have led them to need hospital care, and what becomes of them when they leave the institution? How are they to be handicapped in the struggle for subsistence as a result of disease or injury? How far are preventable social or hygienic influences responsible for their illness? What part does ignorance, or poverty, or evil habits, or simple misfortune play in causing their condition? These and similar questions may well be thought of in studying the collection of sick and unfortunate that are housed together in a hospital. An attempt was made by me a few years ago to study a group of cases that came in my service at the babies' wards of the New York Post-Graduate Hospital, somewhat after this manner. Endeavor was made to find out as nearly as possible the environment and life conditions of these little children on entrance. The study of children is simplified by being divested of many confusing factors which enter into the investigation of adult misfortune.

Of the 600 cases considered, 322 were males and 278 females. The ages ranged from one week to four years, the large majority being under two years. Inquiries were made in regard to certain social facts about the parents, as throwing light upon the past and future lives of the children. Twenty-two different races and nationalities were represented in the families, the three highest being the Irish, 70; the German, 110; and the American, 250, most of the latter, however, being of Irish descent. Of the fathers, 490 were living and 110 dead. Among the living fathers, 245 were healthy and 113 were unhealthy, while the physical condition of 132 was unknown. Of the mothers, 556 were living and 44 dead; 298 were healthy, 75 were diseased, and no satisfactory information could be procured about the health of 227. The parents were unmarried in 25 cases, unknown in 51, and in the remaining 524 cases claimed to be married. In 114 cases the wives had been deserted by their husbands, leaving them with families of little children and without means of support. The common history appeared to be that the man, unable to get steady work, either through fault or misfortune, after spending much of his time at a saloon, would suddenly leave for parts unknown. In such cases drinking habits are both a cause and an effect of misfortune. Among 200 cases in which direct inquiry was made, 14 were drunkards, 140 claimed to drink in moderation, 31 were abstainers, and the habits of 15 were unknown. In a few cases, husbands had been deserted by their wives. In many the poverty was extreme, as might be expected from the disinclination of even the poorest classes to leave an infant or very young child in a hospital. Endeavor was made to find out the earning capacity and resources of the families. In 88 cases the fathers were out of work, in 176 cases the mothers as well as the fathers were obliged to work, while in 107 cases the mothers were the sole bread-winners. The combined earning capacities of the families were, in 150 cases, between five and ten dollars per week; and in 117 cases five dollars or less per week. In many of the latter cases a father and mother with several children were obliged to subsist on a weekly income of from three to four dollars. In 248 cases the weekly earnings were reported to be very small, the exact amount being variable or unknown. In only 85

cases was the earning capacity of the family more than ten dollars per week. These statistics were collected during 1891 and 1892, and hence do not represent the present hard times. They show the usual and chronic condition of many people in average times.

The number of other children in the families from which these little ones came was as follows: No other children in 125 families; one in 148; two in 92; three in 63; four in 38; five in 31; six in 10; seven or more in 14; number unknown in 79. This is not so large a showing as one would expect. Of 200 families, 82 were Roman Catholics, 76 Protestants, 17 Jewish, and 25 were of no religion.

Coming now to the children themselves, the condition at birth was reported to be good in 508 cases, bad in 20 cases, only fair in 12 cases, in 60 unknown. This brings out an exceedingly important point, namely, that the troubles of a large proportion of these infants were acquired and not hereditary. While a tendency to constitutional disease may be inherited, it is the bad surroundings and faulty conditions of life that powerfully predispose to illness. Environment is often stronger than heredity in this, as in many other factors in early life. Poverty and ignorance kill and cripple more than disease germs, or, rather, these malign conditions furnish a fruitful soil for the attraction and development of all kinds of specific poisons.

One of the greatest evils of charitable and philanthropic work is what may be called its segmental character. Results are too often temporary, rather than permanent, from a lack of proper conception and co-operation in the factors aiming at relief. One cannot help noticing how this humanitarian age is abundantly equipped with asylums, almshouses, reformatories, and hospitals of all kinds. If the good accomplished by such agencies could be measured solely by relief of suffering and cure of disease, the results would be nothing but gratifying. A collateral danger consists in the simple temporary alleviation which keeps alive sickly and defective classes, who are often as prolific as they are inefficient. What is urgently needed are homes or retreats, where poor convalescent patients can recuperate after their discharge from the hospital. As it is, such people, in a weakened condition, have no place to seek the needed rest, and either fall victims again to a former disease or become chronic invalids. Here would seem to be a more fruitful field for philanthropy than the building of additional hospitals. By aiming to counteract the evil effects of illness, as well as preventing the causes, we are in the line of permanent results. Municipal governments annually devote large sums of money for the care of the sick, the criminal, and the insane, but devote no energy to investigating and striving to prevent the factors that are constantly at work in producing these classes. Here, if ever, an ounce of prevention is equal to many pounds of cure. In making such an appeal for a broadening of the sphere of hospital effort, it is not intended that there shall be any lessening of the zeal for scientific medical research. As any work tends to compass life in all its relations, each department will be stimulated to do its best, in order to contribute to the common result.

There is a feeling in some quarters that there is a tendency to an unnecessary multiplication of hospitals, as of colleges. Perhaps, if there were fewer, they would be better equipped for their work. Reference is here made more especially to populous communities, where there is little danger of any one suffering for want of hospital care. In such communities, however, most of the hospitals suffer for want of complete equipment for their work. For instance, no splendid architecture or imposing dimensions will make up for the lack of a complete and well-manned laboratory. Most of the advanced scientific work of the hospital

must be done in the latter place. The mere collection of statistics of cases from clinical observation has about served its uses in medical advance. The combination of careful clinical study with accurate bacteriological and pathological observations in the laboratory is now necessary to obtain substantial results. Where this method is pursued more generally, we shall have less "hearsay" in medicine and advance will be in more rapid strides. If all the great hospitals would utilize their vast clinical resources in this way, scientific medicine would be a great gainer. Unfortunately, a laboratory does not appeal to the wealthy governors and patrons of hospitals in the same way as an endowed bed, a gorgeously decorated ward, or even an imposing tower. A laboratory, to do good service, should have a sufficient endowment to attract and keep the best men in its service. They need to be men of special aptitude and training, who should be paid living salaries for giving up their time to this important and exhausting, but not lucrative, work.

In further reference to hospital equipment, there is a deplorable lack, in large as well as small communities, of suitable places to attend contagious diseases of all kinds. These cases are refused admittance to children's as well as general hospitals, and epidemics spread through communities that could often be prevented if there were facilities for collecting the first few cases in one place, and thus stamping out the infection. The nature of these diseases is now pretty well understood, and if there were suitably equipped places for taking patients who cannot be properly isolated and treated at home, widespread suffering would be avoided. The Empress Frederic Children's Hospital, at Berlin, besides the usual medical and surgical services, has separate pavilions for the treatment of scarlatina, diphtheria, measles, and even for whooping-cough. No harm ever comes from the comparative continuity of these pavilions, as all needful precautions are taken. The large class of people living in hotels, boarding-houses, or small apartments is often in sore straits when visited by contagious disease. Such are fortunate if they escape with great inconvenience and possibly pecuniary extortion, but the innocent people following them may likewise suffer. One form of grave contagion is singularly neglected. I refer to ophthalmia neonatorum. These patients require constant and skilful treatment from the first, failing in which the eyesight is hopelessly lost in a large proportion of cases. There is no place to send these children if the parents lack the intelligence or means to command the proper treatment. Children's hospitals, and even most eye hospitals, will not or cannot take them. According to the last census, there are over fifty thousand blind persons in the United States. A conservative estimate places twenty per cent. of this blindness as due to ophthalmia neonatorum. In other words, ten thousand people are blind from shortly after birth, a large proportion of whom could have escaped this awful infliction if proper nursing and treatment had been available.

While the work of the hospital should be broadened out as much as possible to meet all the needs of the community, it must not be forgotten that the profession has peculiar claims for consideration. There can certainly be a more thorough utilization of the work of the hospital for the good of the profession. This may include not only a systematic and scientific study of disease, as hinted previously, but enlarged facilities for teaching and demonstrating any facts or conclusions that may be reached as a result of such research. The hospital should be a sort of Mecca for physicians, where public clinics and free discussion will be offered to all who come. A hospital that does not include teaching in its routine falls very far short of its duty and opportunities, not only to the profession, but in-

directly to the public as well. Again, why cannot some, at least, of the wards of a hospital be utilized by the general profession in the treatment of their cases? It would be a great help if a hospital, in any community, would set aside a special ward for any reputable physician to attend a case specially needing hospital care. Certain facilities for operations might also be afforded, under proper conditions and safeguards.

Finally, a more thorough co-operation between the hospital and the profession at large, in the advance of humanitarian work, cannot but have good results. As the conception of professional opportunity widens, it will be beneficially reflected upon the hospital. The fact that a broadening of professional ideals and opportunity is in the air has already been touched upon in this address. It should be encouraged by all well-wishers of humanity. There are great possibilities for good in this direction. As body and mind and spirit are so closely blended, the two latter depending much for their best activity upon material health, the mere physician may become as well a mental and moral healer. The old Egyptian idea of combining priest and physician was not without its advantages.

ACUTE CATARRHAL SALPINGITIS; ITS RESEMBLANCE TO APPENDICITIS; DIFFERENTIAL DIAGNOSIS; TREATMENT.¹

By HIRAM N. VINEBERG, M.D.,

ATTENDING GYNECOLOGIST TO ST. MARK'S HOSPITAL, MOUNT SINAI HOSPITAL DISPENSARY, AND MONTEFIORE HOME FOR CHRONIC INVALIDS.

My object in selecting this subject is based on the circumstance that there is very little relating to it to be found in the books, and what there is so meagre as to be of little value to the one seeking information. My own knowledge was gained by hard-wrought experience, particularly in one case that puzzled me very much, as it did also an eminent surgeon and diagnostician, who saw the case with me several times in consultation.

I can think of no better way of painting a clinical picture of the disease and of demonstrating the difficulties met with in diagnosis than by narrating the histories of some of the cases that have come under my observation within the past few years.

CASE I.—Miss J— had partaken of a hearty meal, composed of herring and other articles of food difficult of digestion, at 8 P.M., on November 27, 1892. During that night she had colicky pains, radiating from the epigastrium. In the morning she took a tumblerful of Hunyadi water, which produced several watery stools during the day. Still the pain in the abdomen continued with the same severity.

I saw her November 28th, at 6 P.M. She was in bed, complaining very much of pain all over the abdomen. The abdomen was rigid, rather tender, but not distended. No special point of greater tenderness could be elicited. Pulse was 102, small and wiry; temperature, 103° F. I ordered turpentine stupes to the abdomen, and small doses of opium and spirits of chloroform internally.

November 29th, pain no better. Temperature, 101° F.; pulse, 104. I ordered castor oil, half an ounce.

November 30th, she had a large copious stool after taking the oil, and felt considerably relieved. She had much pain all of this day. Temperature, 100° F.; pulse, 116; abdomen slightly distended. A bimanual examination per vaginam and rectum was rather unsatisfactory, owing to the rigidity and tenderness of the abdomen. No mass could be felt at either side of

¹ Read before the Manhattan Medical and Surgical Society, September 19, 1896.

the uterus, nor any mass or marked tenderness in the area of McBurney's point.

December 1st, temperature, 102° F.; pulse, 120. Pain was most severe in right lower quadrant of the abdomen. This area of the abdomen was more tender than the remaining parts, but no one point showed greater sensitiveness than the other. Certainly McBurney's point was no more tender than numerous other areas. A bimanual examination showed a torn cervix (patient had a premature delivery at the sixth month, some months before) and the uterus in forward position and freely movable. There was moderate sensitiveness over the right tube and ovary, and the tube seemed slightly thickened. But the elongated mass, about the size of one's finger, might just as well have been regarded as a prolapsed and adherent vermiform appendix. She was seen now in consultation by Dr. F. Lange. The diagnosis was considered to lie between appendicitis and salpingitis of the right tube. There being no urgent symptoms and the diagnosis being uncertain, it was decided to continue with the palliative treatment and rest in bed.

December 3d, temperature had ranged from 99.3° to 100.5° F. The menses set in in the morning and were unattended by pain.

December 8th, temperature, 99° to 100.3° F. She had been having more or less pain, which, however, was kept in abeyance by small doses of opium regularly administered. She was flowing, the flow being more profuse than was usual with her. On bimanual examination some fulness in Douglas' space was made out. This fulness extended somewhat to the right of the uterus.

December 22d, temperature had ranged from 99° to 100° F. Patient was still in bed, and was not free from pain when the opium was discontinued. She was seen again by Dr. Lange in consultation. A diagnosis could not be made with any greater degree of certainty. Dr. Lange was more inclined to the diagnosis of appendicitis, while I was more in favor of right-sided salpingitis.

January 8, 1893, the patient was allowed out of bed for the first time. Temperature had ranged from 99° to 99.8° F. She could not stand up erect, on account of pain in the right side of the abdomen. No mass was to be felt through the abdominal wall. On bimanual examination an elongated mass, resembling a thickened tube, could be felt pretty high in the pelvis, and apparently running from the right horn of the uterus.

January 14th, latterly the patient had been having higher temperature, 100° to 101° F. (rectum). She had been flowing about ten days and rather profusely. She was not entirely free from pain. It was decided by Dr. Lange and myself to make a thorough examination under narcosis. Accordingly, the patient was narcotized and an examination made. We made out the same mass on the right side of the uterus, but thought it rather high up in the abdomen for a thickened tube. Still, we could not be certain whether it was a thickened appendix or an exudation about the caecum. From this on, the patient gradually improved, and on February 13th was allowed to take a walk.

May 23d, she had had slight pain at times on exertion; otherwise she was in good health. The right tube could be distinctly felt, the size of a lead pencil. The uterus was in good position. The patient was under my observation until a year ago. She had remained perfectly well, entirely free from pain and menstrual disorders.

CASE II.—This patient, a relative, was living in the same house as the writer, and consequently was very closely observed. She was twenty-eight years of age, had been married five years, and had had two

children. Four years ago she had a premature delivery, and after this some fever lasting about ten days, the cause of which was doubtful. There were no exudations in the pelvis and no fetid lochia, and, as the patient was in excellent general condition, it was assumed that she had a slight attack of puerperal sapraemia. She had to be catheterized for some days after delivery, and, as a result of carelessness on the part of the nurse, she developed a moderately severe cystitis, and several weeks elapsed before it disappeared entirely. She made a good recovery, however, and was in the enjoyment of good health until December 17, 1893, when she was suddenly seized with pain in the left hypochondrium and vomiting. I saw her at 8 P.M. The abdomen was then flaccid. No points of tenderness could be felt at any point. Temperature, 99° F.; pulse, 90.

December 18th, she had pain all night and several chills. The abdomen was moderately distended and universally tender. On bimanual examination per rectum and vaginam, I thought that I could feel an ill-defined mass near the left horn of the uterus; but the abdomen was so tender and rigid that a satisfactory examination was impossible. Temperature, 103° F.; pulse, 130. 9 P.M., temperature, 103.3° F.; pulse, 132, small and wiry. Midnight, temperature, 103° F.; pulse, 144. The patient was very restless. If the pain were on the right side instead of on the left, the suspicion of appendicitis would be very strong. The diagnosis of left salpingitis with general peritonitis was made.

December 19th, 8 A.M., temperature, 100° F.; pulse, 108. 11 A.M., temperature, 103° F.; pulse, 132. 5 P.M., temperature, 104° F.; pulse, 132. She was seen by Dr. Lange in consultation, who, after a careful and thorough examination, could not make a definite diagnosis. The pain being situated in the left hypochondrium, and thinking he could make out some enlargement of the left kidney, Dr. Lange suspected supuration in the pelvis of the left kidney. Though recognizing the obscurity of the case, the writer still adhered to the diagnosis of salpingitis. The abdomen was greatly distended, and a bimanual examination was unreliable in the extreme. Opium in small doses was ordered, and cold water compresses were applied to the abdomen.

December 21st, temperature had ranged from 100.4° to 104° F.; pulse, 108 to 132. During the last twelve hours the pain had moderated and the distention of the abdomen had gone down considerably. From this on, the patient gradually convalesced, and in the course of three weeks was able to leave her bed. When the abdomen again became quite flaccid, on bimanual examination the left tube was found to be of the thickness of one's little finger. A prolonged course of treatment with ichthyol, hot baths, pelvic massage, and bipolar vaginal faradization has cured the patient to the extent that she is free from pain, except after some unusual exertion. The tube now is about the thickness of a lead pencil and is but very slightly sensitive. The right tube and ovary are normal. The patient has since gone through a gestation, which was normal in every respect, and has been well since, a period of seven months.

The next case, though strictly not belonging to the disease under consideration, affords another striking example of how a general peritonitis, in some obscure way depending upon the generative organs, can be mistaken for an acute appendicitis. I will give the case in briefest outlines, as it is my intention to write of it more fully on another occasion.

CASE III.—Mrs. G—, about twenty-four years old, married eight months, and pregnant seven and one-half calendar months, had been in the enjoyment of the best of health until the night of August 19th of

this year, when she awoke about midnight, with a slight chill and general pains all over the body. I saw her on the next morning, when she had a temperature of 100.4° F., and pulse of 90. Her tongue was clean and general condition good. A thorough examination of all the organs was attended with negative results. There were indefinite and vague pains in the lower part of the left chest and left side of abdomen, which were called forth only on movement; there were also superficial tenderness over various parts of the chest, back, and abdomen. The bowels had been moving regularly every day. The general impression gained was that the patient had a slight rheumatic attack, affecting the muscles of the chest, back, and abdomen.

August 20th, condition about the same. Temperature, 101° F.; pulse, 116.

August 21st, temperature, 100° to 101° F.; pulse, 120. She vomited once or twice, which she attributed to medicine taken. There was slight distention of the abdomen; she complained more of pain in the right side of the abdomen and in the right hypochondriac and umbilical regions. I was beginning to feel uneasy about her condition, particularly on account of the disproportion between the pulse and the temperature. Abdominal and vaginal examinations resulted negatively; I could not make a diagnosis. The probabilities that occurred to me were:

1. Faecal impaction. Still, she had been having daily stools, and for the past two days had had enemata, with good results.

2. An abnormal incipient typhoid; but there was no splenic enlargement, and the pulse is usually comparatively slow in that disease.

3. Peritonitis from an unknown cause.

The urine had been frequently examined during her gestation, and had been found normal. The same result was now obtained.

August 22d, 10 A.M., temperature, 101° F.; pulse, 120. The tongue was beginning to show slight coating. She had another chill during the night; the abdomen was moderately distended and universally tender on pressure. I asked for a consultation. An able general diagnostician was called in at 1:30 P.M. He diagnosed acute appendicitis, and urged operative interference in the event of the symptoms growing more severe. Though I had not thought of this condition, I must confess that the diagnosis grew upon me, particularly as the symptoms for the next seven or eight hours seemed to point in that direction, the pain now being chiefly located in the right side of the abdomen, between the border of the ribs and the crest of the ilium, over which area the tenderness was the greatest. Temperature went up to 102.4° F.; pulse, 130. The patient was very fidgety and restless when not under the influence of morphine. She was seen at 9 P.M. by a prominent surgeon, who thought he could feel a mass in the right flank and was certain of the presence of pus. He advised immediate operation. At 10 P.M. I performed lateral laparotomy, the patient lying on her left side. The ascending colon was found very much distended; the peritoneal covering was deeply injected and of a dark bluish color. Some thin membranous adhesions of the peritoneum were found. The colon was carefully followed down until the appendix was reached, and it was drawn into the incision. It was found to be quite normal, and was consequently left intact. I passed my two fingers into the incision, and palpated in every direction as far as I could reach. Nothing abnormal was detected. Of course, with the enormous uterus in the way, the exploration with the fingers was limited and imperfect. The abdomen was then closed. The patient rallied nicely from the operation, and excepting for a few hours during the next twenty-four her condition was fairly good. But from then on, the abdominal distention grew more and

more intense, and regurgitation of the liquids taken (so ominous a sign in peritonitis) set in.

On the morning of August 25th, sixty hours after the laparotomy, I began to induce labor by passing a bougie into the uterus. I waited for thirty-six hours, during which time I made use of means, such as hot douches, etc., to hasten dilatation. Slight labor pains set in, and the os dilated to the size of a fifty-cent piece. The patient's condition was now very critical; the abdominal distention was enormous, the uterus was crowded over to the left side by the distended bowels, and the breathing was perceptibly interfered with. Though keenly alive to the risks of employing manual dilatation and extraction, further delay could not be entertained.

Accordingly, on August 26th, at 9 P.M., I rapidly dilated the uterus and extracted a female child, first doing a version. The patient came near dying on the table from the narcosis, though the chloroform was administered by a skilful and experienced anaesthetizer. The whole operation did not consume more than twenty-five minutes. The uterus was irrigated, and there was but a very slight loss of blood. During the following twenty-four hours, though the distention was decidedly less immediately after emptying the uterus, her general condition was worse: pulse and temperature were going up, and the distention was increasing.

At 6 P.M., August 27th, twenty-one hours after the delivery, I gave up all hopes of the patient's recovery. The temperature was 104.8° F.; pulse, 170 to 180, small and weak; and abdomen very much distended. Having observed the marked beneficial effect of opiates all through the illness and the futility of other medication, I decided, as a *dernier ressort*, to bring her fully under their influence. She was accordingly given larger doses of morphine hypodermically and opium by the rectum. At midnight she fell into a deep sleep, and when roused up at 2 A.M. her temperature had fallen to 102.4° F. and pulse to 140. She was at this time seen by a consultant, a well-known surgeon, who still thought the case hopeless. From this on, however, her improvement under the treatment of opiates and enemata was gradual but certain, and she has now been sitting up out of bed for a few days.

I might cite several other cases, but those narrated will sufficiently serve the aim in view. I fully recognize that the crucial test—a laparotomy—in the diagnosis of Case I. is absent. Be that as it may, the case loses nothing in value through that circumstance in accentuating the point I wish to bring out prominently in this paper. Here was a patient who, after an indiscretion in diet, was suddenly seized with pain in the right side of the abdomen. This was followed by fever and symptoms of general peritonitis. Repeated examinations by the writer and by a surgeon known for his skill as a diagnostician and for his vast experience do not determine satisfactorily whether it be appendicitis or salpingitis. Even an examination under narcosis, after the patient had been under close and careful observation for weeks, does not remove the uncertainty in diagnosis.

There can be no reasonable doubt in the diagnosis in Case II. Had it been the right instead of the left tube that was affected, I fear the patient would have been subjected to an operation for appendicitis.

The events in Case III. speak for themselves. Three facts are fully substantiated: 1. The insidious and misleading onset of the affection. 2. The presence of general peritonitis. 3. The absence of appendicitis as a cause of the peritonitis.

We have seen, in the cases reported, that the onset may be sudden and without any apparent cause. But on close scrutiny it was learned that the first two patients had suffered from a uterine discharge—in other

words, from a uterine catarrh—and which, whether it be specific or non-specific, is liable at any time to cause a salpingitis or oöphoritis by extension. Another very common cause of salpingitis is the introduction of instruments within the uterine cavity in the absence of the strictest antiseptic and aseptic precautions. And here it may not be amiss to sound a note of warning against the dangerous procedure recently recommended, of following a curettage for the treatment of an endometritis by daily intra-uterine douches for a week or longer. Intra-uterine douches without very thorough dilatation of the uterus are fraught with great risk, even when every precaution has been taken in regard to cleanliness. But to recommend such a procedure to the general profession, without laying great stress upon the details for carrying out the most thorough surgical cleanliness, is culpable neglect, and shows a lack of sense of the responsibility a writer assumes when he recommends to the profession at large intra-uterine therapeutics. Many a woman has been rendered an invalid for life by the heretofore frequent resort to the sound to ascertain the position of the uterus or the depth of its cavity; and should the advice be generally followed of giving intra-uterine douches for the treatment of an endometritis, many a woman will have grafted upon her a serious pelvic lesion in the effort to cure her of her uterine catarrh. Numerous other causes capable of giving rise to an acute salpingitis might be mentioned, such as exposure to cold during menstruation (a very doubtful cause in my mind, unless there be some pre-existing lesion), extension of infection through the lymphatics, traumatism, and so on. But the first two mentioned are the most important.

We have also seen that an acute salpingitis may be attended with a diffuse peritonitis, differing in no respect from that accompanying an acute appendicitis; and should the tubal lesion be situated on the right side, the solution of the problem of differential diagnosis is difficult in the extreme.

Of course, on paper the solution can be made to appear easy. In the one case, you have tenderness over a certain well-defined area, known now the civilized world over as McBurney's point; in the other, all you have to do is to make a bimanual examination, and you find a thickened and sensitive tube passing from one horn of the uterus. But at the bedside things are not cut and dried for us in this simple manner. It is no easy matter to determine always which is the most sensitive spot in an abdomen that is universally distended and tender, and it is next to an impossibility to palpate a slightly thickened tube when you have a rigid and an extremely sensitive abdomen. The following points the writer has been able to glean from his experience and observation. In appendicitis, the pain is frequently more excruciating than in salpingitis, and is more likely to be limited to the abdomen. It does not usually radiate to such an extent as the pain arising from salpingo-oöphoritis. When the ovary is involved with the tube, as it frequently is, the pain commonly descends the corresponding thigh. Gastric disturbances are common to both. In salpingitis, the very alarming symptoms usually subside to some extent in the course of three or four days; in appendicitis, they may continue or grow more severe. Certainly, it must be our aim to make a diagnosis before the lapse of three or four days; but, if the case be a doubtful one, and no very urgent symptoms are pressing, we can afford to wait that period of time in a suspected case of catarrhal appendicitis. In other cases, when the symptoms are severe, an examination should be made under full narcosis. Even this may not always be decisive, as we have learned in our first case. Still, in the majority of cases, such an examination would be attended with positive results.

The question may be pertinently asked, What good is there to be gained from making a positive diagnosis? If the symptoms are severe, would you not operate in either case? But the answer is that it is just in the matter of treatment wherein lies the importance and value of differential diagnosis. Without entering into any discussion as to the question of operative interference in acute appendicitis, I think the statement may be safely made that the consensus of opinion is in favor of such interference in a large percentage of the cases. But, on the other hand, operative interference is contraindicated, at least in my opinion, in catarrhal salpingitis in the acute stage during the first attack. Further still, it may never be called for, as we have seen that, for all intents and purposes, the patient may be cured after such an attack.

I desire to reaffirm that it is only the non-purulent variety of salpingitis that engages my attention in this article. Whether it be always possible to differentiate clinically between catarrhal salpingitis and pyosalpinx, is a question I do not care to raise here. Suffice it to say that in the vast majority of the cases such a differential diagnosis is possible through an analysis of the subjective and objective signs. Even in pyosalpinx it is certainly wise and feasible, in a large percentage of the cases, to wait until the acute symptoms have subsided before resorting to surgical intervention.

Having reached a diagnosis of acute catarrhal salpingitis, the treatment should consist of absolute rest in bed, opium per rectum to alleviate the pain and subdue the peritonitis, daily enemata to remove contents of rectum and mildly to excite the peristalsis of the upper bowel, light nutritious diet, and ice applications to the abdomen if they be well borne; if not, the ice to be replaced by a Priessnitz compress. In the majority of cases, after the very acute symptoms have subsided, it is advisable to do a thorough curettage under narcosis. This should be performed under the strictest antiseptic and aseptic precautions and with the greatest gentleness. The curettage may be followed by packing the uterus with iodoform gauze, in the event of that organ being large and succulent. Otherwise, the packing may be dispensed with. When the curettage is of benefit, it is so, in my opinion, from its destroying the *fons et origo* of the disease, and not from the much-talked-of drainage. It is so seldom that the contents of an acutely inflamed tube can drain into the uterus that such a contingency may be entirely ignored in the therapeutics of that condition. If you can destroy the source from which further infection may come, the tendency of the natural powers is toward a cure, if certain favorable conditions be maintained. And these are, as already stated, absolute rest in bed, comparative rest of the tissues immediately in contact with the inflamed structures induced by the free administration of opium, and the avoidance of sexual excitement. Even at the risk of repeating myself, I wish to lay great stress upon the importance of prolonged rest in bed—and it is well to tell the patient at the outset, that if she desires to give herself the best chances of a permanent cure she must be willing to remain in bed four, five, or six weeks, and longer if the condition demands it. She ought to remain in the horizontal position as long as there is the slightest elevation of temperature, and as long as there is marked sensitiveness on pressure over the affected tube. Then, for a period of some weeks, she ought to remain comparatively quiet, walking about in the room, but not going up or down stairs, and lying down for an hour in the forenoon and a couple of hours in the afternoon.

By following such a course, one may expect, in a fair number of cases, a permanent cure, if this term may be applied to a condition of freedom from symp-

toms for a period extending over three or four years (my own experience). The tube remains somewhat thickened, and in many cases, no doubt, is sealed at the abdominal end; but it is not sensitive, and is no cause of discomfort to the patient. In other cases, when this course of prolonged rest has not been followed, and in some cases in spite of it, the patient gets apparently well, but only for a short time. Every now and then, after some unusual exertion or exposure to cold, or without any apparent cause, she suffers from pain on the affected side, and may or may not have some elevation of temperature. These seizures are evidences of fresh attacks of inflammation, constituting recurrent salpingitis—another point of resemblance to appendicitis. If these attacks are allowed to recur, it will not be long before the patient will begin to suffer from pain on the opposite side and the disease become bilateral. Of course, it may be bilateral at the very beginning; but, in the majority of my cases, the disease at the commencement was limited to the one side. In my opinion, recurrent attacks after the patient had been subjected to proper treatment call for surgical interference; and now the sooner the diseased tube is removed the better. Just as emphatic as I was before in non-interference, I am equally emphatic now in active intervention, and to my mind the latter course under the changed condition is as strongly conservative as the former one. Nowadays one hears a great deal about conservatism in gynecological affections. This conservatism means different things to different men. With some it means a dallying course until both appendages are hopelessly involved, then doing an operation for their removal and leaving the useless uterus behind. These men are inclined to designate that operator as radical and extremist who, on finding the same conditions, removes the uterus also. The one plan of procedure has just as little genuine conservatism in it as the other.

To my way of thinking, however, true conservatism consists in actively attacking diseased structures as soon as it has been learned that proper palliative treatment has no influence in checking the progress or the recurrence of the pathological lesion. In adopting such a course of action, we are frequently enabled to conserve to the woman at least the tube and ovary on the one side, which will carry on the function of generation just as well as both appendages would.

I can cite many pregnant examples of this within my own experience—one typical of many others will, perhaps, suffice. A young married woman came to me about three years ago, with a gonorrhœal endometritis, which she had shortly before contracted from her husband. She had given birth to her first child some months before. The affection in a short time involved the right tube and ovary. She was curetted and kept in bed for several weeks, under the course of treatment outlined in this paper. There was an apparent cure; the pain had disappeared; the tube and ovary, which formerly had formed a mass about the size of a hen's egg, had gone down to almost normal dimensions. In about three months she had a recurrence of the pain in the right iliac region, and on examination the tube and ovary were found again to be about the size of a hen's egg. Rest in bed for a time was followed by the disappearance of the mass and the pain. During the following fifteen months she had several similar attacks, during the last of which she began to suffer with pain in the left side also. The left tube was now for the first time found to be sensitive on pressure, though not appreciably thickened. I decided not to wait any longer. "Accordingly, on June 6, 1895, at St. Elizabeth Hospital, I performed vaginal section, first delivering the left appendage. The

ovary contained a couple of cysts, which were punctured. The peritoneal covering of the tube was considerably injected, but the fimbriæ were apparently normal. Both tube and ovary were then returned into the peritoneal cavity. The right appendage was delivered with considerable difficulty, owing to the presence of dense and rather extensive adhesions. Tube and ovary were ablated in the usual way. On examination afterward, the tube was found to be the thickness of my thumb, club-shaped, and filled with thick pus, the ovary being completely disorganized by cystic degeneration. The patient made an uneventful recovery and left the hospital on June 23d, seventeen days after the operation. She has remained perfectly well ever since.¹ There is no doubt in my mind that had I waited much longer in the foregoing case, the left appendage would also have become irretrievably damaged."²

The reason that conservative surgical work in female pelvic affections is so often unsatisfactory is that frequently when the woman comes to the operating-table the time has long been past for such a plan of action. My own experience with conservative surgery during the past four years, in patients whom I had under observation during the early stages of the pelvic lesion, has been gratifying in the extreme, and there is no class of cases in my recollection that gives me greater satisfaction than just those in which I feel morally certain that by timely intervention I was enabled to conserve to the woman the tube and ovary on the one side, and in many cases part of the tube and ovary on the affected side. These women have remained free not only from their former pains and attacks of fever, but have been freed from a menace to their remaining generative organs, and in some instances to life itself.

I will briefly cite one more case, in support of the assertion that what at first was evidently a simple salpingitis may prove a menace to life, and I have done. The wife of a physician had some trouble with the left tube and ovary, giving her frequent attacks of pain. She consulted some authorities here and in Germany, all of whom advised her not to have anything done, and not even to allow herself to be examined. She followed this advice for three years, during which time she had several slight attacks, laying her up from a few hours to part of a day. Some months ago she had a more severe attack than usual, and when I saw her she had been in bed for four days, with fever and pain in the lower part of the abdomen. A superficial bimanual examination revealed to the left of the uterus a hard mass of the size of a closed fist. For the next few days her symptoms improved. Then suddenly, after a slight chill, her temperature began to go up, and reached 105.2° F.; pulse, 150, small and thready; and her condition for several hours was one of partial collapse. She rallied from this, and was operated upon the day following by a vaginal incision, which gave exit to a large quantity of pus. Since then, I am informed, she has been operated upon several times to give exit to other collections of pus on the right side, and that she is still an invalid. Comment is unnecessary.

While penning this article, a prominent gynecologist told me of a very unfortunate experience he had recently had, bearing on this question. It occurred, also, in the case of a physician's wife. He had examined her and found a slightly thickened tube and ovary, and advised non-interference. Some hours afterward she was seized with symptoms of collapse. He was sent for, but was not at home. Another gynecologist was called, who opened the abdomen and found free pus in the peritoneal cavity, coming from

¹ September, 1895.

² American Medico-Surgical Bulletin, May 7, 1896.

a ruptured pyosalpinx. The patient died of septic peritonitis.

It would appear that these untoward events are prone to occur in physicians' families. This is, no doubt, from the circumstance that, the subjects being the relatives of physicians, the operator displays more timidity and so-called conservatism than he otherwise would. It might be wise for a physician, in case of illness in his family, to repeat Napoleon's famous answer to the attending physician, who consulted him as to the advisability of following a certain course of treatment. Napoleon replied: "Follow the same line of treatment in the case of the empress as you would in the case of a cobbler's wife."

GONORRHOEA IN WOMEN.¹

BY BERNARD GORDON, M.D.,

VISITING GYNECOLOGIST TO BETH ISRAEL HOSPITAL AND DISPENSARY, NEW YORK, ETC.

GONORRHOEA is such a frequent disease in women that it comes not only to the hands of the specialist of venereal diseases and to the gynecologist, but comes also abundantly to the hands of the general practitioner. Nevertheless, gonorrhœal infection in women finds very little space in our gynecological works. Neither Hart and Barbour, Lawson Tait, Fritsch, Schroeder, Chrobak, Hegar, Kaltenbach and Olshausen give any place to it; nor Zweifel, Winkel, Breisky, Thomas and Mundé ("An American Text-book of Gynecology"), Garrigues, Keating and Coe, Pozzi give any importance to this, one of the most frequent diseases. The following statistics will give you an idea of the wide spread of this infection in women. Noeggerath, for instance, mentioned once with enthusiasm that 80 per cent. (?) of all women treated by him had gonorrhœa. Oppenheimer found (in 1884), out of 108 pregnant women, 30 with gonorrhœa, *i.e.*, 27.7 per cent. Schwarz (in 1886) proved that out of 617 women, 112 had suspicious symptoms of gonorrhœa, of which 77 had the gonococcus of Neisser, *i.e.*, positively 12.4 per cent. Saenger considers that 12 per cent. of all our female patients are suffering from gonorrhœal infection; but, in my opinion, Schwarz's statistics of 12.4 per cent. should be considered the very minimum frequency of the disease, because, if he would have employed the present methods of examination for the gonococcus, he would have undoubtedly found the disease in a great many more of his suspicious cases.

Our gynecologists have devoted separate chapters to dysmenorrhœa, amenorrhœa, sterility, and many other symptoms, which are not diseases, but symptoms, and have neglected to give the proper place to this, one of the most common diseases; therefore, I selected this subject in order to give to the profession the missing chapter in the text-books on gynecology.

Etiology.—Neisser discovered the micrococcus which is the exciting cause of gonorrhœa in 1879, and proved that not only the gonorrhœal catarrhs of the mucous membranes were caused by gonococci, but also the inflammations coincident with gonorrhœa; also the suppuration of lymphatic glands, the parametric infiltrations, the perimetritic inflammations, the parenchymatous thickening of the tubes, the suppuration of the ovaries may depend entirely upon the activity of Neisser's gonococci. They are comparatively large, somewhat oval micrococci, which seldom appear singly, usually in twos, closely adjacent to each other, easily separable, constantly forming groups, but never chains; found in the free fluid or oftener found upon the pus cells and epithelia. By this description they

can be differentiated from many other micrococci. According to Bumm, the most positive sign for recognizing the gonococci is in the fact that they penetrate into the epithelial and pus cells, and multiply until the cells fall to pieces and the gonococci remain in round-shaped groups. The virulence of gonorrhœa depends upon the number and vitality of the gonococci.

Gonorrhœa is always contracted in the acute form; even the infection from a chronic case produces acute gonorrhœa, and when the infection is retransmitted to the chronic case it also will become acute.¹ Neisser and Wertheim made experiments by transferring gonococci from chronic cases upon patients, and produced acute gonorrhœa. Delicate and thin epithelium is predisposed to the infection. That is the reason for the more frequent and more serious affection of blondes and generally delicate women, pregnant women, girls, etc. The disease is usually transmitted through sexual intercourse, but can also be transmitted by cloths, linen, baths, and, according to Suchard,² even through bathing in a stream. He describes an epidemic of twelve cases, caused by bathing together in one place of a river. Weil and Barjou (Lyon) reported³ an epidemic of gonorrhœa in a hospital where the transmitting medium was the thermometer.

Bacteriology.—Since Neisser and Wertheim have proven that the gonococcus is the only cause of gonorrhœa in any part of the genitals and even peritoneum, the most positive diagnostic proof of gonorrhœa is the demonstration of the presence of the gonococcus. Although in a great many cases we are able to diagnosticate gonorrhœa clinically, still there remains a large share of them, especially those of a chronic nature, which can be recognized as gonorrhœal only by the aid of the microscope. Just as diphtheria of a seemingly malignant appearance, with very few Loeffler bacilli or none at all, will be considered a mild case of diphtheria or a simple local inflammation, so will a seemingly severe case of gonorrhœa change in our opinion to a mild one or a simple local inflammation, if the microscope should reveal very few gonococci or none at all. Microscopic examinations during the course of treatment are usually of great value, because the effect as to better or worse can be definitely determined during the course of the disease. Examination for the gonococcus is generally made microscopically. Culture methods, because of the difficulties attending their employment, are only used in exceptional cases. Although the demonstration of the gonococcus under the microscope means positive gonorrhœa, still the failure to find it is not absolutely negative, as gonococci may be so concealed in the depth of tissues, lacunæ, and folds, that the superficial secretion of a mucous membrane which is to be examined is free of gonococci. The value⁴ of the microscopical examination is especially great in cities, where hundreds of prostitutes are yearly withdrawn from their vagabond life and subjected to hospital treatment, who, without microscopical examination, would be pronounced healthy, and permitted to become from day to day the source of further infection.

Staining the Gonococcus.⁵—In cover-glass preparations made from the suspected secretions, the coccus is easily stained by watery solutions of the aniline dyes, preferably methyl blue. It is decolorized by Gram's method. Schwarz recommends staining cover-glass preparations for five to ten minutes in a saturated solution of methyl blue in five-per-cent. carbolic-acid

water; then immersing for three seconds in dilute hydric acetate five parts, water, twenty parts, and washing thoroughly in water; contrast stain in a very dilute solution of safranin. V. Kahlden recommends staining two to three minutes in an alcoholic solution of eosin, and warming. The excess of eosin is absorbed with paper, and the film is then stained for half a minute in an alcoholic solution of methyl blue. Wash in water, dry, and mount in balsam. Sections should be stained in Ziehl's solution and washed in alcohol.

Biology of the Gonococcus.—After a number of experiments for determining the best culture media, the powers of resisting temperature, and the pyogenic properties of the gonococcus, Drs. Steinschneider and Schaefer¹ conclude that:

1. The best medium is blood serum or serous fluid of man, but the serum of the ox, sheep, dog, and rabbit may be substituted, and these media cannot be dispensed with.

2. Urine agar has not proved to be a reliable medium.

3. In Wertheim's plate method, a sterile camel's-hair brush may be profitably substituted for the platinum loop, in spreading the pus over the surface of the serum-agar plates.

4. Exposure to a temperature of 40° C. for twelve hours or more not only inhibits the growth but destroys the vitality of the organism.

5. When exposed to room temperature for not too long a period, proliferation is inhibited but not destroyed.

6. When gonorrhœal pus is mixed with water or urine, gonococci may retain their vitality for one to two hours; under favorable conditions even longer.

7. When introduced into the subcutaneous connective tissue, the gonococci do not produce suppuration.

Medico-Legal Remarks.—Dr. A. Haberd (Vienna)² allowed a few drops of gonorrhœal discharge to dry upon pieces of linen, and by making thorough examinations came to the following conclusions: 1. The gonococcus could be well recognized microscopically by its form, size, and staining after many weeks, and in thickly dried drops even after eight months. 2. Culture tests were successful only twice from thick-discharge stains, which dried in from three-quarters to one and one-quarter hours. Later the plates became sterile. This experiment shows that perfectly dry discharge loses its infectious character. 3. Inoculations upon the urethra by the dry gonorrhœal discharge (after one to four hours) constantly failed.

Latent Gonorrhœa.—Noeggerath (in 1872) was the first man to describe a certain stage of gonorrhœal infection and call it latent gonorrhœa. The wife of many a man, who at any time before marriage contracted gonorrhœa, becomes affected with latent gonorrhœa, which sooner or later makes itself known through some one of the diseases I am about to describe. Wertheim only recently was enabled to give a thoroughly scientific explanation of latent gonorrhœa. He says that only young gonococci³ are recognizable, as they are stained by aniline solutions, while old gonococci lose their typical forms by becoming granular spheres, variable in size and indefinite in outline. This change occurs whenever the culture medium is exhausted and no longer nutritious. He proves this by transplanting the afore-mentioned altered forms into fresh culture media and raising typical gonococci. The logical consequence is that patients proclaimed cured when the microscope revealed no gonococci may possess them in their latent form, which can be detected only when transferred to a better soil or culture medium, when the typical gonococci are raised.

The Organs that Become Affected.—Gonorrhœa in women manifests itself by one or a few of the following affections: Vulvitis, Bartholinitis, urethritis, vaginitis,¹ metritis,² perimetritis,³ parametritis, salpingitis,⁴ oöphoritis,⁵ and peritonitis.⁶ Sometimes the disease⁷ extends from the urethra, causing gonorrhœal cystitis, ureteritis,⁸ and nephritis. Also gonorrhœal proctitis,⁹ arthritis,¹⁰ phlebitis,¹¹ endocarditis,¹² pleuritis,¹³ meningo-myelitis,¹⁴ and conjunctivitis¹⁵ are met with, although located at a great distance from the original seat of disease. Albuminuria¹⁶ is reported to be observed very frequently in the acute stage of gonorrhœa.

Vulvitis.—Vulvitis comes usually in the acute form, and passes very rapidly. It manifests itself by redness and swelling of the labia majora and minora. The parts are covered with a thick, offensive, greenish-yellow discharge.¹⁷ Itching and burning in the external genitals, especially after urination, when the urine passes over the inflamed and sensitive parts, are almost constant symptoms, although the diagnosis can become positive only when the gonococcus is found in the secretion under the microscope. Prognosis is good, if not extended to the other genital parts, as it invariably tends to spread to the adjacent mucosa, resulting in vaginitis, urethritis, cervicitis, etc.¹⁸

Treatment: Since the reports of Dr. Neisser, of Breslau,¹⁹ of the experiments in his clinic, and Dr. Friedheim²⁰ (of the same clinic), in 1890, about the great value of nitrate of silver in gonorrhœa, in solutions of 1 to 4,000 to 1 to 2,000, this drug has become the ideal and most popular remedy abroad and here. The plan described by Dr. Pryor, of New York,²¹ is much in vogue in the United States. Nitrate of silver, a solution of twenty grains to the ounce, should be painted and allowed to dry upon the vulva, meatus urinarius, clitoris, and nymphæ. The vagina should be packed with twenty-per-cent. iodoform gauze, wrung out of a 1 to 5,000 solution of bichloride of mercury. The woman should bathe the vulva every four hours with a one-half-per-cent. solution of lysol. I have been in the habit of using permanganate of potassium in solution, 1 to 5,000 to 1 to 2,000, and it is especially recommended by Klein.²² Columbini²³ recommends five to ten per cent. of ichthyol in glycerin. Abstinence from all kinds of stimulants should be insisted upon. Frequent hip baths with sea-salt dissolved in the water, and frequent sea bathing in the summer, are very beneficial. Nitrate of silver, although very popular at present in the treatment of gonorrhœa, will probably be soon displaced by either

one of the two new remedies—argentamin and argonin. They answer more to the requirements of an ideal remedy for gonorrhœa; namely, while they destroy the gonococcus and penetrate deeply into the tissues, still they do no harm to them.

Argentamin¹ (ethylendiamin-silver-phosphate solution): A colorless, alkaline liquid, turning yellow on exposure. Antiseptic and astringent, like corrosive sublimate, but not coagulating proteids. It is highly recommended by Ashner, of Budapest,² Schaeffer, of Breslau,³ and Albertazzi, of Rome,⁴ in solutions of 1 to 4,000 to 1 to 2,000. It is very similar in its effects to nitrate of silver, with a special advantage, that it does not coagulate albumin. It does not affect, therefore, the epithelium of the mucous membrane, and can permeate into the tissue and attack there the deeply seated gonococci. The following are the conclusions arrived at in experimenting with argentamin:

1. Solutions of argentamin give no precipitate in the presence of albumin and sodium chloride.

2. They penetrate deeply into the tissues without altering them.

3. A solution of argentamin, 1 to 4,000, unfertilizes a pure culture of gonococci in from five to seven minutes of contact, *i.e.*, sooner than a solution of nitrate of silver, 1 to 4,000.

4. Injections of a solution of argentamin into the urethra, even as strong as 1 to 1,000, are well tolerated. The quantity of gonorrhœal discharge increases after a few injections, but afterward gradually and rapidly disappears.

5. Usually on the sixth or seventh day the discharge is already quite thin, and you can hardly find any cells with gonococci in them. If you stop the injections when the gonococci are not found, the discharge will disappear anyhow very rapidly.

6. The treatment with argentamin can be commenced at any stage of the disease.

7. The cases are usually cured within six to fifteen days, the length of the sickness depending also upon general dietary and hygienic conditions.

Argonin: A soluble silver-casein salt. It is a fine, white powder, soluble in hot water; ammonia increases its solubility. It is a non-coagulating antiseptic, like argentamin. Argonin is strongly recommended by Jadassohn, of Breslau,⁵ R. Meyer,⁶ and Schaeffer,⁷ in 1.5 to 2 per cent. solutions. This remedy, combining the good properties of argentamin with its additional advantage of being non-irritating in character, will probably become in time the most popular antigonorrhœicum.

Bartholinitis.—Bartholinitis gonorrhœica takes one of the following three courses:

First, the entire gland may rapidly suppurate. Within three or four days a tumor forms in the labium majus, which may attain the size of a child's fist or even greater dimensions. The labium becomes hard and red. Treat it like a phlegmon, by incision and antiseptics.

Second, the process runs a slower course, and the inner surface of the labium becomes more prominent. In this case the secretion of the vulvitis seals the efferent channel. The secretion of the gland cannot escape from the duct, expands it, and lies at the inner surface of the posterior third of the labium majus in the shape of a cyst, the size of a hazelnut or larger.

The secretion can often be forcibly expressed. In this latter case cysts also form which persist for years without incommoding the patients. These cysts contain yellow or dark brownish fluid, and do not refill if freely opened.

Third, the chronic kind of gonorrhœic bartholinitis is the most pernicious in its consequences, the form probably leading most frequently to the infection of the male. A moderate quantity of pus continually flows from the efferent duct. This pus covers the vulva in a thin layer. It is very probable that precisely the act of coition, owing to compression of the gland by the sphincter cunni or to accidental pressure of the tip of the penis upon the gland, leads to a more copious production of the infectious secretion of the diseased gland.

Treatment depends upon circumstances. Either dilate the canal by a sound and apply antiseptics, such as argonin, argentamin, nitrate of silver, etc.; or incise, if there is an abscess. Should the glandular body be affected, extirpation becomes the most rational treatment.

Urethritis, Cystitis, and Ureteritis.—Urethritis is almost always an accompaniment of gonorrhœal vulvitis. Bumm¹ and Luczny,² for instance, find it as frequently as in ninety per cent. of all their cases of gonorrhœa. Sometimes a periurethritis is developed, and usually in such cases the Skene's glands³ become affected. The glands surround the urethra, and their canals open on either side and behind the meatus urinarius. The gonococci are peculiarly prone to linger in these openings, and often long after all trace of the disease is supposed to have disappeared one or more drops of thick, yellow pus can be squeezed out of them. The gonorrhœal process can also extend from the urethra to the bladder, ureters, and even into the pelves of the kidneys, causing death through pyelitis and pyelo-nephritis. When the patient complains of a burning sensation during and after urination, your suspicion of a gonorrhœal infection should be aroused. Introduce a finger into the vagina against the neck of the bladder and withdraw it while pressing it against the urethra, and if a purulent discharge comes out of the meatus urinarius the diagnosis of gonorrhœal urethritis is positive, as there is no other urethritis that will produce a purulent discharge.

The urethroscope or endoscope, which is easily used in the female urethra, shows that the whole canal is inflamed, and in some instances discloses the presence of small ulcers. In order that an affected urethra may be better distinguished, I will give here a description of a healthy urethra as seen in the urethroscope:⁴ 1, The mucous membrane of the canal is traversed with radial folds; 2, the urethral orifice appears in the shape of a darkish spot; 3, with regard to color, the urethral mucous membrane closely resembles the oral; 4, muciparous glands are invisible. As the scope of this paper does not permit me to give more space to urethroscopy, I take the liberty of referring you to an excellent article on "Practical Urethroscopy," by Dr. Wossildo, of Berlin, Germany, published in the MEDICAL RECORD, September 7, 1895.

Treatment: The best plan of treating the urethra is by local applications daily, either of nitrate of silver, two to five per cent. solution; argentamin, 1 to 2,000 solution; or argonin, one-per-cent. solution.

Cystitis.⁵—When a patient who is suffering from a urethral gonorrhœa complains of severe suprapubic pain, with disturbances in urination, and when on a bimanual examination you exclude the affection of

⁵ Centralblatt f. Chirurgie, March 14, 1896.

the uterus, you can make your diagnosis cystitis gonorrhœica, and your diagnosis will in all probability be correct; but you cannot be positive unless you resort to the use of the cystoscope.

A cystoscopic examination reveals pale red, irregular patches upon a healthy mucous membrane, mostly around the os urethræ. If one of the ureters is affected, an inflammatory patch can be seen surrounding its opening; the flow of urine from that opening is at much shorter intervals than from the healthy ureter.

Treatment: Wash out the bladder once daily. Pour one quart of a solution of permanganate of potassium, 1 to 2,000, into a fountain syringe; then introduce a disinfected catheter (not double current) into the bladder. After the urine has flowed out, connect the catheter with the rubber tube of the syringe and let the solution fill the bladder, until the patient states that she cannot stand it any longer. The catheter is then withdrawn, and the patient has to retain the fluid from one to three minutes. She then passes the muddy and discolored solution; or, if she is unable to pass it, she is catheterized. I have seldom seen a patient not cured within a week or twelve days by this plan. Should I meet an obstinate case of gonorrhœal cystitis, I would try argonin or argentamin.

Ureteritis, when detected cystoscopically, must not be neglected, or it may cost the patient's life. Check it immediately by a local application, by Kelly's method, of either nitrate of silver, two per cent.; argentamin, 1 to 2,000; or argonin, one per cent. The last may be the safest and most reliable gonococcicide.

Vaginitis.—Pathology: Although the pavement epithelium lining the vagina is not so easily penetrable for the gonococci, which is an established fact, and although, according to Doederlein, the acidity of the vaginal secretion depresses their vitality, still we meet a great number of cases of gonorrhœal vaginitis. These cases usually come together with vulvitis, and are called gonorrhœal vulvo-vaginitis; but we meet the affection of the vagina alone very often, especially of the posterior vaginal pouch, and also of the vaginal portion of the uterus, while no other genital part is affected. In the acute stage we find redness, swelling, œdema, erosions, swelling of the papillæ, and secretion of a serous, rapidly developing into a purulent, discharge.

Symptoms: Vaginitis is characterized by the sense of fulness and heat about the genitals, muco-purulent secretions, and slight febrile variations. Duration of the disease is from one to three weeks, and it seldom becomes chronic.

Diagnosis: The diagnosis of vaginitis is easily arrived at by the above symptoms, but the question as to its being of a gonorrhœal nature can be solved only by the microscope.

The speculum shows that the mucous membrane is inflamed and covered with a muco-purulent discharge; the redness is usually in the form of patches, but may be diffuse.

Treatment: My plan is as follows: I prescribe to the patient potassium permanganate in papers, four to seven grains in each, and order her to dissolve the crystals out of one paper in a quart of lukewarm water; then to pour the solution into a fountain syringe and make a vaginal irrigation, while lying on her back with a bed pan under her. If the patient is not ordered to be exact in this, she will very frequently make an injection in the sitting posture, which is certainly much inferior for a thorough washing of the vagina. About eight irrigations within forty-eight hours are made, and then I apply a solution of silver nitrate, thirty grains to the ounce of water, to all the inflamed surfaces through a bivalve speculum and tampon with either boro-glycerin or ichthyol-glycerin, ten per cent.,¹ on

¹ Columbini: Centralblatt f. Gyn., August 11, 1894.

absorbent cotton, or iodoform gauze, ten per cent. The patient removes the packing after twenty-four hours and continues to make injections of permanganate of potassium every six hours for two days. Then a second local application of silver nitrate is made as before. Treatment is continued on this plan until the patient needs no local applications but vaginal injections. Those are gradually diminished in frequency and strength until entirely dispensed with. For a short time I have been using a solution of argonin, two per cent., instead of the nitrate of silver, in my cases of vulvo-vaginitis.

Argentamin in solution of 1 to 1,000 as a local application will also be found more efficient than the nitrate-of-silver solution. Dr. R. T. O'Brien reports¹ a number of cases of gonorrhœa treated by means of injections of sea water. He had the injections given seven or eight times in twenty-four hours. The average duration of the disease under treatment was 8.87 days. Alumol is recommended by Chotzen, of Breslau,² as a good astringent and gonococcicide. Vaginal irrigations are made with a solution of one to two per cent.

Methyl blue, five-per-cent. solution, to moisten tampons, is said to act directly upon the bacteria in vaginitis, causing discharge and pain to cease.³

Pyoktanin and boric acid, in proportion of ten per cent. of the former, are found by Hulbert⁴ to be the most ideal and effective germicidal antiseptic yet presented for the cure of primary gonorrhœal vaginitis. After being cleansed with hot water, the cavity is freely and liberally dusted and packed with any mild antiseptic gauze to the hymen.

Uterine Gonorrhœa.—Pathology: Gonorrhœal endocervicitis is usually mild in its manifestations; the patient never suffers any pelvic lesions, because the cervical mucous membrane is dense, with few lymphatics, and drainage is readily obtained.⁵ The only and the most important danger is the tendency of the infection to spread to the endometrium. Gonorrhœal endometritis⁶ presents the pathological appearance of an interstitial inflammatory process of the mucous membrane of a purulent nature. In quite a number of cases there is an increase in the glandular supply of the mucosa, especially during a chronic course. This may be called endometritis glandularis gonorrhœica.

Gonorrhœal Metritis.—Dr. Max Madlener,⁷ of Munich, gives the following *résumé* of his investigations: Neisser's gonococcus is capable of passing from the endometrium into the muscular apparatus of the entire uterus and there setting up an inflammatory process. This inflammation may reach even to the point of abscess production. This result appears especially to occur in the puerperium. Usually the inflammation remains of moderate intensity. The gonococcus disappears quickly from the myometrium, in that it either perishes or wanders farther. By the introduction of germs into the uterine wall, even as far as the serosa, infection of the peritoneum from the endometrium with evasion of the tubes is a possibility, and in this way perimetritis in gonorrhœa without implication of the adnexa is explained. The uterus is next to the urethra in frequency of affection. Steinschneider found uterine gonorrhœa in fifty per cent. of his gonorrhœal cases, Neisser in sixty-one per cent., and Bumm in seventy-four per cent. It happens often that the uterus directly and alone becomes infected.

Symptoms: Uterine gonorrhœa usually sets in acutely. You can see through the speculum that the

¹ British Med. Journal, November 30, 1889.

⁷ Centralblatt f. Gyn., December 14, 1895.

vaginal portion is swollen, the mucous membrane tense, glistening, and red. In the external orifice of the cervix you can see the dark red congested mucous membrane. A green-yellowish, purulent discharge is flowing out of it, presenting a picture similar to the urethral gonorrhœa in man. In this discharge you will find gonococci as usual near and upon epithelial and pus cells. Uterine gonorrhœa may last from a few weeks to many months. During the second stage or subacute condition the pain, redness, and swelling gradually disappear, the discharge becomes thinner, translucent, and the disease gradually abates, leaving the usual healthy cervical secretion. In many cases the subacute stage gradually turns into the chronic, when gonorrhœa may become latent, disappear, and reappear when certain conditions influence it. Excessive sexual intercourse, alcoholic stimulants, etc., may produce exacerbations of an acute condition.

In gonorrhœal endometritis the muscular wall usually becomes affected before the gonorrhœa extends to the tubes and this is usually a cause for chronic metritis. On a bimanual examination you will notice pain, swelling, and hard consistency due to hyperæmia and infiltration.

There is no doubt that conception can take place after an attack of uterine gonorrhœa, but usually in these cases either an abortion or an abnormal development of the ovum is the consequence. When gonorrhœal infection and conception take place at the same time, there is less chance for the infection to spread to the tube, ovaries, and peritoneum, because by the agglutination of the decidua reflexa with the vera the uterine cavity becomes closed and protected from the spread of the infection. In this way the disease is limited to the lower part of the genitals and can be easily checked, but in case the disease is not cured in time there is extreme danger of its spread during the puerperal state, as the tubal openings are widely dilated and can freely admit the infection.

Puerperal gonorrhœal endometritis is a grave febrile affection, with a temperature often reaching 105° F., but it is not so fatal as the puerperal septic endometritis and therefore should be carefully differentiated.

Diagnosis: Endometritis gonorrhœica is usually a complication of gonorrhœal vulvo-vaginitis or urethritis, and is therefore diagnosed as gonorrhœal by its mere presence, but when there is any doubt the uterine secretions can be examined microscopically for Neisser's gonococcus.

Treatment: Local applications of silver nitrate, ten per cent., zinc chloride, twenty per cent., argentamin, five per cent., argonin, five per cent., or ichthyol-glycerin, ten per cent., are useful. Recently alumol¹ was introduced and considered as very efficient: either alumol gauze, five per cent., or an alumol antrophore, five per cent., is introduced into the uterus. My method is more radical and I claim for it positive success. When there is no complicating salpingitis present, I dilate the cervix, irrigate the uterine cavity with bichloride of mercury, 1 to 4,000, then curette thoroughly with a sharp curette, touch up the endometrium with ninety-five-per-cent. carbolic acid, pack the uterus with iodoform gauze, ten per cent., and tamponade the vagina with ichthyol-glycerin tampons, ten per cent. After forty-eight hours the tampons and packing are removed, and a few fresh ichthyol-glycerin tampons are placed in the vagina. One week later I examine the patient, especially her uterine secretions, and if the disease is still persisting I repeat the above procedure.

Salpingitis and Oöphoritis.—Pathology: (a) Salpingitis occurs according to Bumm in 3.7 per cent. of the gynecological practice, while Schauta finds it in 17.8 per cent. of his own carefully investigated cases.

¹ Dr. Chotzen (Breslau): Centralblatt f. Gyn., October 26, 1895.

The gonorrhœal affection of the tube is therefore less frequent than gonorrhœa of the uterus, probably due to the narrowness of the lumen in the tube. The mucous membrane becomes thickened and the ciliated epithelia are destroyed. In some places the destruction goes so far as to uncover the underlying connective tissue; infiltration then takes place in the intermuscular and submucous connective tissue, and thickening of the wall is the consequence. At times atresia or stenosis of the tube occurs. On account of stenosis in both ends of the tube a fluid accumulates. This is either purulent or serous, but very seldom bloody. We have therefore the pyosalpinx, hydrosalpinx, and rarely the hæmatosalpinx.¹ Wertheim succeeded in proving the presence of gonococci in the tubal wall and in its contents. The gonococci reach only the superficial layers of the connective tissue, which becomes exceedingly infiltrated with pus cells. No other pyogenic bacteria have been found as yet in these gonorrhœal inflammations of tubes, ovaries, and even peritoneum. (b) Oöphoritis: Gonorrhœal oöphoritis may be produced in two ways: either by route of the tubal lumen the gonorrhœal pus flows into an open Graafian follicle,² or the infection spreads from the tube to the peritoneum and then afterward to the ovary. Wertheim found gonococci not only in the pus of the ovarian abscess, but also in the solid tissue of the ovary.

Symptoms: Pain is complained of in the lower part of the abdomen and sacral region, extending down to the lower extremities. There is also pain at times in the chest and upper extremities. It may be either continuous or interrupted, simulating labor pains. Metrorrhagias are very frequent in these cases, also irregular and profuse menses. Painful urination and purulent vaginal discharge are seldom absent. Frequent peritonitic attacks, loss of appetite, emaciation, nervousness, constipation, painful defecation, and a general impaired nutrition can be observed. Hæmoglobin falls to twenty or thirty per cent. Sterility is most frequently the consequence. In case pregnancy is coincident with this affection, it becomes then a source of torture and danger to the patient. Either abortion is produced by the interference of the tumor with the rise of the uterus, or if pregnancy is carried to the full term a pelvic peritonitis is a probable complication in the puerperium.

Diagnosis: Salpingitis or oöphoritis is made out by the usual bimanual examination, like the simple inflammatory affections of the tubes and ovaries, and the question as to gonorrhœal infection is solved by the history of the case. Be guarded against mistaking the tumor for an ectopic gestation.

Treatment: First or acute stage: When a hard tumor is felt bimanually, but no fluctuation is present, when the heat and pain in the pelvis are severe, then an ice-bag full of ice kept on the affected side will subdue to a great extent the acute inflammatory process; morphine (one-eighth of a grain every two hours) will quiet the pain and comfort the patient; quinine or antipyrin will relieve the fever. Perfect rest in bed, ichthyol-glycerin, ten per cent. (a few ounces injected into the vagina t.i.d.), and fluid diet are indicated in this stage. If this plan does not improve the condition of the patient, several leeches or a blister may be applied to the affected side, and vaginal injections of permanganate of potassium, two grains to the pint, should be used. Second or subacute stage: Dilate the cervical canal and introduce an Outerbridge's wire dilator to allow the free exit of secretions from the uterus. Order warm linseed poultices to the abdomen and warm vaginal injections of bichloride of mercury, 1 to 4,000, twice or three times

¹ "Lehrbuch der Gynäkologie," Schauta, Wien, 1896.

² Menge: Centralblatt f. Gyn., July 20, 1895.

daily. Third or chronic stage: This may terminate in two conditions—one, the purulent affection, in which fluctuation is distinct; either a pyosalpinx or an ovarian abscess, or both, can be diagnosed on one or on both sides. Then the best plan is extirpation of one or of both appendages. Professor Schauta, of Vienna, practises simultaneous extirpation of the uterus, when both appendages are to be removed.¹ On the other hand the chronic stage may show a tendency toward improvement, especially in cases in which there is no fluctuation to be detected. In these cases mild saline laxatives, iodides, massage, glycerin tampons, sea-salt baths, or sea bathing will produce a decided effect.

Peritonitis and Parametritis.—Pathology: As long as the view of Bumm was in vogue, that the gonococcus could penetrate into cylindrical epithelium only, it was thought impossible that Neisser's gonococcus alone would be sufficient to cause peritonitis, but that streptococci and staphylococci would have to appear in the field of infection in order to produce a peritonitis. Wertheim by experiments upon white mice and guinea-pigs proved that within twenty-four hours after inoculation of gonorrhœa upon the peritoneum a sero-purulent secretion on the infected spot could be distinctly seen.

Peritonitis usually leaves behind many adhesions, which tie up the pelvic organs in different ways. Very often there are among the adhesions ensacculated accumulations of pus, blood, or serous fluid. Parametritis is one of the rarest gonorrhœal affections, and all that is known of it through operations is that it occurs usually as a sequela to long-standing or recurrent peritonitis.

Symptoms: There is a slight rise of temperature during the first few days, seldom above 101.5° F. Pain and tenderness are distinct, as in simple pelvic peritonitis, but the gonorrhœal peritonitis seldom lasts longer than four days. Cases of peritonitis produced by the sudden rupture of a gonorrhœal pyosalpinx are usually very grave and in most cases fatal. The symptoms of chronic pelveo-peritonitis are usually confused with those of the adnexa, and it is hard to say whether they belong to salpingitis, oöphoritis, or peritonitis. The symptoms of parametritis are also obscured by the affection of the adnexa.

Treatment: It should be the same as in all cases of circumscribed or pelvic peritonitis, namely, rest, ice, and morphine.

Prophylaxis.—(1) Early marriage. This would certainly strike the severest blow against prostitution, the agency of gonorrhœal distribution. I say "early" marriage from a social point of view; still, I mean "timely" from a physiological point—namely, if boys and girls whose sexual organs have completed their development should marry, they would have the least possible chance of falling into the paths of prostitution and be the least exposed to gonorrhœal infection. The pediatricist is frequently asked by the anxious mothers when they shall wean their babies and he wisely answers, as soon as they have teeth and can eat; but the gynecologist is never asked by the anxious mother when shall her daughter marry and what can he advise her? Shall he advise the girl to marry as soon as she menstruates, as nature designed, or shall he advise her to attend college, etc., and wait till she is a thoroughly accomplished woman? Certainly, with the present stage of civilization the latter advice, which is a transgression against nature's laws, is the most proper one. Nature though, as a rule, punishes her transgressors. She gives a tobacco heart to the smoker; provides the drinker with Bright's disease; surprises the mother who neglects the nursing of her infant with mastitis; turns the onanist into a weak and nervous imbecile; she curses the prostitute

with gonorrhœa, syphilis, etc. So also does nature punish society for its late marriages by hard child-births and by prostitution.

2. Isolation: As long as society will recognize the necessity of late marriages, so long will it have to recognize prostitution as an inevitable evil. Nevertheless, a great many people are not decided yet as to the propriety of permitting the establishment of "public" houses and the registration of prostitutes. They think that by such formal allowances they would give prostitution a recognition by which it would become a legalized profession. Nobody though can deny that prostitution does exist and does disseminate venereal diseases; why not have it in isolated quarters and under the supervision of the police and health departments, in order to prevent the spread of gonorrhœa and syphilis? Would this not be the most radical prophylactic? For instance, if all prostitutes should be examined by health inspectors as frequently as practicable and the sufferers from venereal diseases should be sent to a hospital, which they could not leave until positively cured, gonorrhœa and other venereal diseases would certainly become scarce.

3. Warning: The patients must be strictly warned against sexual intercourse or marriage as long as gonorrhœa is present. Many a man is base and careless enough to bring the disease home to his wife and even children. I treated quite a number of families in which all the members were infected. Some men have a superstitious idea that gonorrhœa can be gotten rid of by transferring it to a pregnant woman and they get their unfortunate victims. Lawson Tait¹ relates the cases of several girls who were infected at their first connection. They were victims of the brutal superstition that a man can get rid of his disease by conferring it on a virgin. The prostitutes, as a rule, do not restrain themselves from connection while infected with gonorrhœa, except when they are suffering pain. They are either glad to revenge themselves upon men for their wrongs, or they are compelled to earn their living whether sick or well.

4. Rational and thorough treatment of men by specialists is of utmost importance, bearing in mind the obstinacy of this disease, especially in the chronic and latent stages.

5. Instruments: Thorough cleanliness of instruments and antiseptic precautions should not be forgotten in the physician's office, as well as in the clinic or dispensary.

132 HENRY STREET.

The Blood in Pernicious Anæmia.—Dr. Cabot has published in the *Boston Medical and Surgical Journal* a study of fifty cases of pernicious anæmia. He concludes that the points most typical in the blood of this disease are: 1. A reduction of the number of red cells to about 1,000,000. 2. The absence of leucocytosis. 3. Possibly a relatively high percentage of hæmoglobin in some cases. 4. Increase in average diameter of the red cells. 5. The presence of large numbers of polychromatophilic red cells. 6. The presence of nucleated red cells, a minority being normoblasts. 7. The presence of myelocytes. 8. A relatively high percentage of small lymphocytes at the expense of the polymorphonuclear cells. Post-mortem examination in eight cases brought out nothing not already well known. Fatty degeneration and pallor of all organs were noted in all; the "tiger-lily" heart in six; pericardial and peritoneal ecchymoses in four. The spleen was slightly enlarged in two; no enlargement of lymphatic glands was observed. The marrow was examined in five cases, showing in all a notably red color in the shaft of the long bones.

REPORT OF A CASE OF MALIGNANT UTERINE TUMOR TREATED BY THE TOXINS OF Erysipelas AND BACILLUS PRODIGIOSUS.¹

By R. M. STONE, A.M., M.D.,

OMAHA, NEB.

I wish to present to the readers of your valuable journal a report of the only case of malignant uterine disease, so far as I can learn, treated by the erysipelas and prodigious toxins.

It is particularly appropriate just now, after the unfavorable editorial upon the subject in the *MEDICAL RECORD* of October 19, 1896.

The writer has endeavored to be perfectly scientific in his methods. He had the judgment of four physicians who, upon inspection, pronounced the case as malignant and inoperable. They agreed that the patient was apparently near to death. The opinion of three or more competent microscopists agreed that the specimens were malignant. He may be excused for a slight degree of enthusiasm when, after such conditions, he has seen the patient restored to apparent perfect health, to entire freedom from all symptoms, and to restoration of normal weight. He is not ignorant of the fact that but one year has elapsed and knows that permanent conclusions cannot yet be drawn.

He recognizes the danger of the injections, because an overdose nearly killed his patient.

He thoroughly agrees with the conclusion of the committee that as yet the use of the toxins should be confined to inoperable cases, but it should be noted that Dr. Coley himself has advocated the method only in inoperable cases, and practically only in inoperable sarcoma.

History.—Mrs. L. B.—, aged forty-two, a vigorous woman of excellent family history, the mother of five children, the youngest three years old, called upon me in May, 1895, stating that she was flowing and had been for two or three weeks. I asked her to call again, when not embarrassed by the flow, and let me investigate. In July she met me in a store and remarked that she had flowed very much since May and would surely come and see me soon. Early in November, 1895, six months after the first symptoms appeared, she finally came for examination. She reported that she was still flowing a little and had lost blood every day in October. Her normal weight was about one hundred and twenty pounds; she was now reduced to about one hundred and five. Her color was bad and she was very anæmic. Examination showed the cervix very large, its inner surface eroded, bleeding easily, and open sufficiently to admit the tip of the index finger. Malignancy was quite evident. The uterus was large and heavy, and there was infiltration of the right broad ligament. I called in my friend, Dr. Charles C. Allison, professor of rectal and genito-urinary surgery, Omaha Medical College, for consultation. He confirmed the diagnosis. We advised the curettage of the uterus and the amputation of the cervix. On November 12th Dr. Allison operated. When he took hold of the posterior lip with the volsellum it tore away. Curettage was done thoroughly and a large portion of the uterine tissue, which was found soft and friable, was removed. The anterior lip of the cervix was removed with the scissors. The cautery and the chloride of zinc were thoroughly used, as the hemorrhage from the cervix was profuse. Dr. W. R. Lavender, professor of pathology, Omaha Medical College, very kindly made microscopical examination of the cervix. He made about one hundred sections and found a "decidedly abnormal amount of fibrous connective tissue, in addition to the normal

tissue found in the cervix uteri. There were distinct groups of round cells with very large nuclei without connective tissue between the cells. There were small spaces in which were found red blood corpuscles, the walls of these spaces being formed by cells. A careful search for epithelioma proved negative. There was a hyperplasia of the uterine follicles at the junction of the cervix and the body of the uterus, but a decided absence of the characteristic invasion of normal tissues usually found in epithelioma." His diagnosis was "spindle-celled sarcoma." Unfortunately we were able to send but two sections to Dr. Coley for examination. Mr. B. H. Buxton, assistant pathologist to the New York Cancer Hospital and bacteriologist of the Loomis Laboratory, New York, pronounced the growth to be of epithelial origin. Whether it was epithelioma from stratified epithelium or carcinoma from the glands of the cervix was uncertain. It was probably the former. It certainly was malignant. Dr. E. K. Dunham, pathologist to the New York Cancer Hospital, director of the Carnegie Laboratory, and professor of pathology in Bellevue Medical College, confirmed Mr. Buxton's diagnosis.

To resume our history. Recovery from the operation was uneventful up to November 24th. During this period of twelve days the temperature was between 98½° and 100½° F. The pulse was of good quality and was between 80 and 96. She rested well, had little pain, ate well, and sat up in bed on the 22d, 23d, and 24th. She was cheerful, bright, and happy, with a prospect of rapid recovery.

Hemorrhages.—There followed a period of sixteen days, during which there were five almost fatal hemorrhages. The first occurred on the evening of the 24th, without warning, after a good day. Dr. Van Gieson, living nearer than I, first reached her bedside, and had the horrible hemorrhage under control before my arrival, having packed the vagina thoroughly with ropes of absorbent cotton. On November 28th and 29th and again on December 1st there were equally severe hemorrhages. The last one, somewhat less severe, occurred on December 9th. With reference to the packing I wish to say that the hemorrhages were so violent that they ran right through any ordinary packing. We found that ropes of cotton pushed with great force, completely filling the vagina, were the best. Gauze was too harsh. Packing daily to this positive occlusion of the vagina was continued for twenty-five days. The hemorrhages usually came on in the evening after the packing had settled somewhat. Packing to a moderate degree was carried on daily up to January 15th, both to prevent possible hemorrhage and to allay the nervous tension due to a dread of hemorrhage. During most of the sixteen days during which the five hemorrhages took place life was despaired of and exhaustion was profound. The temperature was within three-fifths of a degree of 100° F. all the time, except before the hemorrhage of November 29th, when it ran up to 102½° F., and before that of December 1st, when it ran up to 101° F. The respiration was from 20 to 30 and the pulse from 90 to 108, usually above 100. Bovine was the sole dependence for food during this period. Strychnine and tonics were freely used. On November 30th we called Dr. A. F. Jonas, professor of surgery, Omaha Medical College, in consultation. Examination by us all then showed decided infiltration and nodulation of both broad ligaments. Dr. Jonas concurred in the diagnosis of malignancy and our prognosis was most grave. Death in the near future seemed imminent. There was no possibility of the removal of the uterus, even if it were at all likely to be of value. The case was without question that of an "inoperable malignant tumor."

Use of the Toxins.—Under these most unfavorable

¹ Read before the Omaha Medical Society, June, 1896.

conditions we began on December 4th the use of the unfiltered toxins of erysipelas and bacillus prodigiosus, received from the Loomis Laboratory, prepared by Mr. Buxton. I began with three minims injected between the shoulder blades. No reaction followed. On the 5th I used seven minims; on the 6th, ten; on the 7th, fourteen; and on the 8th, twenty minims, with no reaction whatever, unless that perspiration, not before present, was a shadow of reaction, and except also that at once sleep was much improved. Communication was had with Dr. Coley, who was greatly interested and very kind with his suggestions. On the 14th I used in the morning two minims, in the evening four; on the 15th, seven minims; 16th, ten; 17th, twelve; 19th, fourteen; 20th, seventeen; all without reaction. During this period, December 4th to 20th, the temperature was between 99° and 100° F. on seventy-two observations; seven times in the morning it was $98\frac{1}{2}^{\circ}$ F. The patient's condition was improving, appetite was increasing, sleep was better. The elimination from the uterus was very free and of most offensive odor. Having failed to secure the sought-for reaction from the use of two to seventeen minims in the muscles of the shoulders, we decided to go closer to the seat of the disease. We had found no directions as to any change in dosage if we approached nearer to the tumor and so decided to keep on increasing our dose. On the morning of December 21st I injected nineteen minims in the vagina near the outlet. I had hardly driven out of sight of the house before trouble began. Rigor and chill were present in twenty minutes. By 10:30 the temperature was 101° F. The face became dark purple, the patient delirious, restless, and pulseless. A most extraordinarily anxious expression of countenance was present. Breathing became labored and exhaustion was profound. Total deafness was soon present. The urine was suppressed and by noon the temperature was $104\frac{1}{2}^{\circ}$ F., and death seemed very near. Dr. Allison and I were both away on surgical cases, and these most dangerous symptoms were met by the nurse, Miss Elmer, from Blockley Hospital, Philadelphia, who gave our patient most skilful and assiduous care for nine weeks and deserves very great credit. She used stimulants, hypodermic injections of morphine and strychnine, and bovine freely. By 12:30 the temperature was down to $103\frac{1}{2}^{\circ}$ F. By 1:30 it was $101\frac{1}{2}^{\circ}$ F. By 6:30 it was 100° F. At 1 P.M., when Dr. Allison and I reached her, the pulse had become perceptible, but barely so, and 120 beats to the minute. The deafness lasted six hours only. Seven ounces of urine were secreted in the following eighteen hours. Perspiration was slight. Nausea and vomiting were present all the afternoon. Intense redness of the face followed, accompanied by vertigo and headache. On the 23d, the third day, there appeared a violent herpes of the lips and tongue, which absolutely prevented the taking of any food for two days and caused very great distress for a week. Sleep was of course very restless and fitful. Vertigo from involvement of the semi-circular canals was present to an annoying degree from December 21st to January 3d. Our patient rallied very slowly from the terrible depression of the toxins injected in the vagina, and was not able to receive another injection until January 2d, when I used three minims in the vagina, in which locality all subsequent injections were made. On the 4th I used three minims; on the 5th, six. This produced a reaction fever of $102\frac{1}{2}^{\circ}$ F. with a pulse of 120. She was not able to bear an injection again until the 10th, when two minims caused a reaction of 100° F., and a pulse of 124. On the 13th two minims, on the 14th three minims produced no reaction. On the 15th four minims caused a chill, a temperature of 101° F., and a pulse of 120. At Dr. Coley's suggestion we now be-

gan the use of the filtered toxins. From January 21st to March 6th I used the toxins twenty-seven times on forty-seven days. The dose used was from three to twenty-three minims. There was a chill after nine of the injections. The temperature rose above $99\frac{1}{2}^{\circ}$ F. and as high as 103° F. on seven occasions. The pulse during the chill was from 116 to 138. On March 15th I began again the use of the filtered toxins injected in the gluteal region, using between this date and the 24th eight injections ranging from five to thirty minims, all without reaction, the only symptom apparently produced being malaise. On April 8th I began the toxins again, now using the unfiltered in the gluteal region. I used five injections, reaching ten minims without reaction except blueness of the finger nails. On May 11th the patient insisted on the injections being made at the vaginal outlet. I used two minims of the unfiltered and on the 22d five minims; neither caused reaction. On the 25th I used seven minims at 10 A.M. By noon she was suffering; at two o'clock there was intense headache with delirium; also pronounced cyanosis, with a very severe pain in the thighs and in a small spot under each breast; there were diarrhoea and vomiting. At three I saw her: she was again, as on December 21st, pulseless, anxious, but clear mentally. The skin was less cyanotic than at two, but was dusky red all over the body. The temperature was 103° F. Herpes labialis appeared the next day. This was the second reaction in point of severity, and the patient, as usual forgetful to a degree of the more alarming symptoms of the former reaction, pronounced this one even more severe.

General Conditions.—Our patient had passed through two critical periods. The first was that of hemorrhages lasting from November 24th to December 9th. Emaciation was extreme, anæmia was profound, the heart's action was very feeble and rapid. Vitality was almost exhausted. Under the use of the toxins elimination through uterine discharge was pronounced and copious. All conditions gradually improved, without reaction fever and chill, until the collapse due to the overdose of the toxins injected December 21st in too close proximity to the uterus. This most violent reaction came near being fatal, and yet most happy results were inaugurated by this overdose.

Menses.—The atrophy of the uterus had caused both Dr. Allison and myself to feel that there probably would be no further menstruation; but on March 5th to the 9th and March 28th to the 31st there was a show of blood. From April 17th to the 22d there was normal menstruation; from May 16th to the 18th there was menstruation, free on the 16th only.

Going back in her history to January 21st, elimination from the uterus had almost ceased and at this early period, only one month from the terrible reaction, neither Dr. Allison nor myself could find any nodulation in either of the broad ligaments and granulation tissue was fast disappearing from the site of the amputated cervix. On January 23d the patient sat up in bed for the first time; on the 26th she sat in a reclining-chair; on January 29th Dr. Jonas could find no nodulation in the broad ligaments. On February 2d she walked while supported. On February 20th she walked unsupported all over the house up and down stairs. On February 24th she rode out and dined. On May 4th Dr. Allison and I made a careful examination and were still unable to discover any infiltration in either broad ligament and the uterus was very much atrophied. The site of the cervical amputation was clean and entirely healed over.

Status præsens, October 31, 1896: The patient now weighs ten pounds more than her normal weight, is rosy, vigorous, eats and sleeps well, has neither pelvic pain, tenderness, nor dyspareunia. She has

resumed all her duties in the household. Her muscles are hard and her spirits are high. The malignancy of the tumor in this case cannot be questioned. It was apparent to both Dr. Allison and myself upon inspection. Dr. Lavender, Mr. Buxton, and Dr. Dunham all confirmed it with a microscope. Dr. Van Gieson and Dr. Jonas confirmed it upon their examinations. We may never know absolutely whether it was a sarcoma, as Dr. Lavender pronounced it, or an epithelioma, as Mr. Buxton and Dr. Dunham pronounced it. The fact that Dr. Lavender examined one hundred sections and Mr. Buxton and Dr. Dunham only two, would lead us to think the diagnosis of sarcoma more probably correct. The favorable results even so far obtained are marvellous, if it was a sarcoma. If it was an epithelioma or sarcoma, it makes our success, as Dr. Coley writes, "all the more remarkable." As far as the present literature upon the treatment of these malignant inoperable tumors by these toxins is recorded the case is unique, in that no other case of a uterine tumor is reported followed by such favorable results. Nearly all the favorable cases so far reported have been of sarcomata in visible regions.

Progress of Medical Science.

The Causation of Dropsy.—Dr. Ernest H. Starling in the Arris and Gale lectures on the physiological factors involved in the causation of dropsy classifies them as follows: I.—Factors causing increased transudation: *A.* Increased intracapillary pressure: (*a*) Venous obstruction. (*b*) Vasodilatation. (*c*) Plethora. *B.* Increased permeability of vessel wall: (*a*) Local injury by mechanical irritants. Local injury by thermal irritants. Local injury by chemical irritants. (*b*) Malnutrition. (*c*) General injury by circulating poisons (?). *C.* Watery condition of blood (hydræmia). II.—Factors causing diminished absorption: *A.* By lymphatics: (*a*) Paralysis of limbs. (*b*) Obstruction of lymphatic trunks. *B.* By veins: (*a*) Venous obstruction. (*b*) Watery condition of blood. (*c*) Concentrated transudations.

Pleurisy with Effusion.—Dr. C. H. Goodrich reports ten cases in the *American Medico-Surgical Bulletin* in only one of which was there a tuberculous family history. The treatment followed was rest in bed and a restricted diet. Potassium citrate and sodium salicylate were the only drugs used. Seven patients were aspirated. Nine of the ten patients were discharged cured. One died. Convalescence was slow. The conclusions were that hard and fast inferences cannot be drawn with the aid of points from only ten cases of pleurisy with effusion, but some evidence may be presented: 1. Delafield, Osler, Pepper Peabody, and others are decisive in commending the timely removal of fluid from the pleural cavity. The outcome of these cases bears witness to the wisdom of the procedure. Weeks or months, "perhaps years," some one has said, might elapse before sixty-four ounces of serum or even one-third that quantity could be absorbed by a serous membrane whose surface is coated by a thick layer of fibrin and whose meshes are choked and distorted by sero-fibrinous exudate and perhaps by the growth of some new connective tissue. 2. It seems reasonable to use sodium salicylate and like drugs in cases of pleuritic inflammation, because of the intimacy of the relations between acute articular rheumatism and inflammations of serous membranes, and because it surely relieves pleuritic pain. Further observations may teach us more on this line. 3. Although careful to include all the recognized methods in our examination, we failed to find any evi-

dence of tuberculosis in these cases. 4. The decidedly slow recovery of general health seems to indicate that there is room for improvement in the methods of treatment of cases of pleurisy with effusion after the removal of serous accumulations. 5. Empyema seems to be an unnecessary consequence of aspiration of the pleural cavity for pleurisy with effusion.

The Palliative Treatment of Cancer of the Cervix Uteri.—Dr. Marocco at a meeting of the Lancisian Society for the Hospitals of Rome (*Wiener klinische Rundschau*, August 9, 1896) reports good results from tamponing with gauze impregnated with tannin, iodoform (ten per cent.), and powdered quinine.

Heredity and Crime.—The following, taken from the *Medical Press*, compiled by Professor Belman, of the University of Bonn, relates the career of a notorious drunkard who was born in 1740 and died in 1800. Her descendants numbered 834, of whom 709 have been traced from their youth. Of these 7 were convicted of murder, 76 of other crimes, 142 were professional beggars, 64 lived on charity, and 181 women of the family led disreputable lives. The family cost the German government for maintenance and costs in the courts, almshouses, and prisons no less a sum than \$1,250,000; in other words, just a fraction under \$1,500 each. It would probably be difficult to find a more remarkable example than this of the evil effects of the transmission of hereditary defects.

Transfusion, Infusion, and Auto-Transfusion.—Dr. Schachner (*Journal of the American Medical Association*, September 12, 1896) compares their merits and indications and summarizes as follows: 1. In enormous hemorrhages the resulting dangers are more frequently due to the reduced intravascular pressure than to the actual loss of blood. 2. In view of this the indications point more decidedly toward infusion than transfusion. 3. That transfusion has not received the attention which its merits justify. 4. In transfusion we possess a measure which in the severest hemorrhages is the only agent capable of restoring the vital functions. 5. The indication for transfusion includes any condition which reduces the total quantity of blood to a fatal degree or which alters the character of the blood to such an extent as to render it incapable of sustaining life. 6. When the transfusion is performed for the relief of a poisoned condition of the blood it should be preceded by venesection. 7. Centripetal is to be preferred to centrifugal transfusion. 8. In centripetal transfusion the injection should be made with a slow steady stream, undue force being carefully avoided. 9. In withdrawing the blood from the donor the veins afford an easier, safer, and better source than the arteries. 10. Indirect transfusion with defibrinated blood is safer than direct transfusion with non-defibrinated blood. 11. In alarming hemorrhages infusion should be performed before transfusion; should, however, the improvement be transient in its nature, the infusion must be supplemented with transfusion. 12. In addition to hemorrhages the indications for infusion include any pathologic state attended with a feeble pulse which is dependent upon a relaxed condition and a diminished intravascular blood pressure, namely, shock. 13. Restoring the tone of the circulation by infusion is not wholly dependent upon the increase of the intravascular pressure, but is in part due to the stimulating influence which the salt solution has upon the heart. 14. In performing transfusion or infusion after an enormous hemorrhage, the use of an anæsthetic is not only unnecessary but absolutely dangerous. 15. In the auto-transfusion we have a valuable measure for combating shock and preventing accidents in anæmic subjects during chloroform narcosis.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, November 21, 1896.

INTRA-UTERINE INFECTION OF SYPHILIS.

To workers in fields of science where knowledge is exact and definite, where laws are made which become true and unalterable for all time, where calculations can be made with that accuracy of mathematical precision which admits of no question or cavil, it must appear strange that there are so many questions in medical science which are still unsettled, though seemingly simple of solution. One of these problems about which opposing views prevail has been brought up by Dr. Abner Post, in a recent issue of the *Boston Medical and Surgical Journal*. The question is one very simply stated, but not, it would seem, so readily and satisfactorily answered: Can a woman who acquires syphilis during her pregnancy transmit it to the fœtus *in utero*?

The elements which have lent confusion in observations bearing upon the question are: The possibilities of hereditary syphilis from the father; of the mother being herself affected prior to the period of supposed infection or at the time of conception; and of the infant becoming inoculated at birth.

In analyzing the views advanced by most American authors, the writer of the essay gains the impression that "no one of them expresses an opinion based on his own experience," and that "all appear to speak from authority or to reason from anatomical facts."

And here lies, we believe, the chief reason for so much difference of opinion concerning a matter which should be definitely settled. It is the old story of negative evidence and the citation of instances admitting of doubt, which are allowed to weigh against the fewer carefully observed cases of a positive nature. The number of observations in which all the requirements for scientific accuracy are fulfilled must, of necessity, be limited. The few coming from observers of recognized ability and accuracy of statement must outbalance any theoretical considerations or laboratory investigations. We must, too, recognize the value of analogy as bearing upon the matter. Thus, it has been demonstrated that, while in the rule variola is not transmitted from the mother to her enwombed offspring, it occasionally is so transmitted. The writer also believes we are safe in saying, at the present day, that the microbes of anthrax, glanders, pneumonia, typhoid, tuberculosis, and the bacterium coli commune pass the placenta to attack the fœtus *in utero*.

The analogy is thus further strengthened for those who believe in the bacillary origin of syphilis. An acceptance of this theory by the writer is implied in the sentence: "Hence, we may infer that intra-uterine infection is not impossible in syphilis."

Three cases are reported in illustration of the possibility of such transmission, and, while they are not absolutely convincing, they add to the cumulative testimony which is of great value in strengthening the proof. The conclusions which are drawn are as follows:

1. It is universally admitted that there is normally no direct communication between the maternal and fœtal blood.
2. There is proof, however, that certain contagious diseases are conveyed to the fœtus *in utero*.
3. In some of these cases it is shown that hemorrhages have destroyed the original structure of the placenta and opened a path of communication.
4. It is, then, no longer possible to say that intra-uterine infection is impossible in syphilis.
5. Clinical observation shows that intra-uterine infection does take place in syphilis.
6. Whether such infection is invariable, or what its limitations are, we do not know.

How much better such a statement of the case would appear in the present state of knowledge than that made in a recent work by Culver and Hayden: "The syphilis of the mother acquired during pregnancy *cannot* be conveyed to the fœtus through the utero-placental circulation."

In 1883 Dr. Taylor wrote almost in the same words, in his revision of Dr. Bumstead's work. In his own treatise, recently published, it is admitted, however, that "full infection may in rare cases occur when the filtrative power of the placenta has been impaired by morbid changes."

Hayden, *plus royalist que le roi*, now says in his "Venereal Diseases," 1896: "Syphilis of the mother acquired during pregnancy may be conveyed to the fœtus through the utero-placental circulation."

When authors are in accord upon the greater question, let them take up the lesser one of the periods during which the offspring is liable to escape infection or to come into the world alive. In the mean time, statistical data from our readers are in order and will be gladly received.

THE DOCTOR'S WIFE IN A NEW RÔLE.

THE doctor's wife is the very essential part of himself. No one questions this who has any knowledge of her varied functions as the efficient and ever-ready help-mate. In season and out of season she is ever willing to fill in vacant spaces in his recollection, to regulate his unthrifty habits, and in various other ways to even out those little irregularities in his living which, being approvingly done, make him the acceptable, jovial, and contented mortal for outside exhibition and general adulation. If in the long run she finds herself with an elastic conscience, she rightly blames the peculiar environment which so necessarily fits the situation. The night bell, if it could speak on its

own account, would as often bring tears to the recording angel's eye as smiles to the father of lies—white lies, translucent fibs, we mean, that balance their imperative utility against the inexorable expediency of protecting the weary doctor on the one hand and punishing the thoughtless and improvident patient on the other. It is she who has settled with her own conscience the difference between in and out as applied to the patient who really needs the doctor and is willing to pay for an ugly night trip, as compared with the other caller who always waits for dark nights, bad roads, and believes in long-standing accounts.

It is reasonable to suppose that she is not solely responsible for these conventionally pardonable and innocent frauds. Oftentimes the man who is making up his mind to go or stay is at her side as the hidden, hesitating, and interested prompter, whose voice is not heard but whose influence is felt. In the darkness of the bed chamber at the proximal end of the night tube there is generally a consultation not accounted for in the bill, which results either in the expectant patient trotting for another doctor or gladly taking the one who is so conveniently found at home. The good creature, hardened to the pressing necessities of this common sin, becomes immune to all ordinary enticements for deception, and because we can so easily forgive her we gladly and heartily respect her.

Being a recognized silent partner in the business she necessarily claims certain privileges without corresponding restrictions. Under given conditions she often says what she thinks and oftener does as she pleases. Bound by no code of ethics, accountable to no committee on credentials, she gradually in her pleasantly assertive femininity becomes a law unto herself and generally equally so to her accessory part. Fortunately she is more discreet, more circumspect, and more diplomatic than most wives of other professional men. Thus there is peace in the family and society is generally safe.

She may in a limited and friendly circle joke of the incapacities of her husband, his social shortcomings, his irregular engagements, his waiting meals, his settled and stubborn indifference to her ailments, his opposition to medication in his own family, and to his careless and shiftless habits, all of which we would gladly forget in writing his obituary, but to the outsiders, cunning and lovable hypocrite as she is, she always pretends to a smiling confidence in the head of the firm and has an assuring word for every doubting Thomas. No one can blame her for this, as the proper motive is always present with the proper feminine discretion to balance it. While all this is true, judge of our surprise in hearing from a distant correspondent the following startling account of a novel way of representing the purely business interests of her husband:

"I want to request you, as a reader of your journal for many years, to devote a little space in the MEDICAL RECORD to the practice of the wives of some medical men, who with their husband's consent act as 'watchers' at the bedside of the sick—the patients of other practitioners.

"I would myself address a communication on the

subject, but I believe an impersonal review of the abuse would be more effective, if it be possible by any means to get beneath the pachydermoid consciences of those who practise this pettifoggery. The reason of my notice of the abuse at this time is the presence this very morning of two women—the wives of other doctors, watching each other and the patient of a third physician, with whom I was called in consultation. Charitably disposed women of this class are never found in the homes of poverty, but always at the bedside of some influential neighbor who does not employ her husband as family physician. A notice of this abuse is not likely to have widespread influence, because the criticism is of those who lack the delicate instincts of ladies and gentlemen, but we are told that there is great joy in heaven over even one sinner doing penance, and maybe some one mind may be broadened enough to appreciate his or her own littleness."

If this information did not come from a trustworthy source we should indignantly deny on the behalf of thousands of doctors' wives throughout the country the possibilities of such meanness. Fortunately we have only heard of two of these Sairey Gamps. They are merely veritable curiosities rather than dangerous examples. It is only in such a light that they deserve any notice whatever.

THE PAN-AMERICAN MEDICAL CONGRESS.

THE second Pan-American Congress, which was held during the past week in the City of Mexico, was a success, not only in point of attendance from distant countries of the continent, but from a scientific standpoint in the great number and variety of topics presented for discussion. The addresses treated on subjects of broad aspect, in which the philosophy of disease and the science of pathology were consistently applied not only to the needs of the individual but to the necessities of the public. In large and representative gatherings of scientific men expressions of opinion on matters concerning public health are always expected and are becomingly respected. It is in discussions on such topics that science shows its higher achievements and commands for itself its rightful dues of respect and authority. In this regard more particularly the congress has vindicated its right to be and has shown a proper appreciation of its high mission. Too much praise cannot be given our Mexican brethren for the earnest manner in which they systematized the work and made available the vast amount of material at their command. We take pleasure in presenting in this issue the first instalment of the proceedings, furnished by our special correspondent, who has been sent to Mexico for the purpose of obtaining an accurate report. In a future issue, when the work of the congress is given in full, the readers can be the judge of the variety and quantity of scientific work that has been done, and can form their own estimate of its value.

Colored Nurses.—A training school for colored nurses is to be established in connection with the New Orleans University Medical College.

THE "INS" AND THE "OUTS."

THE circumstances attending the relative positions of the men who are inside and those who are outside of a given privilege always give rise to radical differences of opinion. This is exemplified in every walk of life. Generally, in order to change the respective ways of thinking, it is only necessary to change places. In a newspaper item it is stated that an architect opposed to the construction of tall buildings was placed upon a committee whose function was to oppose such innovations. While his associates, with his active help, had prepared a suitable protest, the member in question, for some reason not at the time understood, voted to delay the report. This action on his part was afterward explained by the fact that he was not only an active competitor for the building of a so-called "sky scraper," but had actually secured the contract. The human nature of the action has an application to the doings of many a struggling practitioner, who is radically opposed to hospital extension and free dispensary practice, until a coveted position is within his grasp. The illustrations are too numerous to mention. We have known of many such, whose guns were turned by fortune in exactly an opposite direction. This time-honored method of silencing opposition to existing evils changes what would otherwise be defeat on the part of hospital and dispensary managers into a glorious victory for indiscriminate abuse of charity. Hence the independence of men who are in the position to do as they please with the profession. No sooner does a staff of any of these institutions resign, or a particular member drop out by death, than hundreds of aspirants run to their friends for recommendations for the vacant places and, with hat in hand, beg of the self-important managers for the eagerly sought preferment. If successful, the man alters with his change of position, and the evil goes on with one less opponent.

News of the Week.

Diplomas for Sale.—The Wisconsin Eclectic Medical College is still offering diplomas to practising physicians at "much reduced rates, \$35, all inclusive." The prospectus states that they come "as a boon and a blessing" to those who have hitherto practised medicine illegally.

Revolutionary Doctors.—Of the nineteen men who constitute the officers and board of directors of the "Oscar Primelles Club," whose object is to collect and distribute medical and surgical supplies destined for the revolutionary armies of Cuba and Porto Rico, all but three have the title of "doctor" and the great majority that of "M.D." They solicit contributions of drugs, instruments, appliances, and money, which may be sent to Dr. Gastón, the president, at 56 New Street. The club's name is taken from the physician who was the first in this war to seal his devotion to the cause with his life blood.

Deborah Nursery has been ordered by the board of health to vacate the premises occupied in One

Hundred and Sixty-First Street. It is reported that the cause of this action was the lack of care in isolating infectious ophthalmia at the institution, those affected, to the number of twenty-seven, being permitted to mingle freely with the other children. If this is the case, the radical measures employed are not too severe.

Indian Territory Medical Association.—The semi-annual meeting of this society will take place at Vinita, Ind. Ter., December 1 and 2, 1896.

Camden County (N. J.) Medical Society.—At the regular monthly meeting of the Camden County (N. J.) Medical Society, at Camden, on November 4th, Dr. H. A. Hare, of Philadelphia, read a paper on "Unusual Eruptions in Fevers."

Street Dogs.—The board of health has under contemplation the banishing of dogs from public thoroughfares. The lack of regard many dog owners show for the decency of our sidewalks, to say nothing of the public-health side of the matter, would seem to make some action justifiable.

Department of Charities.—On Friday, November 13th, a civil-service competitive examination was held for the position of general inspector, department of public charities. The number applying was necessarily small on account of the fact that candidates for the position must have had executive experience in hospital management and organization. Salary, \$3,000 per annum. Mr. Knowles, ex-superintendent of the City Hospital, Blackwell's Island, was appointed some time ago, his appointment being contingent upon civil-service rules.

The Late Dr. J. Murdoch.—At a special meeting of the Allegheny County Medical Society, held October 5, 1896, the following resolutions were adopted:

Whereas, Dr. J. B. Murdoch, a member of the Allegheny County, Pa., Medical Society, has been called by death from the scenes of his beneficent professional labors; and

Whereas, We realize that in him was typified the skilful physician and surgeon, the genial companion, the upright and honorable man, the good citizen and the Christian gentleman; and

Whereas, The loss to this society is deeply felt, being that of a member always devoted to its advancement in science, one invariably the supporter of the cause of right, of a friend to every colleague, and of a charitable and noble-hearted man: therefore, be it

Resolved, That the Allegheny County Medical Society place upon public record this expression of its sincere grief at the death of Dr. Murdoch, one of its most valuable and highly cherished members; and

Resolved, That these resolutions be spread upon the minutes of the society and copies be transmitted to the family of the deceased, to the medical press, and the daily papers of Pittsburgh for publication.

W. S. HUSELTON,
W. S. FOSTER,
W. H. DALY,
J. W. MCFARLANE,
J. J. BUCHANAN, Sec.

Committee.

Philadelphia Polyclinic.—Dr. W. Oakley Hermance has been appointed instructor in the administration of anæsthetics in the Philadelphia Polyclinic and anæsthetizer to the Polyclinic Hospital.

Roosevelt Hospital, New York.—In response to an invitation of the trustees of the Roosevelt Hospital, a large number of friends of the institution inspected on Wednesday afternoon, November 18th, the private patients' pavilion, located west of the main building.

Black Diphtheria in Pennsylvania.—In Carlisle, Pa., four children in one family have died from hemorrhagic diphtheria, and the father, two other children, and an aged woman have been attacked with the disease.

Contagious-Fever Van.—The Chicago board of health has had presented to it, by the Columbian ambulance association, a mahogany, rubber-tired ambulance, provided with basket stretcher and suspended swinging stretcher, for conveying contagious diseases to the hospital.

Vital Statistics of Philadelphia.—During the week ending November 7th, there occurred in the city of Philadelphia 374 deaths, 14 more than during the preceding week, and 51 more than during the corresponding week of the previous year. Of this number, 113 were in children under five years of age. Pneumonia and pulmonary tuberculosis were again the two largest individual causes of death, the former being responsible for 48 deaths and the latter for 36.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending November 14, 1896: November 11th.—Assistant Surgeon H. La Motte detached from the naval hospital, Norfolk, Va., and ordered to treatment at naval hospital, Philadelphia. November 13th.—Surgeon E. H. Marsteller detached from the *St. Mary's*, ordered home, and placed on waiting orders; Surgeon R. Whiting ordered to the *St. Mary's*.

Bellevue Hospital.—Last week plans were filed at the office of the department of buildings for a two-story brick boiler and laundry house on the grounds of Bellevue Hospital, the estimated cost of which is \$85,000; also on the same grounds a two-story brick isolating hospital at a cost of \$45,000. Bellevue is to be congratulated upon obtaining these much needed improvements. On Blackwell's Island, just west of the City Hospital, the city will erect a four and one-half-story brick and stone water tower at an estimated cost of \$15,000.

The New York State Association of Railway Surgeons, which is now holding its sixth annual meeting in this city, yesterday elected the following officers for the ensuing year: *President*, Dr. J. F. Valentine, of Brooklyn; *First Vice-President*, Dr. George Graves, of Herkimer; *Second Vice-President*, Dr. F. H. Peck, of Utica; *Secretary*, Dr. C. B. Herrick, of Troy; *Treasurer*, Dr. T. D. Mills, of Middletown; *Chairman of the Executive Committee*, Dr. George Chaffee, of Brooklyn.

Johns Hopkins.—Dr. W. S. Thayer has just received the appointment of associate professor of medicine.

Low Mortality.—In the week ending November 7th the smallest death rate ever recorded in Boston was reached, the number being six hundred and eighteen.

A Young Ovum.—In removing a uterus for carcinoma Professor Leopold, of Frankfurt, Germany, found an ovum the size of a lentil, which from facts elicited was pretty clearly eight days old. It will be examined and reported upon.

Rush Monument Fund.—The subscriptions to this fund have reached \$3,886.39.

Dr. Alice Bennett, who for sixteen years has held the position of superintendent of the woman's department of the Pennsylvania State Insane Asylum, has just resigned this office.

Bicycle Exercise for the Insane.—According to *La Médecine Moderne* of October 28th, the wheel has been introduced as a therapeutic measure, with marked success, in an institution for the insane at "Kahlmazov," Mich.

Tetanus Antitoxin has been placed under State control in Germany, and Professor Behring has announced that the Hoechst factory, which produces diphtheria antitoxin, is authorized to dispense it from the laboratory, under direction of Professor Ehrlich.

Obituary Notes.—THOMAS H. BURCHARD, M.D., of New York, died suddenly, aged forty-eight years, of cardiac disease, November 15th, at his home 7 East Forty-eighth Street. He had just returned from a trip abroad for the benefit of his failing health, and was resuming his practice when his fatal illness overtook him. He graduated from Bellevue Hospital Medical College in 1872 and soon after commenced practice in this city, spending his summer months in Saratoga, where he also became a leading practitioner. His genial disposition and kindly manner won for him hosts of friends, who mourn their untimely loss. Always active in professional pursuits, he was a ready writer, a fluent speaker, and an able teacher. His numerous contributions to surgical literature won for him an enviable reputation as an original thinker and necessarily kept him in advance of the less ardent workers of his class. He was a member of all the leading medical societies of this city and was also a surgeon to the Charity Hospital.—DR. HENRY HOLLENBACK died at his home at Burlington, N. J., on November 6th, at the age of eighty-four years. He had at one time been mayor of the city of Burlington.—DR. WILLIAM HAYWARD died at Cambridge, Md., on November 7th, at the age of seventy-eight years.—DR. F. H. RANKIN, formerly of this city, and of recent years one of the best-known practitioners in Newport, R. I., died in that city on the morning of November 9th. He was a graduate of the New York University, class of 1862, beginning practice in New York City in 1871, after serving as assistant surgeon in the German army during the Franco-Prussian war. He leaves a widow, but no children.

Society Reports.

SECOND PAN-AMERICAN MEDICAL CONGRESS.

HELD IN THE CITY OF MEXICO, NOVEMBER
16, 17, 18, AND 19, 1896.

(SPECIAL TELEGRAPHIC REPORT TO THE MEDICAL RECORD.)

First General Session—Monday, November 16th.

THE section work of the Second Pan-American Medical Congress began informally on the morning of Monday, November 16th, in different parts of the city, the formal opening being reserved for the general session. This was held in the evening in the National Theatre. The building was crowded to its utmost capacity by the native and visiting physicians, most of the former and many of the latter being accompanied by ladies, by the officials of the federal and municipal governments, and by many residents of the capital.

The first business after the opening of the session was the

Report of the Secretary.—DR. EDUARDO LICÉAGA, secretary-general of the congress, then read his report. He recalled the fact that the first congress of physicians of the western hemisphere was held in Washington in 1893. Its inception was due to the labors of Dr. William Pepper, who honors us this evening with his presence, to the tireless activity of Dr. C. A. L. Reed, and to the action of the United States Congress, which authorized the President of that republic to invite all the other nations of the American continent to send delegates to the medical congress. At one of the sessions of this congress the honor of holding the second meeting was granted to Mexico.

The Mexican Medical Society, which met in San Luis Potosí, in 1894, named an organization committee for this reunion. This committee found a ready assistant in the President of Mexico, General Díaz, and thanks are due to him for the readiness with which he assented to invite the other nations to participate in this congress.

All the ministers have also lent their valuable cooperation to make the meeting a success, and the various scientific societies have cordially accepted the invitation extended to them. Special mention should, however, be made of the international committee having its seat in the United States, for arousing and maintaining an interest in the congress in the United States and Canada, and for inducing so many to come from those countries to assist at this meeting. Thanks were also extended to the municipal and district authorities, for their part in receiving the delegates to the congress.

The invitation to attend the congress has been accepted by the United States, Canada, Guatemala, Nicaragua, San Salvador, Honduras, Costa Rica, Argentina, Venezuela, Ecuador, Uruguay, Cuba, Hayti, and the French and Danish West Indies. Special delegates have been sent by most of the countries named, by several of the States of the United States, and also by a number of the medical societies in various countries of the western hemisphere. Five hundred and fifty physicians, ninety-six of whom are to be accompanied by their wives, have signified their intention to be present. Titles have been announced of two hundred and ninety-four papers to be read.

We may hope that the scientific results of this congress will redound to the good of humanity. Meetings such as this offer a consoling spectacle to those who have the good of the profession at heart, for they advance civilization and they make one feel the bene-

fits of association and give us a practical proof of the universal fraternity of science. All who come here, those from the distant north and those from the torrid equatorial regions, will meet to discuss medicine alone, and will leave behind all race prejudice and all questions of religion or politics. Those who come here at the expense of separation from family, making long, fatiguing, and dangerous journeys, abandoning for the time their lucrative practice—all for the sake of science, pure and simple—present a pleasing contrast to the picture drawn by Lord Byron of the merchants and traders who run like risks and suffer similar inconveniences, not for the good of their fellows but in the unquenchable greed of gain.

In closing, Dr. Licéaga extended a most cordial welcome to the delegates, in behalf of the medical profession of Mexico.

The Presidential Address.—DR. MANUEL CARMONA Y VALLE, the president of the congress, then delivered his address. At the end of the fourth century after the discovery of America by Columbus, the happy idea of calling together the physicians of the western hemisphere originated and was carried into effect in the United States. This first Pan-American medical congress was a perfect success, whether from the point of view of members, of importance of papers read, or of the welcome accorded the visiting physicians. None who took part in that first meeting can ever forget the warmth of their reception, and in behalf of the other nations of America he would say *gracias! mil gracias!* and he hoped those present would find that the Mexicans knew how to reciprocate, if not with such opulence, at least with a sincerity of affection. It was the speaker's privilege and pleasure (solely, he feared, on account of his age) to have been selected to preside over this second congress and to welcome the visitors.

Medical Education in Mexico.—Dr. Carmona took for his subject the history of medicine and of medical education in Mexico. It had been said that Spain repressed education in her colonies, in order to keep them in subjection; but that was a calumny, as far as Mexico was concerned, at least. Eight years after Mexico fell into the hands of Cortés, the college of San Juan de Letran was founded. The first viceroy of New Spain, Don Antonio de Mendoza, in 1534—thirteen years after the conquest—petitioned the king to permit the establishment of a university, and this was obtained in 1553. The first faculties were of theology and law, since at that time the science of medicine was but little esteemed. In 1578, however, a chair of medicine was established, there being but one professor, who taught all the branches of medicine in a course of four years. Candidates for this course were required to study previously Latin, and to make the courses of arts and astrology or mathematics.

In 1599 a second chair of medicine was established, and, later still, others were added. The first professors were appointed by the viceroy, but later the chairs were given after a competitive examination. The chairs were retained for life, and if any professor became too old for his duties, an examination was held, and a temporary professor appointed to serve for four years; but no full professor was appointed until the old one died.

In 1768 a decree was issued for the creation of a Royal College of Surgeons, with four chairs. This school graduated phlebotomists, dentists, bone setters, midwives, etc. The surgeons graduated from this school were called Romancist surgeons, in contradistinction to the Latin surgeons or graduates of the university.

In 1821 Mexico obtained her independence, and for some years the university continued as before, the Royal College of Surgeons changing its name to the

National School of Surgery. In 1830 it was ordered that no one should be admitted to the surgical school who had not previously obtained the degree of bachelor of philosophy. In 1831 an end was put to the distinction between physicians and surgeons, but one diploma—that of both medicine and surgery—being henceforth granted. In 1833 the university was closed and a general board of education was established, a number of schools being created, among them that of medical science. Then came a series of political changes, during which the medical school suffered many vicissitudes, owing to changes in locality, to changes in the government, and to pecuniary difficulties.

In 1842 the name of the medical school was changed from "Institution of Medical Science" to "The National School of Medicine," a name which it now bears. The speaker entered the school in 1849, which then occupied a part of the College of San Juan de Letran. In 1850 the professors of the school were informed that by yielding \$50,000 of their already overdue salaries they could obtain a permanent habitation. This was agreed to, and for two years all was peaceful; but in 1853 the building was seized by the government for use as a barracks. Lectures were then resumed in the College of San Ildefonso, where the school was entertained as a guest; but a year later the director of the college imposed such conditions that the medical professors felt themselves obliged to leave. At that time it was ascertained that the old acquisition building could be purchased, and the professors again gave up \$50,000 of their unpaid salaries. The peripatations of the school now came to an end. The salaries of the professors were very irregularly paid, and they had to depend in great part upon fees for examinations and the like; but since 1857 the salaries of the professors have been regularly paid, and the number of chairs has been gradually increased, five new ones having been added during the decade ending in 1877.

Dr. Carmona then spoke of the great prosperity which had come upon the country under the wise and beneficent administration of President Diaz, who was a ruler as great in peace as in war. Under him Mexico was rapidly advancing in material prosperity, but not alone in that, for, under the favorable conditions offered by the present era of peace, education was advancing with equally rapid strides. The School of Medicine has progressed along with other schools. At the time it was founded it had eleven chairs, from 1833 to 1877 five chairs were added, but from that date to the present the number of professors has been increased by ten, and very many assistants have been appointed.

The speaker then referred to the requirements of medical study in Mexico. No one is admitted to the study of medicine who has not passed a successful examination in the preparatory studies of five years' duration. These studies include mathematics, French, English, Latin, Spanish, figure and landscape drawing, physics, geography, chemistry, Greek roots, botany, zoology, logic, morality, history, and national and general literature. The medical course is one of five years, and embraces the following subjects: Descriptive anatomy and dissection, normal histology, elements of pharmacy, physiology, surgical pathology (two years), medical pathology (two years), operative and minor surgery, *materia medica* and therapeutics, clinical medicine and surgery, hygiene and medical jurisprudence, medical meteorology, obstetrics, pathological histology, bacteriology, ophthalmology, gynecology, and diseases of children.

Nosological Reforms.—THE PRESIDENT then referred to some of the questions which might profitably be considered at the present congress. In the first

place, the recent advances in bacteriological science had brought confusion into nosology, and a new classification was needed. We ought either to suppress the idea of inflammation as a distinct symptom, or, if that is admitted, we must agree that it may be caused by a number of micro-organisms. Again, we must not lose sight of the fact that in some diseases the microbe appears to be the fundamental part, as in leprosy and tuberculosis; while in others the microbe takes a secondary place, its ptomain being the active injurious agent, as in diphtheria and tetanus. Then, again, there are other diseases which resemble those of microbial origin, and possibly or probably are such, yet until we discover the germ we cannot assert that they are due to the action of micro-organisms. Such diseases are rabies, syphilis, small-pox, measles, and scarlet fever.

Unjustifiable Surgery.—The second subject to which he would gladly call the attention of the congress, he would put in the form of a simple question: "In the present condition of science, can surgeons be so certain in their diagnosis and so certain as to perfect asepsis and antisepsis, that they are justified in undertaking operations for the sake of satisfying the patient, when the operations may be of such character that the slightest accident or carelessness will jeopardize the life of the patient?"

Proprietary Remedies.—The third question was that of the enormous increase in the use of patent medicines. Little by little the drug stores are being transformed into simple warehouses for already prepared medicines, and in many places the druggist has seldom to compound a prescription, all the drugs ordered being already put up in bottles or boxes. When a formula is thought out by an educated physician and compounded by a competent druggist, we have some guarantee that the product will be what it claims to be; but when we use drugs already put up by some foreign manufacturer, there is no guarantee of their genuineness, and the physician can never be certain what his patient is taking. But even with the best guarantee, we cannot make an already prepared remedy fit every case; patients have idiosyncrasies which must be met intelligently, and no drug nor any set combination of drugs will benefit every case of anamia, of tuberculosis, or of dyspepsia. Patent medicines and proprietary articles should be left to the vulgar crowd, to those opinionated individuals who think they can dispense with the services of a physician and treat their own maladies.

In closing, Dr. Carmona expressed the hope that all his hearers would have an agreeable stay in Mexico, that their scientific labors would be crowned with success, and that this would be but the second in a long series of congresses, which would enrich the science of medicine and increase its repute in all the Americas.

Aims of the Congress.—DR. WILLIAM PEPPER, of Philadelphia, president of the first Pan-American medical congress, then delivered an address. It was regarded as especially appropriate, he said, that the second congress should meet in Mexico, since the first had received such cordial support from the government and medical profession of this country. He referred in complimentary terms to the great activity now displayed in Mexico in all scientific and educational matters. The Pan-American Medical Congress was established with definite objects, the most obvious of which was to secure reunion at a stated interval of the medical men of America, in order that a spirit of fraternal relationship might be promoted and that the great current medical questions might be discussed in a broad continental spirit. Of late it had been the habit of the ignorant to decry medicines as uncertain in their action. Some had drawn invidious compari-

sons between the rapid expansion of surgery and the less rapid progress of medicine, but physicians could turn with pride to the advances made in bacteriology, in the study of the infections, of the morphology of the blood and the properties of the leucocytes, and to application of these studies in the prevention and treatment of disease. When we contemplated the discoveries of Pasteur, of Behring and Kitasato, and of Metschnikoff, we had passed before us a dazzling vista of the probabilities as to the power of fortifying the system against infection already acquired and even of overcoming constitutional tendencies, as shown by the action of thyroid extract in myxœdema; but at least equal gain had been made in the direction of accurate diagnoses. The speaker then related some experiments in which he was able to see distinctly the heart pulsations by means of Roentgen rays emanating from a specially constructed tube. Another no less important work of these congresses was the promotion of public health, and it was the duty of the members to urge the recognition of public medicine by the appointment in the cabinet of every government on this continent of a secretary of public health. Dr. Pepper then spoke of the superior board of health of Mexico and predicted brilliant results from its labors. He referred to the settlement of the Venezuelan matter as being of great promise for the future of the nations of America, and also spoke in approval of the proposed establishment of a Pan-American archaeological society, making effective the resolutions of the association.

International Sanitary Legislation.—SEÑOR DON JOSÉ M. GAMBOA then delivered an address with this title. He passed in review, first, the discovery and colonization of America by the Spaniards and later by the English and spoke of the conquest of liberty, first by the English and later by the Spanish. These historical points led up to the question which formed the title of his address. The existence of legislative authority in the different countries of America was guaranteed by their independence, but the problem was how to excite the necessary exercise of this authority. The legislatures should deal with all matters of quarantine and hygiene, and the speaker proposed the following as adapted to secure the desired result: First, the Pan-American Medical Congress should establish a permanent committee in each of the capitals of the American nations and should maintain also a committee of initiative in one capital, preferably Washington. Second, whatever measure seemed, in the judgment of one of these committees, to deserve legislative action should be referred to the committee of initiative. Third, the latter should have all these projects read at the next medical congress. Fourth, the congress should discuss and vote on these suggestions, and if the latter were approved they should be referred to all the permanent committees, in order that each of these might urge upon its respective government the enactment of the project into a law. The speaker believed that by a plan such as this it would be possible to bring about the adoption of necessary and uniform sanitary laws, by all the American republics.

The session was then closed by the president of Mexico, Gen. Porfirio Diaz, who delivered a brief address of welcome to the visiting physicians and their wives, and expressed the hope that the labors of the congress would redound to the benefit of all the inhabitants of the new world.

Second General Session—Tuesday, November 17th.

Yellow Fever an Obstacle to Civilization.—DR. JUAN SANTOS FERNANDEZ, of Havana, delivered the opening address. The discovery of America, he said,

was the greatest event recorded in history, but it had not borne its legitimate fruit in the warmer parts of the western hemisphere, owing to the menace which yellow fever offered to European immigration. The material prosperity and advancement of North America was not attributable to any superiority of the Anglo-Saxon race over the Spanish, but solely to the fact that North America was free from yellow fever. Except for this scourge, Spanish America would be as populous and as prosperous as the United States. The lack of a population of European origin was the cause of the backward condition of Latin America, and the only obstacle to European immigration was the existence of yellow fever in epidemic form. It lay in the power of his hearers, Dr. Fernandez said, to provide a remedy for this evil, and Latin-American physicians should form a league for the extermination of the disease. It had been said that the infection came from the soil, and that we were powerless to prevent it; but this was a grave error. Isolation was the sole means of preventing the spread of yellow fever. Although we were, it might be hoped, on the eve of discovering a means of conferring immunity against the disease, we ought, nevertheless, to insist upon strict isolation. In this way yellow fever could certainly be stamped out, and then the tropics would offer an immense field for European immigration and enterprise.

Bacteriology, Hygiene, and Medicine.—DR. E. P. LACHAPELLE, of Montreal, Can., was the next orator, taking the above title for his address. After a brief introduction, he spoke of the influence upon hygiene of Pasteur's discoveries. This investigator, in showing that water, air, food, and all our surroundings may contain pathogenic germs, had thrown a new light upon the etiology of an entire class of diseases forming one of the chief causes of mortality; and since by the same discovery he had demonstrated the importance and efficacy of prophylactic measures, he placed hygiene in the front rank of the medical sciences, hygiene being but prophylaxis in action. The speaker then showed that the studies of Pasteur had never had any other aim than protection, and that it was only secondarily that they had rendered such immense service to practical medicine. It was worthy of remark that Pasteur's early studies, those which, perhaps, helped most to turn medicine into new paths, were also those which had contributed most to the advance of hygiene. His studies on anthrax had proved the virulence and the inoculability of its germ, and, at the same time, the possibility of attenuation of its virus. Indeed, in all his labors he seemed to be guided primarily by the idea of prophylaxis, and it is this which has made Pasteur one of the great benefactors of the human race. He it was who made of hygiene an exact science.

Dr. Lachapelle then showed hygiene utilizing the facts presented by Pasteur and basing all its action upon the foundation of isolation and disinfection. Hygiene, having become an exact science, was now greatly extending its field of action. The preservation of food stuffs, which had become such an enormous industry, was but one of the many useful applications of Pasteur's discovery. After this rapid study of the progress which hygiene had made in utilizing bacteriology, Dr. Lachapelle then reviewed the advances which hygiene had imposed upon the theory and practice of medicine. Infant mortality had been greatly reduced by alimentary hygiene. Antisepsis was merely prophylaxis applied to surgery. Other points touched upon were the dysenteric origin of purulent hepatitis, the conveyance of cholera and typhoid fever in water, the cure of scorbutus by vegetable alimentation, industrial and food poisoning—in all of which medicine was indebted to hygiene. But

the field of hygiene was still widening. Its laboratories were now in the service of the physicians. It showed him the nature of the disease which he treated, and enabled him to prevent its spread. The importance and the strength of hygiene rested upon the fact that it had but one aim, namely, the preservation of individual and public health. Modern nations understood this, and everywhere hygiene was receiving greater public recognition and was being taught in all the universities. When we should have accomplished the diffusion of the precepts of modern hygiene, and should have popularized a knowledge of the conditions of the spread of infectious disease, we might then hope that the people themselves would second our efforts to preserve public health, and then the execution of sanitary laws would give results which would be the pride of civilized nations.

Orrhotherapy.—DR. RAFAEL LAVISTA, of Mexico City, then delivered an address, taking for his subject the treatment of disease by the injection of toxins and antitoxins. The question was of intense interest to all physicians, since it seemed to point a finger toward the goal to which all aimed and which was the ultimate object of every branch of medical study, namely, the cure of disease. The researches of Pasteur, Koch, Roux, Behring, and many others had paved the way for this new science, which was as yet in its infancy but which offered hopes of a wonderful future. It was as yet too early to speak with any positiveness of the results of orrhoterapy, but it was only by collecting and recording the experiences of many observers in many lands that we could obtain the necessary facts upon which to establish the indications for this method of cure.

Dr. Lavista said that he wished to record his own experience and that of his Mexican colleagues, and would not dwell upon the results obtained by observers in other countries, with which his hearers were already familiar. He therefore reviewed very briefly the principles upon which orrhoterapy was established, and proceeded to give the results obtained by him in the treatment of a number of infectious diseases, referring also to the methods employed when these differed from those in use elsewhere.

In tuberculosis a number of experiments had been made, but the results obtained were not of a satisfactory or encouraging nature. In leprosy also no distinct benefit had followed the injection of serum; in some cases there seemed to be a slight improvement, but it was usually very evanescent and the patients soon relapsed into their former condition. A number of injections of toxins had been made in cases of cancer with varying results. Like other observers he had obtained the best results in cases of sarcoma, but he had never seen any benefit follow when the neoplasm was an epithelioma. He had at times been pleased with the effect of double toxin injections in sarcoma. In syphilis quite marked temporary benefit had been observed as regarded an amelioration of the more distressing symptoms, such as the headaches, the pains in the bones, the skin eruptions, and the like, but a cure of the disease had not been obtained in a single instance. The fact, however, that the accidents of the disease could be controlled by orrhoterapy was one of great importance, and this would be a decided gain in the therapy of the disease, even if we never succeeded in eradicating it entirely from the system by this means.

Diphtheria was a very uncommon disease in Mexico; consequently the speaker's experience in its treatment had been slight; what he had seen of orrhoterapy was good, but he had seen so little of it that he would not venture to formulate an opinion concerning it, in the presence of those of so much wider experience. Typhoid fever was also rare. The results of serum

injections in typhus had hitherto been *nil*; in mild cases the patients recovered, in severe ones they died, and as yet no specific treatment had been discovered. Experiments with serum were being continued, however, and it was possible that with a greater approach to perfection in the methods of preparing and using the serum more satisfactory results might be obtained.

In septicæmia no great benefit had been obtained thus far, and of his personal experience the speaker could say nothing, for he had had none. In tetanus he had employed antitoxic serum to some extent, but his best results had been obtained by the use of corrosive sublimate in fairly large doses.

Dr. Lavista then spoke of the use of injections of normal salt solution after extensive hemorrhage, and as a preventative of shock after surgical operations. His results had been almost uniformly excellent. He had employed the intravenous method chiefly, but had occasionally passed the fluid into the subcutaneous connective tissue of the abdomen. The latter method was more troublesome, and the results obtained were no better; the injection directly into a vein was easy and perfectly safe if the proper precautions were employed.

Leprosy in America.—DR. RICARDO CUTIRREZ LEE, delegate from Colombia, took "The Prophylaxis of Leprosy" as the subject of his address. He spoke first of the danger for the future that there was in the continual spread of leprosy unless prophylactic measures were speedily adopted. In Colombia, especially, the situation was grave by reason of the increase of this disease, but there was no occasion to despair. He compared the condition of that country to that of England, France, and Germany in the fourteenth, fifteenth, and sixteenth centuries, when leprosy prevailed to an enormous extent. He believed the spread of the disease could be checked by the adoption of certain economic and social measures: first, obligatory public education; second, the opening of ways of communication so as to facilitate communication between different countries and different parts of the same country; third, immigration of people of the white race from Spain or elsewhere, this immigration being encouraged by government bounties. In this way new blood would be introduced and the habits and customs of the natives would be changed. Leprosy would no longer find a soil favorable to its growth and it would die out, as it had done under similar influences in European countries.

(To be Continued.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, October 22, 1896.

SIMON MARX, M.D., CHAIRMAN PRO TEM.

An Alloy for Instruments.—DR. GRISWOLD presented some gynecological instruments, including a vaginal speculum, cast from what he said was an alloy of silver, but which had about the weight of aluminum. Its elasticity was represented to be about that of brass. It did not tarnish. The cost was about one dollar and a half per pound.

Residual Water in Cystoscopic Work.—DR. P. A. HARRIS presented an instrument with which to withdraw the residual water when doing cystoscopic work. He said the method which Dr. Kelly employed, it seemed with entire satisfaction, had resulted in his hands causing a little injury to the bladder surface, attended by slight hemorrhage. That method consisted in withdrawing the small amount of residual water or urine by suction. Others had absorbed the water by a piece of cotton held in forceps; but there

was danger of losing the cotton in the bladder, and difficulty in causing it to absorb the water when compressed in the blades of the instrument. The instrument presented by Dr. Harris to replace the other methods, some of which have been mentioned, consisted of a glass tube with a conical distal end. Into this tube a pledget of cotton was inserted down to and projecting beyond the end. The somewhat narrowed opening of the tube would prevent the cotton from escaping into the bladder. It readily absorbed the water. Tubes of two or more sizes were made.

DR. POLAK said he used, as a means of taking up the residual urine, an ordinary applicator carrying cotton.

DR. VALENTINE used uncut match sticks, ten inches long, in the male urethra. Cotton could be wound on both ends, each end being used in succession in drying out the posterior urethra. He thought it might be a desirable method in cystoscopy of the female bladder.

DR. VINEBERG performed cystoscopy on the female with the patient in the knee-chest position. In this position any residual water in the bladder flowed toward the fundus, and there was no necessity for using any of the instruments spoken of this evening.

Infantile Uterus; Sterility.—DR. BERNARD GORDON presented a woman, twenty-seven years of age, in illustration of a condition which was seen every day in clinics for the diseases of women—infantile uterus. She had been married six years, had had no children, no miscarriages; had first menstruated when fifteen years of age, a year later had her second menstrual period, after which she was regular until her marriage. She menstruated a few weeks after her wedding, then ceased altogether. When he examined her and found the cervix measured an inch, the body but half an inch, he was surprised that with the uterus in such an infantile state she had menstruated regularly five years.

Gonorrhœa in Women.—Dr. Gordon then read a paper on "Gonorrhœa in Women" (see page 740).

The Birth of a New Remedy Gives Him Pain.—DR. F. C. VALENTINE said he must confess that the birth of a new remedy for gonorrhœa gave him pain—not because he believed there was but one remedy for the disease, but because of the scores of disappointments which we had had in the employment of new drugs. His experience with argentamin had been as short as it was not sweet. The patients did not improve. A friend of his in Berlin wanted him to try argonin, and he did so religiously; but his patients damned him irreligiously. In fact, he failed to see what was to be gained by using a drug which was directed toward killing the gonococcus. His belief, founded on experience, was that there was only one method of destroying the gonococcus, namely, to remove its pabulum—destroy its culture medium. To direct remedies against the gonococcus itself would fail. He did not propose to dwell again upon hydrostatic irrigation, nor would he assert that hot water and permanganate of potassium would cure all cases; but those who tested them would not waste time on other methods. In some cases it was necessary to use nitrate of silver, 1 to 5,000 or 1 to 2,000, and it was necessary at times to add to the permanganate of potassium corrosive sublimate. Regarding prevention of gonorrhœa, if early marriage would do it, what would become of specialists in this line of work? Marriage did nothing of the kind. The author had spoken of regulating prostitution. There was no place where it was better regulated than in Berlin, yet in that city there were only two thousand regulated, while there were twenty-five thousand who were not regulated. One of his assistants had asked each of his patients where he had contracted gonorrhœa, and

the answer was almost exactly in accord with statistics published by a European author: venereal disease, especially gonorrhœa, was oftenest contracted from, in the order named, factory girls, house servants, seamstresses and milliners, married women, kept women, lastly, prostitutes. It was the prostitute's business to keep herself clean, and she was more likely to do it than the other unfortunates named. If it was intended to regulate the female disseminators of gonorrhœa, let it be directed toward those who did the largest amount of harm. He would rather the author would permit the general practitioner to treat gonorrhœa, but would teach him to do it properly. If the work were thrown entirely upon the specialists, they would have to labor forty-eight hours a day. Regarding marriage and contamination of the wife, Dr. Valentine thought that any man who loved a woman enough to give up his liberty, his life, for her, ought to be willing to spare half an hour for several days before the wedding, to be cured of all signs of urethritis.

Gonorrhœa in Children.—DR. LOUIS FISCHER said said he had not seen in children more than five cases of true gonorrhœal discharge, such as was seen in the adult, in seven years. They had, however, in the last two years treated at a large city dispensary not fewer than forty-two cases of true vulvo-vaginitis in children, and in twenty-four of these the gonococcus was found. In the majority of the cases the disease was a sequel of other diseases, especially diphtheria. The most obstinate of the cases came after diphtheria. In ten per cent. there was ophthalmia as well as vulvo-vaginitis. Dr. Valentine's statement that treatment should not be directed to removal of the germ was in accord with the views held for years by the speaker, that one should rather seek to bring the system up to as near the normal point as possible in all germ diseases, in order that the germs might have no culture medium suitable for their propagation. His treatment had been, in addition to constitutional treatment, thorough irrigation of the vagina twice a day with warm salt solution, a teaspoonful of table salt to a pint of water, and wearing a pad of sterilized gauze during the intervals. Sometimes he used a solution of pyoktanin, 1 to 10,000; sometimes of bichloride solution, 1 to 10,000.

DR. VINEBERG said surgical treatment should not be employed in the first attack of acute gonorrhœal salpingitis. Surgery should be reserved for recurring attacks, and then the sooner the diseased tube and ovary were removed the better; otherwise, the other side would be likely to become involved.

DR. R. A. MURRAY did not believe that gonorrhœa was the cause of so much salpingitis as some persons had claimed. He thought gonorrhœa was usually cured; otherwise, instead of there being few women sick with salpingitis, there would be few who were not so affected. The working classes were more exempt than the upper classes. It was the people at the top of the social ladder who had kept the disease going, and it was mostly in that class that we saw the effects of gonorrhœa. The first thing to insist upon when one saw a case was to carry out the treatment to the end. The physician should have his own medicine and require the patient to come for his treatment. If he were given a prescription, it would pass from one patient to another, and would be applied in stages of the disease when it ought not to be used. He believed thoroughly in the antiseptic method. Cleanliness could be secured only when aided by antiseptics. The uterus should be entered only when it was infected; otherwise, the doctor would be the cause of infecting it. He again mentioned six cases of gonorrhœal salpingitis reported by him, in which the tubes emptied pus into the uterus, were cured, and the women subsequently bore children. In all of them certain gynecologists had said the tubes would have to come out.

Dr. Murray used permanganate-of-zinc solution in gonorrhœa in preference to permanganate of potassium, believing that it not only cleansed the parts, but was beneficial in contracting the mucous membrane and preventing penetration of the gonococci. He had seen four deaths from acute endocarditis, occurring less than two months after contraction of gonorrhœa. For cleansing, he first required the patient to irrigate with quarts of borax solution, then employ permanganate of zinc, one grain to the pint to begin with, increasing up to one grain to the ounce. For the urethra he made the applications himself.

Dr. SELL reported a case of gonorrhœa in a woman from the South, who went on to have all the "itis's" one could think of, and who, after having been abused by certain advertising specialists, came to New York and, under long and painstaking treatment, mostly constitutional, finally quite recovered.

A Disease Principally of Filth.—Dr. H. L. COLLYER regarded gonorrhœa as a disease principally of filth, and it thrived on a filthy soil. But not all filthy women had it. He did not believe it was present in so many as eighty per cent. of gynecological cases. One writer had divided the cases into three classes, according to the depth into the tissues that the gonococci had penetrated. In the first stage, when only the epithelium was affected, the disease could be easily eradicated in women. He had not seen gonorrhœal salpingitis relieved short of removal of the tubes. He did not believe in early marriage as a prevention, nor in establishing assignation houses, for prostitution was not a necessity.

Dr. GORDON said, in some concluding remarks, that gonorrhœa was a local disease and required local treatment. A treatment, such as he had mentioned, might be appropriate in women when not in men. He had not recommended early marriage, but simply had stated that it would be more physiological. The general practitioner had a right to his livelihood, but he thought the specialist could treat gonorrhœa more successfully.

Bladder Tuberculosis Successfully Treated by Kelly's Method of Direct Medication.—Dr. JOHN O. POLAK read the history of the case. It was that of a girl, about eighteen years of age, who had been treated eight years in early life for hip-joint disease, which healed with limited motion and shortening. She menstruated at fourteen. About three years later, when in an anæmic state, she began to suffer from frequent and painful micturition and hæmaturia. She was seen by several specialists, who diagnosed urethral fissure and chronic cystitis. Dr. Polak was called in in an attack of hæmaturia, when more than the usual quantity of blood was lost. He gradually dilated the urethra, introduced Kelly's speculum, but the source of the hemorrhage could not then be determined by direct inspection. The finger was introduced, and an ulcer the size of a silver dollar was detected at the base of the bladder, including part of the trigone. It was raised, and ragged, and studded with tubercles. They were removed with the finger. The treatment until cure was effected consisted of washing out with boric-acid solution and applications to the ulcer of iodoform in linseed oil or glycerin; later, of strong nitrate-of-silver solution, and irrigation with salicylic-acid solution. Tubercle bacilli, which had been present in the urine, entirely disappeared, the ulcer healed, and urination became normal.

Dr. VINEBERG related two cases with bladder symptoms, which had been attributed to disease of the kidney, etc.; but cystoscopic examination showed fissure near the ureteral orifice, which he proceeded to cure by direct applications of nitrate of silver. In ninety-five per cent. of cases of supposed bladder trouble, he

had found the difficulty located near the base of the bladder, which showed how useless it was to make general injections when the disease could be much more satisfactorily treated by direct applications.

Dr. P. A. HARRIS related a case of tuberculosis, in which he thought bladder trouble was secondary to tuberculous degeneration of the kidney.

Dr. VALENTINE asked a question, and Dr. POLAK closed the discussion.

SECTION ON GENERAL SURGERY.

Stated Meeting, November 9, 1896.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Plastic Operation on the Ear.—Dr. W. W. VAN ARSDALE presented a child, six months old, which was brought to him four weeks ago with congenital deformity of the left ear. The left face was also small. The ear was drawn down; the tip and back were adherent in front of the meatus, so that the child could not hear on that side. He freed the attachment in front, but the ear then drooped, and in order to overcome this he took out a piece here and there until it had come to stand up fairly well and was of good shape. He asked for suggestions how best to maintain the lobe so that it would not droop. There was also tendency to contraction, as usual after such operations. The external auditory canal and meatus were now free, and the child could hear on that side.

Tuberculosis of Axilla following Tuberculosis of the Hand.—Dr. R. A. SANDS presented a boy who last spring cut his hand with some object in a back yard where a tuberculous patient was in the habit of expectorating. The boy was brought to Dr. Sands in July, with a sluggish sore of the hand and a swelling in the axilla. He let out pus from the axillary abscess and scraped the sore on the hand, but was surprised in September to find that the wounds were not healed. Tuberculosis being suspected at this time, microscopic examination was made and this diagnosis was confirmed. He then cleaned out the parts more thoroughly and the wounds healed. The case was of interest as being probably one of tuberculous infection from wounds of the hand by a contaminated instrument and spread of infection through the lymphatics to the axilla. There was no family history of tuberculosis.

Result of Bassini Operation.—Dr. W. B. COLEV presented a man in illustration of permanent good result from a double Bassini operation for hernia after failure by another method practised previously. The cure had existed three years and seven months.

Irreducible Hernia Complicated by Inflamed Appendix in the Sac.—Dr. JOHN B. WALKER presented a boy of seventeen years, who was said to have had a rupture since a baby. He wore a truss from time to time. In 1895 the hernia became irreducible, and at times would be larger and cause pain. Dr. Walker operated in October of this year, found a large mass of omentum and another mass, the size of his thumb, which proved to be the appendix, inflamed and club-shaped at the lower end, adherent to the testicle, and containing over a drachm of sero-purulent fluid. The adhesions to the sac and omentum were firm, and the probability was that the pain from which the boy had suffered had been caused by pressure of the truss upon the appendix. Dr. Walker excised the appendix and performed Bassini's operation for closure of the inguinal canal with complete success.

Hydatids of the Back.—Dr. SAMUEL LLOYD presented a man on whom some weeks ago he had ope-

rated, removing a large and many smaller hydatid cysts from the back. Among the points of interest in the case was the fact that the patient had letters from many surgeons, stating that they regarded the tumor as inoperable sarcoma. The man was paraplegic, both as to motion and sensation, caused, as the neurologists informed him, by pressure on the cord in the region of the seventh or eighth dorsal vertebra. The tumors extended from the sacrum to the right scapula. Dr. Lloyd said he was at first misled by the letters to think it was sarcoma, but on reflection it seemed hardly likely there would be multiple sarcomatous tumors up the back and not elsewhere. Hydronephrosis was thought of, but was not sufficient to explain the chain of tumors. Some fluid being withdrawn, it was shown to be hydatids. An extensive incision, reaching from over the right scapula down to the sacrum, was made and the hydatid cysts were removed. The man recovered both from the operation and the cord symptoms. The active symptoms had dated from 1889.

Discussion on the several cases being in order, Dr. CURTIS said he then had a case of deformity of the ear similar to that in Dr. Van Arsdale's case, except that there was no bony canal, and all that could be done was to straighten the ear for the cosmetic effect.

Dr. WYETH suggested anchoring the ear to the scalp to prevent drooping. He also thought a strip of platinum might be inserted between the outer and inner skin near the edge of the ear, whereby it could be made to assume the desired form. Platinum did not corrode, and would remain indefinitely if introduced with all aseptic precautions, so that primary union would result. Such had been his experience in operations on the nose.

Dr. LLOYD, referring to Dr. Sands' case, said that in New York tuberculosis had been found limited chiefly to certain houses occupied at a prior time by consumptives. The case related pointed to the danger of local infection.

The chairman, Dr. CURTIS, mentioned the case of a woman whose husband died of tuberculosis. She had nursed him and broke the spit cup, which infected a wound of the hand and caused tuberculous inflammation of the tendinous sheaths. The parts healed after he removed the diseased structures. She had been in good health in other respects, and was well when last seen after the operation.

Dr. TUTTLE mentioned the thinness of the hernial sac in the uninfamed area in Dr. Walker's case.

Dr. COLEY spoke of the indication for removal of the appendix vermiformis when in the hernial sac. He had seen about eight cases, but had removed the appendix in only two, and then only for gangrene or strong adhesions. Ordinarily he would leave it.

Dr. WALKER concurred in this view.

THE CHAIRMAN remarked that it was rather contrary to the practice of some who always removed the appendix on sight, whether it were diseased or not. In one case the chairman had found the appendix in a left inguinal hernia and returned it, and Dr. Erdman had yesterday made an autopsy in such a case.

Dr. COLEY had seen the appendix in a left inguinal hernia in a child.

Dr. Coley had seen Dr. Lloyd's case of hydatids of the back, had considered it inoperable sarcoma, and congratulated Dr. Lloyd on his correct diagnosis and very successful operation.

Formalin in the Treatment of Septic Wounds.

—Dr. EDWARD M. FOOTE read a paper relating experience with formalin, dried in gelatin and powdered, in the treatment of wounds, more especially suppurating wounds. Schleik had reported two hundred wounds treated by filling them with this preparation, and claimed that in every case he had obtained aseptic

union—blood clot formed with the gelatin in the wound and union took place without any suppuration. Dr. Foote had had no such results, yet they had been very satisfactory. He had chosen suppurative wounds, forty-five cases, because if the powder would destroy sepsis and cause healing in these, it was more than probable it would prevent formation of pus in clean wounds. He had been able to follow thirty-five of the cases. In three of these it was a failure; in the remainder the gelatin dried the wound up, checking suppuration, and led to healing in a comparatively short time by granulation. As was well known, formalin was antiseptic, and when dried in gelatin it remained a longer time in the wound. The powder disappeared as the wound healed, perhaps partly by absorption, partly by drying up. It caused a little pain. Acetanilid was tried in a few cases, was painless, but did not prevent suppuration. The author concluded that formalin in gelatin powder was a marked advance in the management of suppuration, and was of special benefit when there was moderate cellulitis in the case.

Dr. Foote presented a man with glanders infection of a wound on the chin, to which this powder had been applied. There was now no suppuration, but swelling and induration had increased rather than decreased. Constitutional symptoms were absent.

Dressing of Balsam of Peru in Castor Oil.—Dr. GALLANT called attention to a dressing which Dr. W. W. Van Arsdale had used for wounds over ten years, consisting of about five per cent. of balsam of Peru in castor oil. Gauze was soaked in this and introduced into suppurative wounds or abscesses. Many abscesses when simply emptied and filled with this dressing became entirely free from pus within three days and healed. Cellulitis nearly always subsided in twenty-four hours and pain disappeared at once. Of twenty-eight thousand cases so treated, ten thousand six hundred and thirty-three were of abscess. Drainage was not necessary with this dressing.

Dr. COLE thought the formalin dressing did more than simply permit drainage; it seemed to act by antiseptics and removal of the suppurative process, after which healing took place as when a scraping operation had been performed.

Dr. DEGARMO said he had had occasion to use formalin gelatin in a case at the hospital last spring, and the result seemed to be so remarkable that he spoke of it to the house surgeon, who had since employed it in a number of cases with, it seemed, equally satisfactory results.

Dr. R. A. SANDS had tried the formalin gelatin in a few cases and had been very much disappointed. In some cases the wounds healed rapidly, but in a number there was scabbing, which he thought was not desirable in suppurative wounds, and in some there were more disagreeable results. It did not control the cellulitis. He had used the dressing of Dr. Van Arsdale, balsam of Peru in castor oil, with decided benefit.

Dr. JOHN ERDMANN had used formalin solution on a sinus following removal of the inferior maxilla, and he thought it would kill his patient, for within two hours it began to produce hardening and most disagreeable results.

Rupture of the Bladder.—Dr. John Erdmann related a case of rupture of the bladder in a man, without known cause. The patient was brought to the hospital drunk, and while in the hospital symptoms pointing rather indefinitely to rupture of the bladder manifested themselves. He made abdominal section and after considerable search found an opening of three-eighths of an inch in the bladder, which had permitted leakage into the peritoneal cavity. The man recovered.

SECTION ON GENITO-URINARY SURGERY.

Stated Meeting, November 10, 1896.

F. K. OTIS, M.D., CHAIRMAN.

Initial Lesion of Syphilis on the Hand.—DR. G. K. SWINBURNE presented a man with the initial lesion of syphilis on the hand, followed by roseola and other symptoms of syphilis. The epitrochlear gland was enlarged. The source of infection was probably from inoculation of a sore, present on the hand, by using a towel which a fellow-workman who had syphilis used.

THE CHAIRMAN remarked that when he first saw this lesion there was some question of its being syphilitic, but at present it was perfectly typical of chancre.

DR. J. BLAKE WHITE had found on investigation that when one or both epitrochlear glands were enlarged in cases of suspected syphilitic lesion the diagnosis of syphilis could be made with safety nine times in ten.

Healing of a Chronic Suprapubic Sinus without Operation.—Dr. Bangs being absent, the case was shown by DR. PETERSON. The patient had come to Dr. Bangs in July, with a history of operation for stone in December, 1895, and a second operation subsequently. Both suprapubic and perineal cystotomy had been performed. The sinus above the pubes refused to heal, but the patient had had such disagreeable experience with operations that he refused further operative interference. By rendering the urine bland and making patient use of simple measures the wounds had quite or nearly healed.

Whalebone Filiform Urethral Dilator.—DR. GUI-TERAS presented Dr. E. A. Banks' whalebone filiform dilator. The instrument was of filiform size at the distal end, and gradually enlarged. The small end, which would pass through a narrow stricture, coiled up in the bladder as the instrument was pushed farther along to dilate the stricture.

Trocar and Cannula.—Dr. Guiteras presented a trocar and cannula, the latter being a modification of the grooved director, for use in perineal operations for tight stricture. The knife could be passed along the groove.

Stone Obstructing the Urethra in a Child.—DR. SAMUEL ALEXANDER presented a stone which he had removed by operation from the urethra of a child, three years of age, after symptoms of urinary obstruction had existed for three months. The urinary symptoms had gradually increased until only one or two drops would pass every few minutes. The stone was phosphatic with an oxalate nucleus. The latter had probably passed down from the kidney and lodged in the urethra, where it increased by phosphatic deposit. He removed it through an incision into the membranous urethra, pushing it back to that point with a staff.

The chairman, DR. OTIS, thought stones could best be removed from the urethra by pushing them back into the bladder, there crushing them, and washing them out.

DR. ALEXANDER would agree with the chairman if the stone was in the first place in the membranous urethra and the canal was large enough not to require dilatation.

The Treatment of Strictures of the Male Urethra.—DR. JOHN A. WYETH read the paper. He would deal only with organic strictures due to fibrillation of the connective tissue which resulted from cell proliferation under the stimulus of an infectious inflammation, specific or non-specific. Clinically strictures of the urethra might be divided into three groups, according to their location: 1. Those in the anterior half-inch of the urethra; 2, those between this point and the bulb; 3, those in the bulbo-membranous portion.

A true organic stricture of the meatus was rare, but narrowing out of proportion to the lumen of the urethra was not infrequent. The majority of cases in his experience had resulted from the abuse of urethral syringes in the hands of the patient. Applications of corrosive substances were also causes. As a rule, he incised these strictures along the middle line of the floor, but when there was considerable cicatrization he did not hesitate to incise the roof or sides. Interrupted dilatation was the after-treatment. He treated stricture in the second division either by direct incision or by modified divulsion. When the stricture would admit the Otis urethrotome, after carefully locating the anterior and posterior boundaries, he put the stricture fairly well on the stretch and passed the blade back and forth once or twice along the middle of the roof. He then separated the bars of the instrument still farther, and practised divulsion if the stricture bands yielded readily, otherwise the still unyielding fibres were divided. It was his aim not to wound the urethra more than half an inch in front of and behind the stricture. If the Otis urethrotome would not pass, he made partial preliminary dilatation with the dilating filiform bougie of Dr. E. A. Banks—one of the most useful instruments ever invented.

Stricture of the bulbo-membranous portion was far the most difficult to deal with satisfactorily. In the rare cases in which the Banks dilating filiform bougie would not pass, or in which there was perineal abscess or urinary fistula, he performed external urethrotomy or perineal section.

A large proportion of strictures at the bulbo-membranous junction could be relieved by a modification of the internal cutting operation. For the last ten years he had practised this method in a large number of cases and in not a single instance had he met with a result which contraindicated the procedure, and he was firmly convinced that perineal urethrotomy was done in many instances when a less formidable procedure would suffice. The method was as follows: Presuming that the stricture would not admit the urethrotome, the anesthetized urethra was injected with sterilized sweet oil, some pressure being used in order to force a small quantity through the obstruction. As was well known, the cut-off muscle readily yielded to hyperdistention of the urethra. A Banks dilating filiform was introduced and the stricture partially divulsed until it would admit the urethrotome, the straight instrument being used, as for the anterior portion. It usually required a little force for its passage. He then gave the compressor urethra two or three minutes to get tired of the grip with which it seized the instrument, after which a better idea of the density and tightness of the stricture could be obtained. Without any separation of the bars of the instrument, the knife was drawn from behind forward along the roof of the membranous portion of the urethra. The bars of the instrument should now be separated, and, if the bands yielded readily under ordinary pressure, divulsion was accomplished, the fibres tearing in the line of the partial incision already made. If the instrument blocked as the screw was turned, the effort at divulsion should cease, the blades be approximated, then separated very slightly, and the incision repeated. Divulsion could then be accomplished accurately and satisfactorily, without danger of breaking the instrument.

This modified method of divulsion was to be preferred to the simple divulsing instruments which were used without incision, because in the one the surgeon intelligently selected the line of cleavage, while with the other it was blind explosion in any direction. After divulsion as described, interrupted dilatation was carried out. For this purpose he preferred the straight sound to the curved instrument. In broad dense

strictures it might be necessary subsequently to pass a sound once or twice a month to prevent recurrence. When early reconstriction took place, requiring so much attention as to be annoying to the patient, a perineal section should be advised.

Regarding sterilization of the urethra before operating, the author effected this by local cleansing and rendering the urine sterile. For the latter purpose he administered twenty drops of a mixture of two drachms of oil of gaultheria and one drachm of salol three or four times a day. This would sterilize the urine in twenty-four hours. Locally he irrigated the urethra with permanganate of potassium, 1-3,000, for five minutes before the operation, or by ballooning the canal three or four times under sufficient pressure to overcome the cut-off muscle and thus reach the whole canal.

Anæsthesia could be secured from the meatus to the compressor urethræ by using from one to three drachms of a two to four per cent. solution of cocaine according to the susceptibility of the patient. Anæsthesia of the membranous portion could be obtained by carrying the Keyes-Ultzmann syringe point down to the cut-off muscle, pushing it slightly within, and injecting ten to fifteen minims of a four-per-cent. solution. Anæsthesia beyond the cut-off muscle was practically impossible, because the urine was in contact with the cocaine, diluting it.

Hemorrhage was controlled by external pressure, using a compress of cotton and bandage.

Dr. Wyeth had not used electrolysis. When it could be proved that cicatricial tissue could be dissolved by an electrical current without of itself producing an eschar, he would be compelled to accept the superiority of electrolysis over urethrotomy. Until then he would believe in the operation just described.

DR. R. W. TAYLOR opened the discussion. He had never seen strictures of the meatus due to injections. They were usually caused by venereal lesions. He was unalterably opposed to overdilatation or dilatation of the urethra. He thought the large number of cases of crooked penis seen of late years were due to turning up of the urethrotome and cutting, and that most of the mischief was done by the overdilatation rather than the cutting. The cut would heal up; the injury from overdilatation would remain. When dilatation alone was not sufficient, a cutting operation might be resorted to, but it was only a prelude to dilatation at best. Overdilatation should never be made. He had had considerable experience with Fort's method of electrolysis, and had found it a very valuable method in many cases.

DR. ALEXANDER agreed with Dr. Wyeth in the treatment of stricture at the meatus and in the anterior portion of the urethra. In stricture at the bulbo-membranous junction he followed his teacher, Dr. Keyes, and dilated. The results were as permanent as by incision. But if the patient could not spare the time he cut; also when the stricture was dense and broad he used the knife, but in marked cases it was best to make perineal section and dissect out the stricture material. First he would treat the urethral discharge, get the urethra in fairly aseptic condition, then overcome the stricture, and then it would be possible to cure entirely the existing inflammation.

DR. CULVERT no longer believed in using the very large sounds, and had learned while in Vienna that Ultzmann was satisfied to get the urethra up to No. 26.

DR. SWINBURNE avoided instrumentation of the urethra until the canal had been put in as healthy a condition as possible without it. After cleansing treatment and reduction of inflammation in the urethra and bladder, strictures could be treated with much greater safety.

DR. F. C. VALENTINE had treated ten strictures by Fort's method of electrolysis, with two absolute fail-

ures and eight successes. He thought those who followed the method of treatment of Oberländer had no reason to complain of their results.

DR. KLOTZ agreed with Dr. Taylor that strictures in the anterior portion or at the meatus were due to chancres or chancroids. Overdilatation in the anterior urethra resulted in leaving the urethra as a bag without any elasticity, so that the patient was unable to expel his urine properly.

DR. EUGENE FULLER feared that those who should read the paper would be led to cut too much, although that might not be the author's practice. The last few years there had been too much cutting of the urethra. Yet there was a place for cutting, especially in the deep urethra. He thought abundant diuresis would be of more benefit than attempts to render the urine sterile by administering drugs by the mouth.

DR. GREEN said that at clinics he had observed some of the unfavorable results of cutting operations: 1, cases in which the Otis urethrotome had been used and was followed by deformity; 2, in which external urethrotomy had been done, some nerve cut, and the patient left impotent; 3, in which nearly the whole lower portion of the urethra had been a mass of cicatricial tissue and an operation (divulsion) had led to destructive sloughing. Many strictures could be prevented by attention to a urethritis accompanied by small ulcers.

DR. WYETH thought there was not a great distance between himself and Dr. Taylor or the other speakers. He had for a long time practised simple dilatation, but by the method described in the paper he got as good a result in a much shorter time. He believed if there had been deformities the patients would have returned. He had seen no deformities. Organic stricture was never absolutely cured, but there might be no subsequent obstruction. Cicatricial tissue always remained wherever present.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

GASTRIC VARIX—RESECTION OF DILATED SIGMOID FLEXURE—NEPHRECTOMY FOR RUPTURED KIDNEY—VAGINAL HYSTERECTOMY—THE MEDICO-CHIRURGICAL DINNER—HOSPITAL REFORM—BERIBERI AGAIN—LIBRARIES FOR HOSPITALS—DEATH OF DR. GEORGE HARLEY.

LONDON, October 30, 1896.

A RARE case was brought before the Clinical Society of London on Friday by Dr. Cronier Lancaster, of Swansea. It was gastric varix which ruptured, bringing about fatal hæmatemesis. He showed the part of the stomach containing the varicose veins. The bowels acted twice on the day of admission (July 28th), the stools being dark and tarry. From the history gastric ulcer was diagnosed. On August 7th the patient, a married woman aged thirty-six years, became unconscious and remained so until her death at 11:30 P.M. She had not vomited once while in the hospital. The bowels acted on August 5th and 6th; the stools were pale and formed; but on the day of her death she passed one stool containing freshly poured-out blood. At the autopsy, sixteen hours after death, the principal points observed were as follows: 1. Several branches of the gastro-epiploic veins in the great omentum and gastric submucosa were typically varicose. 2. The largest of the gastric varices presented on its upper surface a small circular smooth-edged aperture about the size of a pin's head. 3. Except for the varices the mucosa of the whole of the digestive tract was healthy. 4. No cause for the

varicose state of the veins was discovered; the thoracic and abdominal viscera were healthy. 5. There were no left kidney and no left adrenal. Dr. Lancaster said that varix of the veins of the stomach was apparently of extreme rarity, but suggested that a certain number of cases supposed to be of gastric ulcer, cases in which hæmatemesis is the only prominent symptom, might in reality be cases of varix.

Mr. G. H. Makins observed that if physicians could diagnose this condition in the stomach the arrest of the hemorrhage might be effected under far more favorable conditions than in the case of ulceration, and the operation would not be much more dangerous than for the removal of a foreign body.

Dr. Kingston Fowler, referring to the cases of pseudo-hæmatemesis in association with cirrhosis of the liver, in which blood came from the veins of the œsophagus and cardiac end of the stomach, mentioned that in a recent post-mortem examination at Middlesex Hospital this condition was found to exist.

Mr. H. H. Clutton related a difficult case of resection of dilated sigmoid flexure for chronic obstruction. The patient was a lady, aged fifty, who had suffered as long as she could remember from chronic constipation and occasionally from attacks of distention accompanied by pain. During the last five years she had had frequent attacks of obstruction, lasting from five to ten days, accompanied by great distention of abdomen and occasional vomiting. Her trouble increased so much that in hope of obtaining relief she gladly submitted to operation. On November 19, 1895, a very large dilated sigmoid flexure was removed, and the two ends of the divided bowel were united by a Murphy button. The operation was perfectly successful except for the fact that the button remained *in situ*. She has had no attacks of obstruction since the operation, and has led an ordinary life. She has been so comfortable, indeed, that she declined even to submit to an examination under an anæsthetic to determine if the button was movable. Lately she developed gradually increasing symptoms of obstruction, and last Sunday Mr. Clutton performed median laparotomy; the small intestines were collapsed and empty, but the large intestine was enormously distended with liquid fæces and practically filled the abdomen. He could feel the button high up in the splenic flexure. He made an incision and evacuated two basinsful of liquid fæces, and then he managed to move down the button as far as the site of the original operation, but no farther. He therefore cut down upon it and took it away. At the line of junction left from the previous operation there was a stricture admitting the finger, so he made a longitudinal incision, which he sutured transversely. The operation was done under great difficulties, and took nearly three hours.

Mr. J. C. Wallis then related a case of abdominal nephrectomy for ruptured right kidney in a groom, aged twenty-two. On February 27, 1896, he fell through a distance of twelve feet from a ladder on to a spiked railing. On admission he was conscious, but in evident pain and somewhat collapsed. One of the spikes—three inches in length—had pierced the abdominal wall, nearly an inch below the tenth costal cartilage on the right side. On operation a lacerated wound of the peritoneum was seen, through which bruised intestines presented. The peritoneal wound was enlarged and large masses of blood clot were turned out of the abdomen. Sponges were inserted and the sides of the abdomen held apart by two long silk ligatures. The under surface of the liver and gall bladder were exposed and found intact. The intestines were then examined in the wound track and were seen to be bruised; one piece of small intestine had the external coats torn, and the mucous membrane bulged through the opening. No fæces could

be seen nor fæcal odor detected. At the bottom of the cavity the kidney could be felt torn almost in two; blood welled up through the wound at a great rate. The left kidney was next sought for and its presence made out. The peritoneum was now divided along the outer edge of the ascending colon and this portion of the gut pushed in toward the middle line. The left hand being passed in behind the colon, the kidney was rapidly freed and brought out of the wound. The ureter was clamped, tied, and cut; the vessels were treated in the same way, and the kidney was removed. The deep muscles were considerably lacerated and bled freely. Sponges were temporarily inserted, and the abdominal cavity was washed out with saline solution. The wound was packed with iodoform gauze in strips, dressed with cyanide gauze and blue wool, and bandaged. The patient, being greatly collapsed after the operation, was left on the table for an hour. He rallied from the shock very rapidly during the next twenty-four hours, and made an excellent recovery, the wound being thoroughly aseptic throughout. The gauze was removed on the fifth day after operation and the stitches were removed on the tenth day. The patient was discharged on April 13th quite well, and has been seen three times since. He is now at work as a groom.

A few years ago vaginal hysterectomy for cancer was pronounced an unjustifiable operation. Now, as stated by the president of the Gynecological Society, it is a "recognized procedure and even in cases in which the disease seems most advanced there is often no recurrence." This statement was made after a paper by Mr. Jessett, who from the results of seventy-five cases offered the following conclusions: 1. In all cases of leucorrhœal discharge a vaginal examination should be insisted on. 2. If on examination discharge is seen escaping from the os in a woman at or past the menopause, which discharge is occasionally slightly colored or offensive, the canal should be dilated and the cavity of the uterus curetted for microscopic examination. 3. If the report is unfavorable, total extirpation should at once be urged. 4. Even in advanced cases, so long as the uterus is movable, much relief can be afforded and life prolonged by vaginal hysterectomy. Dr. Purcell presented a table of sixty-three cases with twelve deaths. This was a higher mortality than Mr. Jessett's, but it included early operations before the technique had been perfected. Dr. R. T. Smith congratulated Mr. Jessett and Dr. Purcell, and said they had fully justified their position as surgeons to the cancer hospital—a sentiment generally accepted.

The Royal Medico-Chirurgical Society met on Tuesday and the next evening there was a dinner at which about one hundred and fifty fellows and friends were present. The president, Dr. Howship Dickenson took the chair, and was supported by Sir R. Quain, Dr. Wilks, and other leaders. The toast of the evening was proposed by Mr. Hutchinson, who quoted from the first volume of transactions. He coupled with the toast the name of the president, who in reply remarked that fifty-nine volumes of transactions had appeared in the ninety-one years of the society's existence, and gave examples of the exceeding importance of some of the papers they contained.

A "Hospital Reform Association" has been started in London on the initiation of Dr. Garrett Horder, of Cardiff. It is not proposed to confine membership to medical men, but to enlist all philanthropists who see the evils of the out-patient system and are willing to join in the effort to abate them. The subscription is only five shillings. It is hoped to enlist the public press in the cause and to circulate pamphlets, etc. The managers of hospitals and the Sunday and Saturday funds are to be appealed to. I am sorry the new

association will not keep clear of the Charity Organization Society, which so many regard as useless and meddlesome, and which seems to exist chiefly for the benefit of its officers.

Beriberi has again broken out in the Richmond Lunatic Asylum, Dublin. Some eighty cases have appeared. You will remember I apprised you of the epidemic of two years ago when it occurred, and mentioned that the asylum was overcrowded. This is still the case, and the lesson of the last outbreak seems to have been lost. At an inquest lately held, Dr. Norman had to give evidence and stated that there were seventeen hundred patients in the asylum, the nominal capacity of accommodation being ten hundred. Dr. Norman has again and again called attention to the overcrowding, but so far without effect. Both phthisis and dysentery have prevailed in this institution, and a searching inquiry is called for.

The West Haven Public Library gives books and papers which are withdrawn from circulation to the hospital for infectious diseases. Simple rules have been adopted and circulated. Both patients and staff are said to highly appreciate the boon. The committee and librarian may be congratulated on having organized this considerate scheme.

I have again to report the death of a distinguished and honored member of the profession. Dr. George Harley, F.R.S., aged sixty-seven years, died suddenly on Tuesday from rupture of a coronary artery. His remains are to be cremated this afternoon. I knew him for many years, a genial and cheerful companion, whose intense interest in the scientific aspect of medicine never abated. You will remember his researches on the urine and on the liver, and important as these were he made many others of equal value. He was a very highly trained scientist. After graduation at Edinburgh he spent two years in Paris under Magendie and Claude Bernard. Then he took two years in Germany, working under Scherer, Kölliker, Virchow, and others. On returning he was appointed to the chair of histology and practical physiology at University College and physician to the hospital. Soon for his elaborate researches, among which those on the chemistry of respiration had great influence, he obtained the scientific blue ribbon, F.R.S. He naturally became a fellow of both the Edinburgh and London colleges of physicians. He had to fight against ill health for a long time, and he did it with a courage deserving of admiration and sympathy. I remember his attack of glaucoma, for which, on account of the state of the other eye, extirpation was advised; but he retired to a darkened room for several months to try what rest would do and recovered sight in both eyes. He recorded a number of observations he made on his vision as he recovered. He was always ready to experiment on himself, and on more than one occasion he ran considerable risk from doing so. A careful, exact experimenter and fluent lecturer, his pupils had the greatest respect for his work, and many will mourn the loss of an ardent devotee of scientific medicine and a cheerful, skilful, and learned physician.

OUR PARIS LETTER.

(From our Special Correspondent.)

ALCOHOLISM ON THE INCREASE IN FRANCE—ALCOHOLIC CHILDREN—GOVERNMENTAL ACTION—THE MILK EXHIBITION—THE GENERAL ASSOCIATION OF PARIS STUDENTS—SUICIDE OF PROFESSOR HANOT.

PARIS, November 1, 1896.

ALCOHOLISM threatens disaster to the French race. The danger is greater than ever before, because the distilleries and absinthe shops are more numerous, the use of wine is more general, and the habit of drinking

any of the numerous liqueurs or *apéritifs*, as they are called, is more common. French doctors and writers have accused the Americans of burning their stomachs with alcohol in the form of whiskey, the effects of which upon the stomach and circulation are far less deleterious than those of the sweetened mixtures used by Frenchmen. These are nothing more nor less than pure alcohol of very inferior quality, into which is put a large quantity of a powerful essence, such as anise, absinthe, mint, or coriander, all having convulsive and stupefying properties, affecting less the stomach and circulation than the brain and cerebro-spinal nervous system.

The government has several times seriously discussed the question, and it is thought that by limiting the number of licenses and, above all, guaranteeing that the alcohol used in the manufacture of drinks, cordials, and liqueurs shall be of the highest quality, some check will thus be put upon this steadily increasing evil.

The Chamber of Deputies did, it is true, express quite recently, in an order of the day, the desire that the minister of finance should study the subject. Accordingly, he appointed an extra-parliamentary committee—that is, a committee whose members are not deputies. This is a very convenient way of shelving an embarrassing problem, and it is thought to be the end of the matter, notwithstanding the fact that the minister assures the chamber, and the public as well, that he is endeavoring to eradicate the fraud and protect the public health. This is the tenth attempt of the kind that has been made, and it is destined to prove, like the others, fruitless.

On October 25th, Mr. Algaive held a conference at Rouen, under the patronage of the Normandy Society of Hygiene, presided over by Dr. Cerné, on the monopoly of alcohol and its importance from a hygienic standpoint. Many doctors and men of science were present. There was also a goodly showing of wine merchants and liquor dealers at the meeting, and these became so uproarious when it was proposed to take really serious action in the matter, especially financially, that the meeting was adjourned. It seems as if all efforts in this direction are doomed to be alike futile, and distillers are to be allowed to go on manufacturing their poisons and the public absorbing them to its own detriment.

Another beverage, at times as dangerous if not more so than alcohol, is just now attracting official attention. We refer to milk—that has not unfrequently been the direct cause of typhoid fever, cholera, and tuberculosis; and as several children, whose ages vary from eight to thirteen years, are now under treatment in the hospitals of Paris for confirmed alcoholism, it would be interesting to know exactly how many began to acquire the habit unconsciously at the breast of an alcoholic mother or nurse. There have been so much adulteration of milk and so much consequent falling off from the standard, that it has become urgent for the public to know where that nourishment, so indispensable to infants and children generally, to which also many adults are obliged to resort, can be best obtained fresh, pure, and unadulterated. Some of our most distinguished physicians and professors have, therefore, decided to organize a competitive exposition of milk—a *concours de laiterie française*—to which milk and dairy men and women near Paris, and those keeping cow stables, also milk venders in the city, are invited to send their wares. The jury will be composed exclusively of physicians, pharmacists, and veterinarians. A committee of patrons is to be appointed, consisting of deputies, municipal councilmen of the Seine, and the presidents of the syndical chambers of alimementation. Prizes, such as bronze works of art, pieces of silver, etc., will be given to those furnishing the

best specimens of lacteal fluid. Manufacturers of milk apparatus of all kinds are also invited to take part in the concourse. No doubt the very best and purest milk will be exhibited, but will it guarantee to the consumer that the milk furnished every day throughout the year is up to the exhibition standard as an article of nutriment, leaving septic germs and sterilization out of the question? At any rate, the *concours* will undoubtedly be productive of much good as regards the sale of adulterated milk, and not without beneficial influence on public health and hygiene.

The Students' General Association of Paris has just treated us to another one of those scholastic revolutions so common in the Quartier Latin. The president and all the other officers have just resigned in a body, because the members of the association had blamed them for expending, without having consulted their comrades, certain sums necessary for participation in the recent Franco-Russian festivities. It seems that for some time past the direction of the affairs of the association had been in the hands of an executive committee, composed chiefly of students at the Sorbonne, whose rule the association at large found tyrannical. The new president, officers, and executive committee are students in medicine, pharmacy, law, etc., but not one of them is from the Sorbonne. The new *régime* ratified at once, purely, simply, and without discussion, the credits spent during the Franco-Russian fêtes, the whole movement having been only a manœuvre to get rid of the old management.

We have just lost by suicide one of our most prominent (*agregé*) professors at the Faculty of Medicine—Professor Hanot. He had returned to his apartment in the Rue de Rivoli on Tuesday evening last, after having lunched with one of his students, and went directly to his study, where his servant saw him open a work on medicine, and retired, leaving him, as he supposed, at work, according to his custom. When he went to call his master for dinner a few hours later, he found Professor Hanot stretched upon the floor, his body lying upon the right side, the head under an armchair, the right hand holding a small vial. A confrère was called in at once, and stated that death was due to poisoning by cyanide of potassium. Dr. Hanot's appointment to a full professorship in the chair of external pathology had been decided upon for some time, and to prepare for his new field of labor he had given himself up to such excessive mental work as to bring about a state of constant cerebral hyperæmia, accompanied by melancholia of long standing, and in a moment of aberration he committed the regrettable act. Professor Hanot was very highly esteemed by the profession and friends, who mourn alike his loss at the early age of forty-five.

THE MOSCOW INTERNATIONAL MEDICAL CONGRESS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: *À propos* of an editorial in this week's MEDICAL RECORD, entitled "Politics and Medicine in Russia," I desire to ask for some space in your esteemed and most widely circulated journal in order to express my opinion upon the subject. My at first, perhaps, somewhat startling opinion and advice is that the members of the medical profession throughout the world should, collectively or individually, resolve to have nothing to do with that congress, to ignore it completely. This opinion is shared by quite a number of my colleagues, and the reasons upon which it is based are as follows: A country in which the popular and higher education is in the palm of the hand of Constantin Pobyednoszeff, a narrow-minded, marble-

hearted bigot, as cruel as Torquemada, with the only difference that he does not burn his victims at the *auto da fé*—this being out of fashion now—but sends them instead to pine their young lives away in the Siberian mines and prisons; a country in which the students are watched and spied upon like penitentiary convicts; a country in which the most brilliant university professors are treated like lackeys, discharged and exiled at the caprice of the above-named autocrat; a country in which the possession or reading of the Declaration of Independence or of the constitution of the United States is considered a heinous crime and is punished by from three to five years' solitary confinement in a prison or subterranean dungeon (this is fact, not fancy); a country in which citizens of the highest ability and integrity are debarred from university education, from certain professions and positions, on account of professing a certain faith; a country which in the last quinquennium of the nineteenth century establishes a school of medicine for women and inserts a clause rigidly excluding women of Jewish faith from entering its portals—such a country, I say, should not be honored by the holding of an international medical congress in one of its capitals. And in this opinion I do not stand alone. When in Berlin I spoke to many physicians upon the subject, and several of them who participated in previous congresses expressed their resolution to have nothing to do with the Moscow congress, neither as readers of papers nor as visitors. And if the entire medical profession throughout the world decided to do likewise, the rebuke would have a wholesome effect upon the pitiless Northern despot.

The case of Erismann is not by any means unique. Many a Russian professor has been forced to resign or has been exiled, only to be received with open arms by the universities of Switzerland, France, and Germany.

WILLIAM J. ROBINSON, M.D.

112 EAST ONE HUNDRED AND TWENTY-EIGHTH STREET.

THE LEPROSY COMMISSION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In an editorial of November 7th you say: "Would it not be well to have a national leprosy commission appointed to determine what is to be done with the leper here at home before we send delegates to an international leprosy congress in London to decide upon what to do with the lepers of the entire world?"

You must permit me to observe that the question what we shall do with the corporal's guard of lepers at North Brother Island is just one of those questions which will be presented to the congress. It is to frame laws suitable to this country and to every other country that we wish such a congress to meet. If the decision is left to each country separately, one country will set the lepers loose, as our health commissioner here proposed to do; another will pen them up like animals, in utter disregard of such human and religious rights as certainly ought to be left them; another country will put its leper asylum in a moist climate, like Louisiana, for instance, which favors the multiplication and propagation of the bacilli, and also that of innumerable species of insects, which all may contribute to the spread of the disease, etc.

No State board of health (I have already put myself on record with this statement) should have anything to do with the disposition of a leper. The local authorities will, in many cases, wink at the escape of lepers, or let themselves easily be persuaded that they are not dangerous. Our national government should have full authority to take from every State its lepers, and put them in a national lazaretto or reservation. No

better place could be found for this than some part of the Yellowstone Park, where the climate is unfavorable to the lepra bacillus and where there is plenty of room for leper colonies, that is, for the lepers and their families, if the latter chose to follow them.

According to Hansen, the tubercular leprosy is found in moist climates, the maculo-anæsthetic form in dry climates, and the only difference between the two forms is in the degree of virulence and multiplication of the microbe. Wherever "cures" have been reported, it was always in the maculo-anæsthetic type. This type has a natural tendency spontaneously to "cure" without any medication whatever. (By "cure" is meant here only the cessation of the activity of the disease, the anæsthesia and previous ravages, of course, remaining.) Now, if we put all our lepers in the driest climate to be found in the country, away from the seacoast, whose influence is baneful, we must of necessity prevent the multiplication of the lepra bacilli in the human body and diminish their activity.

It is not likely that any government will formulate laws in accord with this scientific statement, unless urged to it by such an imposing body as would be formed by the competent and official representatives of all the countries of the world.

Let me add this: The opinion of a man in anything pertaining to this question can have weight and authority only if he has for a considerable time lived in countries where lepers are very numerous, where they are counted by the thousands, ten thousands, the hundred thousands, and where the population has for many centuries been compelled to observe the disease, to fight against it, etc.; and the studies made during a few days, on five or six lepers, entitle no man to speak with authority on any such question. All the competent men say that the disease is inoculable and that isolation is indispensable.

ALBERT S. ASHMEAD, M.D.

A SIMPLE MEANS OF THROAT EXAMINATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It is well known that many children have a dread of the doctor's visit—especially should the visit be made because of throat disease. The fears are increased if a spoon or tongue depressor is thrust down into the throat without ceremony. All of this may be overcome by a method used by me for the past twenty years, which can be successfully practised in nearly every patient over three years of age. It consists in simply teaching the child to use the index finger of either hand, thrust back along the tongue as near the base as possible, with the injunction to open the mouth wide and press down the tongue. In this way can be secured, after one or two attempts, a perfect view of the tonsils and in many instances even of the epiglottis and the adjacent folds.

The reason why this is preferred is based on, first, the fact that a child, or even an adult, does not fear any injury from his own finger; second, his own effort will not provoke emesis or straining, as a trial will convince the reader; third, there is no danger of contamination by a dirty spoon or depressor, and no possibility of auto-infection, and finally, the fingers are always at hand. This plan of course is impracticable in the moribund and in infants, but at least ninety-five per cent. of all instances of acute and chronic disease of throat or of foreign bodies can be more successfully examined by it than by any other method. The purpose of this note is particularly directed to the busy every-day doctor and not to the specialist.

J. D. MILLIGAN, M.D.

—BROcq AND JACQUET.

Salicylate of Methyl locally applied in subacute and chronic rheumatism, during painful paroxysms, acts at times as well as when salicylates are given by the mouth.—LANNOIS AND LINOSSIER.

Trional, in from one to two grain doses shortly before bedtime, gave favorable results in thirteen cases of insomnia. It may be given in warm milk. No bad effects upon the heart were noted.—KOSTER.

Carbonic Acid in its nascent state is a new agent in the treatment of blennorrhagic vaginitis, proposed by Piéry (*Abeille Médicale*, No. 23), for which much is claimed.

Large Doses.—Do not enter into competition with the object of seeing who can give the largest dose. A small quantity will often do all that is required of a drug, and a large dose may do harm.

Antitoxin.—Dr. Billings' observations upon the hæmatic effects of antitoxin prove that the corpuscles and hæmoglobin are diminished less with the injections than without them.

Asafœtida.—The tincture, combined with milk of magnesia, furnishes the best remedy for colic due to intestinal acidity. As a diffusible stimulant in catarrhal pneumonia and capillary bronchitis, it is exceedingly valuable.—*Pediatrics*.

Inoperable Cancer.—Dr. Snow, surgeon of the London Cancer Hospital, says that morphine, associated with cocaine, given in large doses for a long time, exercises a favorable and curative action upon carcinomatous neoplasms and retards recurrences.

Puerperal Eclampsia.—Norwood's tincture of veratrum viride in large dose (ten to twenty minims), preferably by hypodermic injection, is said to be distinctly an American practice. The initial dose can be safely followed, in from thirty minutes to an hour, if necessary, by a dose of from five to eight minims.—BAUER.

Pertussis has been successfully treated for fifteen years by Dr. Josset (*La Méd. mod.*, March 28th), with the aid of hypersulphurous baths, seventy-five centigrams of polysulphate of potassium per litre being employed. The temperature of the bath should be 36° C., and the duration twenty-five to forty-five minutes, according to the age. Fifteen baths are, at most, required.

Unusual Effects of the Bromides.—In certain epileptics the prodromal signs of an attack and the subsequent manifestations take on an intensity altogether unusual when bromides are being employed in high dose. In cardiac epileptics the bromides are likewise injurious, cardiac asthenia leading to a state of collapse. In children paralytic phenomena with ptosis, loss of memory, etc., have been noted. Homicidal tendencies and melancholia with attempts at suicide may be observed.—S. WEIR MITCHELL.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 14, 1896:

	Cases.	Deaths.
Tuberculosis.....	161	83
Typhoid fever.....	22	7
Scarlet fever.....	85	8
Cerebro-spinal meningitis.....	1	2
Measles.....	66	4
Diphtheria.....	173	27
Small-pox.....	0	0

Small-Pox in the German Army.—Only two soldiers in the immense German army have died from small-pox since 1873, owing to the strictness with which vaccination is enforced. During the Franco-German war the Germans lost only three hundred, compared with a French loss of twenty-three thousand four hundred men from small-pox.

Curious Pharmacy.—Toward the end of the sixteenth century, Sir Henry Unton was sent on a mission to the French king in Paris, and there became ill, whereupon the court physician gave him a "*confectio alcarmas*"—compounded of musk, amber, gold, pearl, and unicorn's horn, "with pigeon's dung applied to his side, and all other means that art could devise, sufficient to expel the strongest poison, and he be not bewicht withal." It is almost needless to add that, after the administration of this extraordinary medicine, the ambassador promptly expired.—*British and Colonial Druggist*.

A Ring on Penis for Fourteen Years.—An extraordinary case of a ring buried in the penis for fourteen years has recently been reported. In September last Dr. Leflaive was called to a patient who complained of not being able to urinate except by drops and with exquisite suffering. On being questioned, the patient confessed that when twelve years old, at school, he passed his penis through a brass curtain-ring, when the organ swelled considerably, so that the ring could not be withdrawn. In spite of his sufferings the boy kept the matter quiet. By degrees the ring ate its way through the skin into a circular groove and in course of time the parts healed completely over it, so that it was lost to sight, his sufferings being all the while almost intolerable. Twelve years afterward the patient married, but at the first attempt to fulfil his marital duties the penis became greatly inflamed and contact very painful. He bore valiantly with his infirmity for two years longer, but at last had to appeal for medical aid. When examined, the prepuce and the glands were found to be enormously swollen and of a phlegmonous aspect. It was impossible to find the meatus, and all attempts at catheterism increased the agony. About the middle of the penis could be seen a circular white band representing a cicatrix, and at this point could be felt the ring, embracing the cavernous bodies. After having chloroformed the patient, Leflaive made a longitudinal incision through the dense cicatricial tissue, which gave issue to a certain amount of pus; at the bottom of the wound could be seen the ring. A director was passed under it, and the foreign body was cut through by means of bone forceps and thus removed. The patient recovered quickly. Nowhere else in the annals of medicine can be found a case of a metallic ring thus buried for so long a period without calling for surgical interference.—*Medical Press and Circular*.

Epileptics recover in this country in one per cent. only, while in Germany, under the village system, between five and six per cent. recover, and more than half of those admitted are greatly benefited.—*Philadelphia Polyclinic*.

Anatomy an Explanatory Science.—The *New York Medical News* publishes an article by Dr. Stiles, in which he writes as follows: "To the zoologist you owe the transformation of anatomy from a descriptive into an explanatory science. He has already solved the riddles of many of the rudimentary organs of the human body. You are no longer taught that the pineal gland of the brain is an unexplained organ, possibly the seat of the soul; but you are told that it represents a rudimentary third eye, which has been traced through a long series of animals until found developed to such an extent in certain reptiles that it is probably capable of perception of lights and shadows, while the paleontologist has here come to our aid and shown that in certain fossil reptiles this organ must have been a comparatively well-developed interparietal eye. You no longer learn a minute description of the plica semilunaris and then wonder what it is, for you are told that it is a third eyelid, very rudimentary in most human races, slightly better developed in the Malay, while it is well-developed and functional in birds and frogs."

The Prosecution of Quacks.—A quack of the name of Thomaso, though fortified with the usual bogus American diploma, was fined £20 last week at the Southwark Police Court, under the apothecaries act, for practising medicine. It is only by the byway of this ancient enactment of 1815 that a quack can be punished for practising in England. In Ireland no such protective enactment exists, for which reason quacks can do as they please in that country, as long as they do not publicly represent themselves as registered practitioners. Fortunately there are, in Ireland, practically no quacks. The good St. Patrick banished them along with the toads and other venomous animals, and since then, though many of the tribe have sought to effect a lodgment, they have always died of inanition.—*Medical Press and Circular*.

Magical Remedies.—In former times many curious remedies were used in the treatment of disease. Thus, the magi or priests of the Persians, the wise men of the East, knew of herbs which, wrought into pills and swallowed in wine, would make the guilty confess their secrets. They also had an herb for begetting good and handsome children, and a wort to revive old love, even when it had turned to hate. All these had magic names. They thought highly of the common mole, and taught that, if any one swallowed its heart, palpitating and fresh, he would become an expert in divination. The heart of a hen, they said, placed upon a woman's left breast while she slept, would make her tell her secrets, if only her memory served her. The magi also taught to drink the ashes of a pig's pizzle in sweet wine, and so to make water into a dog's kennel, adding the words, "Lest he, like a hound, should make urine in his own bed." If a man, in the morning, they said, made water a little on his own foot, it would be a preservative against *mala medicamenta*, or drugs intended to do him harm. Pliny mentioned many curious remedies. Thus, speaking of ague, he tells us how to cure it by amulets; by the dust in which a hawk has rolled; by the longest tooth of a black dog; by a solitary wasp caught in the left hand; by the head of a viper cut off, and by its living heart cut out and wrapped in a piece of cloth; by the snout and tips of the ears of a mouse, and so on. Marcellus recommended, in order to avoid inflamed eyes, that when you see a star fall or cross the heavens

you should count quickly, for you will be free from inflammation for as many years as you count numbers. If a man, he says, have a white spot or cataract in his eye, let him catch a fox alive, cut his tongue out, let him go, dry his tongue, and tie it up in a red rag, finally hanging it round the neck. For toothache you are requested to spit in a frog's mouth and tell him to make off with it. Ettmüller is conspicuous for recommending disagreeable and even revolting remedies, a prominent feature of his treatment being the employment of the excrement of various animals. *Album canis*, or album græcum—in other words, the “whites of dogs”—he recommended for bleeding, and also as a gargle for sore throat.—WILLIAM MURRELL, in *A Manual of Pharmacology and Therapeutics*, p. 2.

Malaria.—The importance of careful microscopic examination of the blood in obscure cases of illness cannot be overestimated. It is futile in many instances, but invaluable in others. We must not assume, however, that antimalarial treatment will correct grave functional derangements, even when these are primarily due to the disease.—F. S. JOHNSON.

A Full Stomach.—A paragraph is now going the rounds which states that a gastrotomy performed on a woman in a hospital at Odessa disclosed the following objects in a state of incomplete digestion: A fork, a piece of iron, two teaspoons, a needle, a piece of lace with the crochet needle, two two-and-one-fourth-inch nails, four pieces of glass, eight buttons, and a key.—*Boston Medical and Surgical Journal*.

Dispensary Abuse.—The following extract from a London letter by Dr. Boyes to the *Occidental Medical Times* is worth a moment's thought: “In America, even more than here, there are many such issues that are becoming burning questions in these days of excessive competition on all sides. There seems, and with great good reason, to be a feeling abroad that many things demand rectification in our profession, which, by the way, has increased out of all proportion to population in most localities. We need but turn our attention for a moment toward our general environment to observe that the majority of the institutions founded so generously and conducted so zealously for the benefit of the sick poor, whether on charitable or co-operative principles, are entering into keen competition with us, and that, of course, greatly by our help. The association instances Birmingham, England, showing that the hospitals and dispensaries treated last year a grand (?) total of about one hundred and twenty-eight thousand patients, out of a population of five hundred thousand. Just think what it means. Imagine what inroads must have been made in the incomes of the rank and file of the profession. And remember that such detriment is at the hands of their brethren. Nor is this an isolated instance, but rather the rule, with amazingly few exceptions, in the towns and cities of Europe and America. It is a spectacle for the gods to laugh at—a body of learned men exerting their best efforts toward their own undoing. The worst of it all is that this philanthropy gone mad, this misguided generosity, has gone a long way toward pauperizing the public at the expense of the profession. It simply destroys the prospects of many medical men who otherwise could get along nicely and with benefit to the community. Assuredly it is a great injury to allow numbers of wage earners to profess the need of charity and to demean themselves as paupers to avoid paying fairly and in accord with their means.”

Progress at Craig Colony During the Eight Months Since the Opening.—This has been the crucial year in the evolution of Craig Colony. All of

the buildings which were in the Shaker settlement at the time of its purchase by the State for dependent epileptics have been thoroughly remodelled and put into complete order for the reception of patients. A perfect system of water supply, sewerage, plumbing, heating, and electric lighting has been installed, and on February 1, 1896, the colony was informally opened for patients. One hundred and forty-nine patients have been received thus far, and as soon as the hospital building now in course of construction is completed, and the west group of buildings heated, the accommodations of the plant, as it now stands, will be ready for a population of over two hundred epileptics. In spite of the shortness of the time now elapsed since the opening of the colony, two very important facts have become evident: First, that remarkable improvement has taken place in the condition of the patients admitted; and secondly, that the economic success of the scheme is assured. Nearly every subject has gained in weight and in general health. In all cases the epileptic seizures have diminished in frequency to a marked degree, and in some instances this has been even extraordinary. The expression of the inmates has altered, so that, instead of the dull, hopeless look of the almshouse epileptic, one sees on all sides happy faces, in which intelligence and hope are being re-awakened. The school has been successfully started for fifteen or twenty of each sex. Much of the printing of the colony is now done by two or three epileptics in the colony's own printing-office. Carpentry, sewing, painting, etc., are being carried on by the patients. They have their own epileptic blacksmith. Naturally, the great work of the inmates of both sexes is in the field and garden. Eighty-three per cent. of the males and seventy-six per cent. of the females have given us eight hours' daily work. This labor has had a great effect upon the income of the colony, demonstrating the economic value of the scheme. From the report of the superintendent and steward for the year ending September 30, 1896, we learn that the products of the farm and garden for the year 1896 amounted to \$14,230.20. The cost of maintenance of patients, from the date of opening, February 1, 1896, to October 1, 1896, a period of eight months, was \$28,258.24. The colony has, therefore, actually produced already one-half of the cost of maintenance. Appropriations are asked for this year, to increase the productivity of the agricultural department especially, because upon this the economic success of the scheme depends so largely. At the same time there is most urgent need for accommodations for the hundreds of patients seeking admission. There are nearly a thousand patients still a public charge in the almshouses, insane asylums, and various charitable institutions, who need to be provided for at Craig Colony. The managers will ask the legislature to provide, this coming year, dormitory accommodations for at least three hundred more patients.

The Physician's Relation to Society.—The trusted physician sees intimately many classes of society, whether he live in the country or the city. In the city he sees the well-to-do in their houses and the poor at the hospitals and dispensaries. In the country he visits all the different kinds of people in the town. The experienced physician is familiar with the causes of poverty and misery, and he is equally familiar with the ill-effects of wealth and ease unaccompanied by mental and spiritual cultivation. He can recognize the socially normal and the socially abnormal, and distinguish unerringly between them. In the city he knows the evils which result from crowded tenements, and dark, ill-ventilated workplaces; in the country he knows all about the wet cellars in which decaying fruits and vegetables are stored;

the bad cooking; and the careless disposition of the household sewage on the surface of the ground near the dwelling. He should be the best adviser on all social defences against the physical evils which the greed, ignorance, or carelessness of individuals inflict on the community; on the building of hospitals, large or small, in city or country; and on the training of competent nurses, whether for hospital or family service. The physician should be the chief defender of society against the superstitions which still prevail and the impostures which still thrive. His training being essentially the training of the naturalist, he should be the defender of the community against all forms of unreason. If the physician have the needed persuasive force, no one can defend society so effectually as he against those unreasonable persons who are constantly protesting against dissection, vaccination, and vivisection; for no one can understand so well as the physician the benefits which these processes have conferred upon the human race. The medical profession has before it an entrancing prospect of usefulness and honor. It offers to young men the largest opportunities for disinterested, devoted, and heroic service. The times are past when men had to go to war to give evidence of endurance, or courage, or capacity to think quickly and well under pressure of responsibility and danger. The fields open to the physician and surgeon now give ample scope for these lofty qualities. The times are past when the church alone asked men to devote themselves patiently, disinterestedly, and bravely to the service of their fellow-men. The medical profession now exhibits in highest degree these virtues. Our nation sometimes seems tempted to seek in war—that stupid and horrible savagery!—for other greatness than can come from vast natural resources, prosperous industries, and expanding commerce. The pursuits of peace seem to pall for lack of risk and adventure. Would it might turn its energies and its longing for patriotic and heroic emotion into the immense fields of beneficent activity which sanitation, preventive medicine, and comparative medicine offer it! There are spiritual and physical triumphs to be won in these fields infinitely higher than any which war can offer, for they will be triumphs of construction and preservation, not of destruction and ruin. They will be triumphs of good over evil, and of happiness over misery.—*Dr. Eliot, in His Address before the Medical Society of the State of New York.*

Anæsthetics.—The subsequent history of the men who introduced anæsthesia is instructive—and encouraging. Wells, after his failure at Boston, went home disheartened, and was long ill and unable to practise his profession. He gave up dentistry and went into picture dealing. He tried to get some reward for the priority of discovery, but was constantly disappointed, and finally committed suicide. Twenty years afterward his statue was set up in Hartford; and five years later, his widow being destitute, a subscription was raised on her behalf. Dr. Long lived quietly and little known till 1878, when he died. He received no reward nor honor of any kind. Jackson was equally unsuccessful in his endeavors to obtain recognition, and finally ended his days in a lunatic asylum. Simpson was made a baronet; had a statue erected to him in Edinburgh, and a bust in Westminster Abbey.—*WILLIAM MURRELL, in Manual of Pharmacology and Therapeutics, p. 233.*

The Tribulations of a Big Head.—Dr. Max Nordau's name was originally Dudfield, and Nordau was at first simply a pseudonym, which, with the consent of his father, he afterward legally assumed. He lives in Paris, above a wineshop, and here is his description

of his modes of work: "I spend my day in paying visits to my clients and receiving visitors. In the intervals I attend to my journalistic duties, for I am the Paris correspondent of the *Vossische Zeitung*, of Berlin, and I also contribute to the *Frankfurter Zeitung*, writing on all subjects. It is not till after dinner—that is to say, at about half-past eight—that I sit down to my table to write books. I then write till eleven o'clock, or midnight, as the inspiration goes. When I set pen to paper, I am as sure of the last word of what I am going to write as I am of the first. But I find it hard sufficiently to concentrate my mind at first, and the work of the first hour is about equal to the work of a quarter of an hour later."—*Literary Digest.*

Good Old Age.—On October 26th, died at Fitchburg, Mass., Mrs. Berube, at the ripe age of one hundred and nine years. It is said that her grandfathers lived to be respectively one hundred and fifteen and one hundred and five years of age. Her eldest son lives at Marlboro, Mass. He is eighty-seven years of age.

Obituary.

JAMES COOPER MARTIN, M.D.,

KANSAS CITY, MO.

DR. JAMES COOPER MARTIN, a leading practitioner and prominent citizen of Kansas City, died November 7th, aged sixty-four years. He had been in failing health since February, 1895, when he suffered a severe attack of pneumonia, which developed into consumption. A few months ago he went to San Antonio, Tex., and, although he derived some benefit from the change of climate, yet his advanced age precluded the possibility of his recovery. He was born in Fayette County, Pa., in 1832. When a young man he took up the study of medicine. The first course of lectures he attended was at the Ohio Medical College in Cincinnati, in 1861. He then went to Long Island Medical College, New York, and, upon graduating from that institution in 1866, went to Madison County, Ill., near the city of Alton. There he was engaged in the practice of medicine a number of years, and it was there he was married to Miss Jennie W. Gadd, a sister of Joseph H. Gadd, of Kansas City, Mo.

Dr. Martin went to Kansas City in 1880, and began practising in the city of Wyandotte. Although he was not a politician in any sense, he took an active part in municipal affairs. He was nominated for mayor of Wyandotte by the Democrats in 1885, and defeated Thomas C. Foster, the Republican candidate, at the election held in April of that year. About that time the cities of Wyandotte, Armourdale, and old Kansas City, Mo., were growing rapidly, and during Dr. Martin's administration the movement to consolidate them into one municipal government assumed definite proportions, resulting in the issuance of a proclamation by Gov. John A. Martin, on March 6, 1886, under which the three cities were merged into one, to be known as Kansas City, Mo.

Dr. Martin occupied the mayor's chair until April, 1886, when Thomas F. Hannan was elected mayor at the first election held in the new city. Dr. Martin then served as a member of the common council three years, when he retired from office. As a public official his acts were free from criticism, and during his administration there was not a shadow of suspicion of corruption.

Dr. Martin was an elder of the First Cumberland Presbyterian Church of Kansas City, Mo. He was one of the founders of the Y. M. C. A. in Kansas City, Mo., and was at one time its president.

MEDICAL ADDRESS AT THE TWENTY-NINTH ANNIVERSARY OF THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK, NOVEMBER 18, 1896.

BY T. GAILLARD THOMAS, M.D.,

PRESIDENT OF THE MEDICAL BOARD.

MR. PRESIDENT AND LADIES AND GENTLEMEN, GOVERNORS OF THE WOMAN'S HOSPITAL: In these days of national ambition and cupidity, our ears are from every side saluted by the echoes of conventions called for congratulation and rejoicing over the great victories accomplished by the terrible and bloody hands of war. Of late England, Germany, Russia, and the United States have rung with pæans of praise for the success of their contending armies. We meet here to-day to glory in a victory of peace; to give thanks for one of its triumphs, the growth, development, and fruition of which we have watched with anxious eyes; and with fervent sincerity to join hands over its cradle and pledge ourselves to cherish, sustain, and honor it.

Happy is the nation which can with complete sincerity accept the grand truth which is beautifully expressed in the epigram: "Peace hath her victories no less renown'd than war." For the reception and full admission on the part of a community of this truth, so charming in its setting of poetic diction, testifies to a signal advance in civilization, refinement, and Christianity. "The normal state of man," says Hamilton, in his great work upon "Military Surgery," "is war." In the normal state of man peace hath no triumphs at all comparable with those of war. For the hospitable reception of the seed of such doctrine as this the land must be prepared. Upon no rough and inclement soil will it germinate; in the bosom of no cold, harsh earth will it "burgeon and blossom." The minds of men have been prepared for it by civilization and Christianity. It was the Christian era which made its real appreciation possible among men. In the stirring ages which antedated this era, the eyes of all were so intently fixed upon moving hosts of mailed warriors, their ears so filled with the martial cries of contending armies, and their senses so inflamed by the lust after plunder and revenge, that he who had then pronounced these words would have made himself an object of ridicule and contempt. But now, two thousand years of accumulated evidence have convinced us of their truth, and caused us to imprint them in letters of gold upon the banners of advancing civilization. Two thousand years of trial of the doctrines emanating from the Man of Nazareth have taught us to turn with loathing from the grim and awful visage of war, and to hail the fair and smiling face of peace with the enthusiastic declaration, truly, truly, "Peace hath her victories no less renown'd than war."

Of all the glorious triumphs of peace, so great in their number as to baffle enumeration, not one out-values the hospital, that outcome of the brotherhood of man, which is of such recent development that no

evidence of its existence in pagan times rewards the searcher of ancient literature.

We have met here to-day to honor the anniversary of one small hospital out of the immense number which are performing beneficent work in every city, nay, even in thousands of small towns, throughout this and every other civilized country in the world. And yet, while I acknowledge in these words our apparent insignificance, I shall be greatly disappointed if I do not in the end make you feel proud of the institution which you have fostered, satisfied with the service of your medical colleagues, and astonished at the great work which in this world and the next must be already credited to your account.

It is not often that, in our self-seeking and aggressive age, any body of men and women can be charged with want of appreciation of the good which they have accomplished; and yet I hope to show you, ladies and gentlemen of the governing board of the Woman's Hospital, that I shall to-day sustain myself in such a charge against you. Forty years ago that department of medicine entitled gynecology, which is to-day saving millions of lives annually, assuaging pain and sorrow for millions of women, and shedding the light of happiness in millions of households throughout the world, did not exist. Its benefits lay dormant in the minds of medical men, even as the magnificent diamonds of South Africa have lain fallow and useless for centuries in the bowels of that land. Let me tell you as simply as I may, the story of the early beginnings of modern gynecology. All great things have small beginnings. The lifting of a kettle's lid suggested steam to Count Rumford; tropical plants floating upon the ocean gave to Cristobal Colon the idea of a new continent; a Yankee printer's kite introduced the world to electricity; and a Boston dentist, by a kind of accident, stumbled upon anæsthesia—"magnum Dei donum." So, forty years ago, a country doctor from Alabama brought here to New York and offered free to certain men and women living here, some new views and new methods concerning the practice of this department of surgery. These views were appreciated, and for their carrying out this Woman's Hospital was built, and here it stands to-day. The man who came out of the far away South with a gift in his hand was called Marion Sims; and the men and women who have aided him in trying his methods stand before me now as the authorities who guide the destinies of this institution. Sims worked out a great result for science and humanity; but it was by your aid that he did so, by your generous assistance that through the instrumentality of this hospital he attained his ends. You were offered a glorious opportunity, and you were wise enough to embrace it. Come what may in the future, nothing can ever deprive you, or Sims, or this hospital in the wards of which we now stand, of the glory of having inaugurated a beginning which has led up to grand results.

Great discoveries in medicine are not by any means always recognized and appreciated, either by the medical profession or by the public. Were you to ask me to-day what I consider the greatest discovery which has ever been made for clinical medicine, I would answer, the use of the clinical thermometer; and were

you then to ask what I regarded as the greatest advance in the treatment of that deadly affection, typhoid fever, I would tell you, the use of cold bathing for the control of high temperature. You will be surprised to learn that about a century ago, Dr. Curry, of England, made both these discoveries, employed them generally, and wrote a large volume for their dissemination; and that both were utterly ignored until about a quarter of a century ago, to be rediscovered then and to be recognized as sheet anchors, one in diagnosis, the other in treatment. You were better advised, and the world reaped the benefit of your wisdom.

Many years ago a prophetic philosopher declared that the evolution of medicine was becoming, after a slumber of centuries, so rapid and promising, that the day was not far distant when all that was old would become effete, and what was new would be contained in prophylactic or preventive medicine and surgery. Truly, his prophecy seems advancing to fulfilment. The remedies which have lived and flourished for diphtheria, tetanus, small-pox, and a rapidly growing list of other diseases are being thrown aside in consequence of antitoxins, vaccine, and the like. So that loathsome surgical affection, incurable until the times of Sims, which more than anything else incited the erection of this hospital, is now rarely seen within its walls. Its prophylaxis, or prevention, has been accomplished by the improved teaching of obstetric medicine, ignorance of which, in the olden time, betrayed the confidence of woman in the grandest moment of her existence. But this is a digression, and I return from it to the line of my argument. When, forty years ago, "The Woman's Hospital in the State of New York" was built and devoted to the surgical treatment of the diseases peculiar to women, no similar institution existed or had ever existed in any part of the world—not in England, France, Germany, Scandinavia, nor in any country of Europe; not in America, nor any of the Eastern lands. To-day there are, in New York City alone, twenty-five public hospitals devoted in whole or in part to this special work; while similar institutions exist in Brooklyn, Jersey City, Albany, Buffalo, and almost all the cities of this State. The same statement holds true as to the large cities of our whole country: Boston, Philadelphia, Chicago, Cincinnati, St. Louis, San Francisco, and others too numerous to mention. Now, add to these the cities of Europe: London, Paris, Berlin, Vienna, St. Petersburg, etc., and you will begin to appreciate that the keynote which was struck here only forty years ago has resounded throughout the realms of civilization. If those who were so fortunate as to have been identified in so grand an enterprise as this do not feel their hearts swelling with honest pride, they must surely be either more or less than human.

During these forty years, the medical men to whose hands you have entrusted the fortunes of this hospital have worked, with such capacity as has been accorded them, to advance its interests and those of the department of medicine which it represents. In simple justice to themselves, they declare that they stand before you to-day, proud of the outcome of their labors, and firm in the consciousness of honest effort and faithful endeavor. That their tenure of office in connection with this hospital has given them a vast deal of pleasure and profit, they acknowledge with willingness and gratitude; but, from the very nature of their position, the very history of this institution, they have been exposed to trials which up to this very moment they have borne in silence. Would that their vindication had a stronger advocate than I; but "truth is strong and will prevail," without reference to its enunciator.

One of the most uniformly fulfilled laws of human nature from the infancy of time has ever been this: Every man, every society of men, and every institution

which has done for the world great work and bestowed upon it lasting obligation has sooner or later been subjected to detraction and misrepresentation. Had this hospital not been accorded this proof of its bestowal of benefits, I would not have dared to write what I have just read to you; for I should have felt doubtful as to the authenticity of my statements. As it is, I feel that I stand upon strong ground and need have no misgivings. You have heard from various sources that the results obtained by the Woman's Hospital in major operations are and have been much worse than those of similar institutions throughout our country; that the shortcomings of its surgeons as to the matter of success have been by comparison lamentable; and that it behooved those in charge of its interests to examine and reform the existing state of affairs.

It is quite evident to you that these reports, kept up for years, are calculated to prove injurious to the hospital, unpleasant to your board, and not absolutely agreeable to your surgical staff; and that it is high time that the charges should be met. Anxious to inform you upon this momentous subject, and determined to report the facts in the case "without fear or favor," I requested my friend, Dr. Freeborn, the pathologist of this hospital, to make me a full and impartial statement for presentation to you to-day. To the uninitiated an appeal to statistics carries with it the idea of mathematical accuracy, perfect certainty, and an assurance against fraud or misrepresentation. But the initiated know that statistics are either perfectly reliable or absolutely misleading, in accordance with the method of their preparation. So wonderful are the effects which may be produced by juggling with figures, so passing strange the deductions which may be drawn from their manipulation, that the wittiest of Englishmen, Sydney Smith, was induced to remark, "There is only one thing more unreliable than figures—that is facts." Sometimes the calculation of the statistics of a hospital is made up by some youthful and inexperienced subordinate who is deeply interested in a creditable display of success. In the Woman's Hospital this work has always been allotted to the pathologist of the institution, who takes no especial interest in the facts, except as they bear upon pure science. For many years our statistician was Dr. William Welch, whose name has been rendered famous in connection with the Johns Hopkins University of Baltimore; and for a long time, ever since his resignation, the place has been filled by Dr. George C. Freeborn, who is too well known in New York to need introduction to you from me. The latter of these gentlemen, having carefully made out the statistics of this hospital for the year 1894, compares them for the same year with those of six equally large institutions of this city and Boston, selected at random, to the following effect.

The following table represents the statistics of abdominal sections published by the seven hospitals, the names of which appear, for the year 1894:

	Number of Cases.	Re- covered.	Died.	Percentage of Deaths.
Boston City Hospital	24	18	6	25.
Roosevelt Hospital	66	50	16	24.24
New York Hospital	67	52	15	22.37
New York Cancer Hospital	104	86	18	17.3
Mount Sinai Hospital	55	46	9	16.36
Massachusetts General Hospital.	114	96	18	15.79
Woman's Hospital, New York..	153	130	23	15.03

In a note from Dr. Freeborn accompanying these statistics he says: "The tables are made up from the published reports of these hospitals." There are three points connected with them to which I desire before we proceed to draw special attention. 1st. That all

the hospitals with which comparison is made are large and highly respectable ones, having as surgeons the ablest men in the medical profession in America. 2d. That of the seven hospitals the statistics of which are quoted the Woman's Hospital has very much the largest number of capital operations accredited to it, one hundred and fifty-three being thus accredited, while one hundred and fourteen represents the next largest number; and 3d, that this institution has the best statistics recorded by Dr. Freeborn. The only reason for the choice of the year 1894, for taking the statistics, was that the report for that year was the latest publication from the seven hospitals which was obtainable. To make the matter of statistics still more certain, Dr. Freeborn has further put at my disposal the statistics of the Woman's Hospital for the last thirteen years, carrying the inquiry back to the days when antiseptics, the sheet anchor of the surgeon of to-day, was just being discovered, and when it was of very little use. During these thirteen years 1,391 abdominal sections were performed, with a death rate of 22.43. Remember that one of the six hospitals with the statistics of which comparison was made for the year 1894 reports a death rate of 25 per cent., another of 24.24, and still another of 22.37; and then decide whether you need feel ashamed of our statistics, extending back thirteen years, which give a percentage of only 22.43 deaths.

The surgical staff of this hospital has absolutely nothing to do with the making of its statistics. Dr. Freeborn, the pathologist of the institution, and not a member of its medical board, is entirely responsible for them. The statistics of the hospitals with which comparison is made are gotten from their own published reports, and the books of the Woman's Hospital are at the disposal of all for investigation. Surely the truth can be ascertained with absolute certainty, under circumstances so favorable for investigation, and truth once being recognized should not fall a victim to the attacks of falsehood.

It gives me great pleasure to state that Dr. Freeborn's report for 1895 has just been handed in by him and that it is better than that for 1894, which I have just read to you. During the year one hundred and eighty-four capital operations (abdominal and intrapelvic sections for removal of diseased organs) have been performed, with a mortality of twenty-six, making the percentage of deaths 14.02.

Once upon a time a Jew who lived in Venice, by name Shylock, turned to his hostile and biased judge and asked this question: "Are you answered?" I imitate that outraged old Hebrew merchant to-day, and ask of those who have traduced this hospital, "Are you answered?"

But I am admonished that I have in the performance of a labor of love, this effort to defend the Woman's Hospital from misrepresentation and wrong, imposed upon your patience. Let me hope that the justice of my cause may plead my pardon.

May that happiness which is born of an approving conscience reward your faithful labors, and may your noble work which has accomplished so much good in this world find favor for you in that solemn hour when you cross the threshold of that which is to come.

Strangulated Hernia.—Many a case of strangulated hernia has been overlooked and the patient has been treated for colic, epididymitis, bubo, and even for "idiopathic" peritonitis, until at last the almost fatal symptom of fecal vomiting appeared. It is wise in all cases of acute abdominal disease to examine for hernia, and, by the way, do not forget that this condition is not limited to the inguinal regions.—*International Journal of Surgery.*

SUPPLEMENTARY NOTES ON TENDON GRAFTING AND MUSCLE TRANSPLANTATION FOR DEFORMITIES FOLLOWING INFANTILE PARALYSIS.¹

BY SAMUEL E. MILLIKEN, M.D.,

NEW YORK.

At the last annual meeting of this association I presented a successful case of tendon grafting for infantile paralysis (see *New York Medical Record*, October 26, 1895). My other cases of a like character at that time were too recent to call for other than a passing comment. However, at present it affords me great pleasure to state that the past year's experience has brought forth results beyond the expectation of the most ardent advocate of this comparatively new treatment.

While the operative technique has not been changed, the applicability for such surgical interference has proven to be much wider than I had first expected. In other words, the number of patients with the various group or individual muscle paralyses due to anterior poliomyelitis can in many instances be relieved by tendon grafting or by muscle transplantation when other measures, such as electricity, mechanical appliances, and even tenotomy, have furnished only temporary or partial restoration of the function of the paralyzed member.

Since February 14, 1894, I have performed fourteen operations upon nine patients afflicted with various degrees of deformity due to infantile paralysis. Of this number, five of the patients required one operation, three patients two operations each, and in only one case were three distinct tendon graftings performed.

Operations.—Class I. Partial or complete transplantation of the sartorius muscle into the sheath of the paralyzed quadriceps extensor of the thigh. (Twice performed.)

Class II. Grafting of the extensor proprius pollicis to the paralyzed tibialis anticus. (Five times.)

Class III. The gastrocnemius was attached to the paralyzed peroneus longus and brevis. (Twice.)

Class IV. Extensor longus digitorum was attached to the paralyzed tibialis anticus. (Once.)

Class V. The tibialis anticus was attached to the paralyzed extensor longus digitorum. (Once.)

Class VI. The extensor proprius pollicis was attached to the paralyzed extensor longus digitorum. (Once.)

Class VII. The flexor longus pollicis was transplanted on to the anterior surface of the leg and attached to the tendon of the paralyzed tibialis anticus. (In one instance.)

Class VIII. A graft was taken from the deltoid and attached to the tendon of the paralyzed triceps of the upper extremity. (Once.)

It will be seen by the above that of the fourteen operations upon nine patients eight distinct forms of paralysis were encountered.

In my first paper I emphasized the importance of asepsis and minute technique in dealing with the tendon grafts and also the preservation of their respective sheaths, as it is essential that we should obtain primary union of the wound throughout, thus insuring the greatest degree of usefulness for the grafted or transplanted muscle upon which additional work has been placed.

In but one of the fourteen operations did I fail to obtain the union between the transplanted muscle and its new attachment, and that was in my first attempt to transplant the sartorius muscle on to the anterior sur-

¹ Read at the thirteenth annual meeting of the New York State Medical Association, October 15, 1896.

face of the thigh, with the hope of supplanting the quadriceps extensor, which was paralyzed. This failure of obtaining union between the sartorius muscle and its new attachment, the patellar sheath, might be accounted for in part by the fact that the flexors of the leg on the thigh were greatly contracted, thus making too much tension at the site of union.

However, my second attempt at supplanting the paralyzed quadriceps by transplanting two-thirds of the sartorius into the sheath of the vastus internus and attaching it to the patella is best shown by the patient whom I present to-day (see Figs. 1 and 2).¹

The operation just described was performed on December 19, 1895. A previous operation, that of taking a graft from the extensor proprius pollicis and attaching it to the tibialis anticus, had been done by me on November 4, 1895.

This little patient was referred to me by Dr. W. A. Goodall, of this city. The history of the patient was that usually given in cases attacked with anterior poliomyelitis, which is too well known to call for any

power in these two muscles rapidly increased, and since June the faradic current has not been applied and we are depending solely upon the natural use of the limb, together with massage, which is carried on by the mother.

The atrophy of the quadriceps extensor clearly demonstrates that without the second operation, that performed on the sartorius muscle, our patient would otherwise be compelled to wear a brace which would stiffen the knee in order to walk. The fact that the limb is somewhat abducted is due to the partial attachment of the sartorius at its original site on the inner side of the tibia, and in my future operations for this deformity I shall transplant the whole muscle instead of, as was done in this case, taking only two-thirds of it.

Of the second series I have been able to follow all five of the cases, and it has been clearly proven that the extensor proprius pollicis can be sufficiently developed to carry on the work of the paralyzed tibialis anticus.¹

FIG. 1.

FIG. 2.

FIG. 3.

description. The attack occurred August 2d, which was about eight weeks before I first saw the patient, and resulted in the loss of the use of the left lower extremity so far as the ability of the child to walk was concerned.

This very flattering result I consider can, in a certain measure, be attributed to the fact that the operation was performed while the patient was yet young, only two and a half years of age, and before the usual contractions and distortions had resulted.

In this case a long spring was worn until June 1st, a little more than five months after the second operation, which enabled the patient to walk by stiffening the knee. During those five months the faradic current was applied twice a week, together with the daily use of massage to the sartorius and the extensor proprius pollicis muscles.

As soon as it was found that the patient could walk without the use of the brace, it was noticed that the

Third series: In the two cases in which the gastrocnemius was made to supply the peronei both patients were kept under observation for over twelve months, and the apparatus in each instance was left off and the walk was greatly improved (see Fig. 3).

Fourth series: In the one case in which the healthy extensor longis digitorum was attached to the paralyzed tibialis anticus there was a decided improvement in the position of the foot, when I saw the patient some three months after the operation. This patient was operated upon by me before the members of the Dutchess County Medical Society, in Poughkeepsie, on January 8, 1896, the patient having been referred by Dr. John S. Wilson, health officer of that city (see Fig. 4).

Fifth series: Just the reverse of the above, that of taking a graft from the tibialis anticus and attaching it to the paralyzed extensor longis digitorum, was performed on one of the cases of Series III.

Sixth series: The extensor proprius pollicis (Fig.

¹ See MEDICAL RECORD, October 26, 1895.

¹ For the accompanying illustrations I wish to thank my friend, Dr. Sidney Yankaur, of New York.

5), which was once made to supply the paralyzed extensor longus digitorum, was the other case of Series III. in which there was paralysis of the peroneal muscles. This case, it will be seen, required three distinct graftings in order to re-establish the normal symmetry.

Seventh series: In the one case in which the flexor longus pollicis was transplanted on to the anterior surface of the leg and attached to the tendon of the paralyzed tibialis anticus the wound healed primarily, but I question whether the result justified the operation, although I have not been able to follow the case as the patient resides in Providence, R. I.

Eighth series: The little boy of two and a half years whom I am happy to present to-day was referred to me by Dr. W. A. Goodall, of this city, on March 30, 1896. The history was that of infantile paralysis occurring one year previous, and affecting the triceps of the right upper extremity. On April 28, 1896, a graft was taken from the deltoid muscle and attached to the tendon and sheath of the paralyzed triceps, although not with the hope of obtaining such marked improvement as is shown. The atrophy of the triceps remains, but the deltoid seems now to be carrying on the work fairly well.

Conclusions.—1st. Infantile paralysis in the major-

FIG. 4.

FIG. 5.

ity of instances attacks groups of muscles or an individual muscle of a group.

2d. Operative interference should be practised with the hope of re-establishing the symmetry of the limb and can be accomplished in one of two ways:

(a) When the whole group is paralyzed a healthy muscle with the proper origin must be transplanted and given the insertion of the paralyzed group.

(b) When only part of the group is involved tendon grafting should be performed; that is, making one or more muscles do the work of those paralyzed.

3d. Animal suture material, preferably kangaroo tendon, should be employed on the tendons and muscles and in the closure of the sheath. As this material requires twenty-one days for absorption, it will usually be found that at the expiration of that time perfect union will have been obtained.

4th. The skin wounds should be closed with interrupted catgut and the sealed dressing of cotton collo-dion applied.

5th. Perfect immobilization of the limb can best be obtained by the plaster-of-Paris splint.

6th. The best results of such operative procedures can be obtained only in young subjects, so as to take

advantage of the natural growth of an otherwise undeveloped muscle, upon which we place additional work, as it would be unreasonable to expect a man who has led a sedentary life up to the age of fifty to assume at that time the arduous labor of a mechanic.

640 MADISON AVENUE.

THE TECHNIQUE OF INTUBATION OF THE LARYNX IN CHILDREN, WITH SOME REMARKS ON THE TIME FOR OPERATION AND AFTER-TREATMENT.

By THOMAS J. HILLIS, M.D.,

NEW YORK.

It is not the object of this paper to treat on the history of intubation, nor to follow the progress of its development, from its infancy to the present time. That could not be crowded into a short paper like this; indeed it would take a volume to do the subject justice.

While, then, confining myself to the practical aspect of the case, in passing it is impossible not to pay tribute to O'Dwyer, whose energy and intelligence have inspired this operation with a new life and whose marvellous mechanical skill overcame obstacles to others insurmountable. The brilliancy of his genius has shed lustre on the profession to which we have the honor to belong. He has bequeathed to posterity a heritage rich in amelioration of human ills and built for himself a monument imperishable in the hearts and affections of a grateful profession, and now, while he is still pointing the way to further progress in the higher development of our art, it is our privilege to follow in his footsteps and profit by his example.

To begin, the larynx of a child differs widely from that of an adult. Speaking broadly, seen from above down, the larynx of the adult has the appearance of a mortar hod, the handle of the hod not inaptly representing the trachea. In the young child there is seen a pealike slit behind the hyoid bone at the base of the tongue. This is the larynx. Immediately above and, as it were, looking down is an eminence, the epiglottis. In a child from one week to two months old the glottis and epiglottis are very apt to be overlooked. It must be understood we are working in the dark and only by the sense of touch, our objective point the glottis, our guidepost the epiglottis.

The ability to do good and rapid work entirely depends upon the recognition of those landmarks by the operator. If he dilly-dallies, beats about the bush, and chases after the larynx with the index finger of the left hand, while the right, armed with the introducer, is prodding the adjacent tissues in a vain effort to enter the glottis, he must surely fail by finally slipping his tube over into the œsophagus, the graveyard that hides his incompetency. To avoid this grave mistake, keep ever in mind the anatomical difference between the larynx of the child and that of the adult. Again, the larynx of the adult is much more deeply set than that of the child. Before any attempt to intubate is made, the physician should practise on the cadaver and be able at a moment's notice to place the tip of his finger on the spot where the larynx is supposed to lie. In short, he must locate the glottis. If he is not able to do this he has no business to try. It will bring defeat and humiliation on himself, and increase the sorrow of the family.

The instruments used in intubation from their nature are frail. If ever the word "handle with care" had any meaning, it is in this case; for either any jabbing or shoving is sure to be resented by the breaking of the instrument, or else, if the operator is unlucky enough by accident to get into the larynx, he will tear

the ventricle, wound the cords, or punch a hole in the wall of the trachea, probably the anterior wall.

It would be well for any one intending to practise intubation to make himself acquainted with his instruments, to spread them on his office table, and take note of each joint and hinge, and every weak and strong point they may possess, and by various passes and motions practise on some phantom subject.

In order to use his instruments well, he must know them well, they must have an active place in his mind. A good swordsman is acquainted with his steel. A huntsman knows the points of his rifle. The Arab is attached to his steed; he knows the horse and the horse knows him. Between them there is a mutual understanding and from this understanding the best results are attained. Then, finally, the operator must know and understand the tools he is to work with, more particularly when it is known that any bungling on his part may mean death to a fellow-being.

The operation is said to be most simple and easily accomplished after a little experience. I cannot quite agree with this opinion and regard it as hedged in with difficulties and dangers. In fact there is no branch of medicine or surgery in which the technique is so easily forgotten as this one now under consideration, and in order that it should not be forgotten the operator must keep in touch with the cadaver as well as with his instruments, and not lose sight of it unless he has unusual opportunities of practising on the living subject.

While the sense of touch is of the first importance, it is not all. There is the faculty, as it were, of seeing in the dark and being dexterous in manipulation. The trained finger of the gynecologist loses its cunning here, and the laryngologist, so well acquainted as he is with the topography of this region, this land of his adoption, the pillars of the fauces, the roof of the mouth, the base of the tongue and the walls of the pharynx, at his first attempt to introduce a tube into the larynx of a child suffering from croupous laryngitis is beaten on his own ground. His efforts end in signal failure. He cannot locate the larynx, and will not be able to do so until he studies the technique of intubation.

Preparing the Child.—If the surrounding conditions permit, the child should be stripped naked and with neatness and dispatch rolled in a piece of strong muslin or other cloth. It is much to be referred to the bulky and clumsy blanket usually employed. It should be arranged so as to have it pinned behind—the arms hanging by the sides, forearms and hands crossed on the abdomen. This is done to keep them off the chest, as any bulging or enlargement here is apt to interfere with the movements of the operator, who wants a clear field.

The child now recognizes that something is being done and grows more fretful and uneasy, but will in a short time be reconciled to the situation.

The child is now held by a nurse, a trained nurse if possible, upright in her lap. She grasps the child's legs between her knees, facing the operator. The assisting physician standing behind holds the child's head firm and binds, as it were, nurse and child to the chair. The position is now directly upright, and, as the saying goes, the child is hanging as it were from the top of his head.

Placing the Gag.—The vast majority of children develop croup between the eleventh month and fourth year, so for this reason the gag must be brought into requisition very frequently. It is a powerful instrument and looks not unlike bulldog forceps, and is provided with a groove above and below for the reception of the teeth of the upper and lower jaws.

The physician is assumed to be right-handed. He

may have to force the mouth open with a spoon or tongue depressor, but, as a rule, in croup and stenosis of the larynx the mouth is involuntarily open, the nose and mouth making strenuous efforts to drink in the particles of air.

The operator places the gag quickly to the left, opening it gradually and carefully and sliding its grooves over the teeth far back between the jaws; in fact as far as it can be got. By this method there is less liability to dislocate or break the jaw, an accident that happens not infrequently, than by first carrying the instrument to the angle of the jaw and suddenly and abruptly opening it. If the gag is properly placed the handles will not lie snugly on the side of the cheek, but pointing a little outward.

Too much stress cannot be laid on the value of placing the gag; in fact it is the first step toward success.

Now we are ready to introduce the tube. The physician should sit on a chair or stool, preferably the latter, as in sitting there is more composure, more self-possession, and the operator is more at ease. The assisting physician holds the gag firmly by the handles so that it cannot slip off the cheek. The mouth is now open wide. Let us look for a moment at this open mouth. We can see the gag filling up a not inconsiderable space to the left. Above, the teeth look angrily down, while the right corner is reserved for the index finger. From this it can be seen that there is little space left and that the operator must utilize this space to the very best possible advantage. There are now two ways of proceeding:

First Method.—First slip the index finger of the left hand rapidly but gently along the floor of the mouth. Keep as much as possible to the angle of the jaw. Draw the hyoid bone upward and forward, the so-called hooking up of the epiglottis process. Then with dexterity push the finger to one side, of course the outside, and with the right hand introduce the tube riding on the obturator, travelling under the roof of the mouth exactly in the median line to the chink of the glottis, which it enters just behind and below the base of the tongue. Elevate the handle of the introducer as the tube enters the glottis until its perpendicular is at a right angle to the plane of the floor of the mouth. After the cricoid cartilage is reached, the direction is downward parallel to the plane of the long axis of the trachea. It is easy to observe these points when their value is appreciated, as maintaining these planes and perpendiculars will keep the tip of the tube off the walls of the larynx and greatly, wonderfully facilitate its introduction. When the tip of the tube engages in the glottis, push it gently but with a firm hand by the trigger which plays in a groove running up the handle of the director. When the collar is caught in the grip of the larynx, hold it by the margin of the finger and withdraw the obturator. The tube is now in place.

Second Method.—The operator, sitting or standing as suits him best, tilts the child's head a little on the shoulder of the nurse and gently thrusts his left index finger backward along the margin of the tongue until its tip recognizes the slitlike aperture known as the glottis. Then he slips the instrument transversely across the tongue until its nose comes in contact with the finger. After righting the director and elevating the handle, he passes the instrument along the finger as a guide, when it will become immediately engaged in the larynx. Then he pushes off the tube with the side of the finger and withdraws the obturator. Now, as before, the tube is in place. If it require any considerable force to press the tube down, stop at once; there is something wrong. It is of the first importance to know when to stop, indeed second only to knowing how to do the operation well.

The peculiarities of the second method are, first, that the tube lies flat across the tongue, the convexity of the instrument just touching the gag; second, the median line need not be considered at all; third, the instrument is made to right itself as it travels backward toward the larynx; fourth, the tilting of the head, while altering the anatomical lines and angles, will put the tissues of the part on the stretch, thereby increasing the facilities for recognizing the larynx. Further, by tilting the head we have the teeth a little out of the way. These teeth are a formidable obstacle in the path of the operator, hampering him from above and often pinching the first phalanx of his index finger, causing annoyance if not actual danger from blood poisoning. Then again, by the tilting process the chin is lifted from the breast, which is an advantage of supreme importance when accurate and rapid work is the thing desired.

It may seem strange to depart from the median line when the objective point is the terminus of that line; but, however paradoxical the assertion may appear, a straight line is not always the shortest distance between two points, especially if a mountain intervene. In that case it is easier to go around than to climb the mountain; in the other it is easier to enter the mouth with the instrument on the flat, resting across the tongue, than in the perpendicular and median line; in short, the object of the second plan in passing from without inward is to take advantage of and be accommodated by the most favoring conditions.

How to Take Out the Tube.—To do this there are four ways. The first is very simple; the string being attached, pull in the direction of the median line, when the tube slips out easily.

The second way is called expressing the tube. If the child is under a year old, the cartilaginous rings of the trachea are yet soft and yielding and respond to manipulation. Place the child on his back, as in Silvester's method for artificial respiration. Put a small block or pillow under the neck and press the head back. This will bring the trachea prominently into view. Now manipulate the sides of the trachea, as in delicate massaging. Direct your force upward and backward, with the tip of the index finger of the right hand on the larynx to steady the tube; then turn the child on his side, elevating the buttocks, and slip the index finger and thumb into the mouth, when the tube can be easily and quickly withdrawn.

Third, for this purpose there is an instrument called an extractor. By placing the nose of this extractor in the mouth of the tube and pressing with the thumb on a spring, the nose or jaws open widely, biting the calibre of the tube and holding it tightly in its grip. Now withdraw the instrument and the tube comes also. There is an old saying that the best way of catching a bird is by first putting a little salt on its tail. The same way with the extractor. First put it into the tube, and as with the salt on the bird's tail the catching is easy. Now, how are we going to put salt on the bird's tail, or the nose of the extractor into the mouth of the tube? They are both very difficult undertakings, and require agility and tact. At present we will confine ourselves to considering the latter proposition.

The gag being in place, the tip of the index finger tries to locate the collar of the tube, which may be hidden or embedded in a mass of organized deposit or adventitious membrane. That very often practically buries the tube. The metallic click of the instrument when it touches the collar gives warning, and by delicate play the finger may direct it into the lumen of the hidden tube. Some clever operators and writers have argued ingeniously that the arytenoid cartilages may assist in locating the tube, but this is very doubtful, for the reason that those cartilages are in

the child rudimentary and soft, and sometimes require the most delicate and exquisite sense of touch to be recognized.

Since it is so difficult to enter the mouth of the tube with this instrument, and since while trying to do so much injury may be done to the larynx and adjacent tissues by opening and closing the blades of a mechanism that has such tremendous leverage, it has been considered wise to discard it altogether. To this end a tireless and ceaseless worker in this field, Dillon Brown, adjunct professor of diseases of children at the New York Polyclinic, has invented an ingenious little instrument in the shape of a ring open at the centre with a small perpendicular bar having a hook at its extremity. This little ring is placed on the index finger of the left hand, so arranged that the hook will look up from the palmar surface. The tube is the same as before, only that a semicircular thread of wire rises from the centre of the collar and passes upward and backward, its convexity about two lines above and parallel to its posterior wall.

Now slip the finger armed with this ring in the median line to the root of the tongue, when it will at once become engaged in the segment of the wire rising from the head of the tube; then the extraction is easy.

The only disadvantage of this method is that the tube, especially if too large, may rotate and bring the loop parallel to the median line, thereby increasing the difficulty of hitching on to the wire. Even with this drawback, it is immeasurably superior to the clumsy and dangerous old extractor. The wire loop, so valuable in the fourth method, will not interfere with the field of operation of the few who prefer the third style of procedure.

The Time for Operation.—There is no duty connected with his profession that weighs so heavily on the mind and heart of the physician as this one—when to interfere mechanically to save the child. He is confronted by three problems, namely: Can the child get well without interference? Is it too early to interfere? Or is it too late? He has ghostly memories of meddlesomeness on a previous occasion, when in his excitement he mistook simple for croupous laryngitis and laryngismus stridulus for stenosis of the larynx. These memories haunt him. The spectre clings to him. Now these grewsome recollections contribute not a little to make him nervous and unhappy. He wishes this time to make no mistake, and will not by keeping in mind the following suggestions:

He is called suddenly into a sick-room; there is a child suffering from croup. He knows nothing of the previous history or treatment. The child's skin may be cold or hot. There is clammy perspiration with cyanosis, often not marked. The face may or may not be anxious and drawn; the pulse is feeble and beats irregularly, whether fast or slow. On percussion, over the region of the back on both sides there may be slight or marked dulness, according to whether air or water or both are in the pulmonary cells.

To the ear the normal vesicular murmur is wanting. The sounds are those transmitted from the trachea, now the seat of riot and turmoil, and they are mixed, coarse, irregular, without vibration or interval of repose. Further, he sees the diaphragm, the great fly-wheel of the respiratory system, slow down to a few revolutions per minute, and he observes that the seat of respiration has been transferred from the thorax or chest to the trachea and larynx—the so-called shallow breathing.

Then the efforts of this new respiratory system at inspiration are long, vibrating, and labored, while expiration is short, shallow, and jerky. At every effort at inspiration the auxiliary muscles of respiration at the root of the neck contract violently, drawing the

head downward and forward on the chest, making great gaps and depressions in the supraclavicular and suprasternal regions. The heaving of this region is like the rolling of the billows, and as regular as a clock. The *alæ nasi* contract and expand and flap like sails in a cross-wind. The mouth may be in repose, or the lips slowly move in unison with the nose and muscles of the neck.

It takes some time to describe these symptoms, but the physician will take in the situation at a glance and recognize that the time to act is now or never.

Since it is a bloodless operation, he will have no difficulty in gaining the consent of the family, and even if his efforts are not crowned with success, he may still be able to command their confidence and gratitude, in that he at least lightened the labors of their little one and that the last moments of their darling were those of repose.

The After-Treatment.—How long should the tube be left in the larynx? Just as long as it is necessary—until the danger of the development of false membrane has passed. As a rule, more danger is encountered by taking it out too soon than by leaving it in a little longer than required. The danger of the tube exciting inflammation downward decreases the longer it is in place. Following the general law, the tissues soon become accustomed to the altered conditions and the tube speedily usurps the functions of the trachea.

If the child begins to look like himself again, take notice of his playthings and surrounding objects, and if the temperature is normal or nearly so, and the child shows a disposition to eat well, the danger is in all probability over and the tube can be removed, whether it is in one day or seven.

The physician would do well to remain on the premises for half an hour and be within call for six or eight hours, as the larynx may get blocked by shreds of broken-down membrane, or, the pressure being removed, the parts may swell and fill the lumen of the canal. However, the physician must not get frightened and rush for his case the moment he detects an obstruction, for there is always more or less after the removal of the tube; but if it becomes marked and progressive he must act at once by replacing his tube. After placing the tube there should be immediate relief, all the urgent symptoms at once subsiding. The air will pass through if the tube is not blocked by shreds of broken membrane that it pushed down. A few drops of water in the child's mouth will excite the act of coughing and probably clear the air passage.

If no matter is coughed up and the breathing remains bad, withdraw the tube by the string or thread you placed in the eye at the collar when preparing for the operation.

The tube withdrawn, further coughing may free the trachea and there may be no further trouble, when rapid convalescence will ensue.

When the tube in place fails to give relief and when no relief comes upon its withdrawal, the false membrane has extended down below its further extremity. Now tracheotomy holds out the only hope, and in this instance is to be preferred to intubation.

Feeding the Child.—No matter what position a child is placed in while feeding, there is danger of particles of food passing into the larynx. However, some advantage is claimed for feeding with the head bent over, the child resting on its back on the lap of the nurse. It is that the food that may not be carried in the act of deglutition to the pharynx cannot block or choke the tube by dropping into the larynx, since it must gravitate into the mouth, when the body is placed in this manner or on an inclined plane. The

anatomical position being altered, the glottis is poorly if at all guarded by the epiglottis.

Now, with the head in this awkward position, the food passing over the larynx is apt to act on the reflexes and excite increased coughing, which often leads to death from exhaustion. Further, the diaphragm itself, being more active, gives a suction-pump action to the trachea, which may draw particles of food into the larynx, even though counteracted by gravity.

A good way to feed a child is to let him lie on his stomach with his face down. This method is not so liable to excite coughing, and there is an inclined plane, but of course not so marked as in the other position.

It is certain (though the act is involuntary) that he has more command of the constrictors, and that the larynx is more fixed and the act of deglutition as a whole is more complete, than with the body in the dorsal position and with the head down and backward.

Some patients do very well in swallowing with the body in the upright position, and will resent, and make that resentment permanent, if any effort is made to depart from the natural manner of feeding. Give the child no food for half an hour; better still if feeding could be postponed for an hour. That would give the lame and crippled tissues of the constrictor group an opportunity to recuperate, and by their increased activity and watchfulness prevent the particles of food in passing over into the pharynx from dropping into the larynx and finding their way into the bronchi, when speedy inflammation would follow.

The best food for a child wearing an intubation tube is bread soaked in milk or beef juice, or oatmeal porridge.

Feed the child at stated intervals, a small quantity at a time, and about every two hours. Do not take him at a disadvantage; let him see you prepare for feeding. By this method he will cough less, and it will decrease the liability of some particles slipping into the larynx.

After the Operation.—A great deal toward its successful termination rests with the family. If its members are careless, forgetful, and indifferent, notwithstanding the warning of the physician that the danger is only half over, the probabilities are the child will die, though the operation itself was in every way successful and a road to recovery opened.

Then intelligent nursing is a factor to be reckoned with, and the want of this nursing in the tenement districts is the secret of so many failures, not only in intubation but in every form of disease.

If those ever eager to do good, always prating in lecture rooms and on church platforms about the dear neglected poor, who go about hawking their philanthropy like hucksters and fishmongers in a marketplace, always ready to plant the plague spot called free dispensary, would only consult those best able to give advice and inform themselves on the real needs of the poor, it would be to wipe out the pestiferous dispensary and plant on its ruins a school to train and instruct the people in the value and importance of self-reliance, temperance, fortitude, and hope. They would recognize that these are the weapons with which to combat disease and the ladder with which to climb to convalescence and health; and further, that while we have the poor always with us, we have the physician too, their tried, sincere, and abiding friend.

Then philanthropy would run in its proper channel, and the moral and material welfare of the poor be advanced and elevated, and the mortality of the city materially decreased.

51 CHARLTON STREET.

Cremation in England.—The third crematory in England is now being built in Liverpool.

THE EFFECT OF PERITONITIC ADHESIONS
ON THE DIGESTIVE TRACT.

BY BYRON ROBINSON, B.S., M.D.,

CHICAGO,

PROFESSOR OF GYNECOLOGY IN POST-GRADUATE SCHOOL.

DURING four hundred autopsies by myself on the human subject I have made careful observation of the appearances of the peritonitic adhesions, in various regions of the abdominal cavity. It may be stated that scarcely a body above twenty-five years old could be found without some form of local peritonitis. The situation of local peritonitis and consequent adhesions is quite constant, two factors being closely related, viz., muscular action and bowel flexures. The effect of the peritoneal adhesions might be considered in two respects, viz.: (a) as to the pain, and (b) as to the narrowing of the lumen of the bowel. In the history of medicine few have considered the subject from the point of anatomical pathology and still less from the clinical standpoint. The old classical writers of Latin gave the subject the exact title "*Constrictio et adhesio intestinalis et peritonitide*."

In the first place we may consider the common seats of local peritonitis as actually found in the autopsies of adults. So far as I have carefully observed and recorded them in three hundred cases the following is their order of frequency: 1. Spleen, which includes the flexura coli lienalis (over ninety per cent.). 2. Meso-sigmoid (over eighty per cent., left surface). 4. Coappendicular apparatus (over seventy per cent.). 5. Flexura coli hepatis (about sixty-five per cent.). This might be called the gall-bladder region, but I am convinced the chief causes lie in the colonic and duodenal flexures. 3. The pelvic region (over seventy-five per cent., i.e., the mouths of the Fallopian tubes). 6. The point where the duodenum crosses the right psoas and crus of the diaphragm (over forty-five per cent.). 7. The point behind the stomach which lies on the left diaphragmatic crus, i.e., at the foramen omenti majoris, or at what I designate as Huschke's foramen (over thirty-five per cent.). 8. At the hernial orifices (this is accidental).

The five regions of local peritonitis in adults are the meso-sigmoid, the pelvis, the cæco-appendicular apparatus, the splenic and gall-bladder regions. Observe that four of them are over the long range of the muscles, i.e., over the psoas and diaphragmatic muscles. The three regions of dangerous peritonitis are the pelvic, cæco-appendicular, and gall-bladder regions, in which abdominal surgery has shown its brilliant successes and its dismal failures. Before children walk the common local peritonitis does not arise, as muscular action has not been sufficient to irritate the gut. The etiology of the adult local peritonitis is due to muscular action and microbic invasion. In the pelvic region the peritonitis is chiefly due to an infectious invasion from the ends of the Fallopian tubes. In the other four common regions it is due to muscular action irritating or acting on a bowel at times when it contains virulent microbes. The irritation of the bowel induces the microbes or their products to pass through the mucosæ and muscularis of the gut wall to the serous coat, producing plastic peritonitis. Now, the muscle itself is not the cause of the peritonitis, but it is an essential feature. When the bowel comes in contact with the long range of action of the muscles of the peritoneum adhesions are deposited in that region. One can find also localities where infection has passed through the gut wall, entirely away from muscular action, as marked by white glistening peritoneal cicatrices; but such are irregular, not frequent, and have no definite anatomical distribution.

Accidental local peritonitis plays an important rôle in the life history of the peritoneum. I mean by accidental local peritonitis that which occurs outside of the common regions, due to muscular action or leaking Fallopian tubes. We may have an accidental local peritonitis, due to an ulcer of the mucosa allowing infection to pass to the superadjacent peritoneum, involving an area as large as the tips of the little finger to that of the palm of the hand or larger. I have frequently found such points. A mesenteric gland may ulcerate and break down, inducing adjacent peritonitis. Strangulated and reduced hernia, a blow on the abdomen, or perforation of the peritoneum by a gall stone may induce an accidental local peritonitis. We may find Meckel's diverticulum accidentally adherent by its distal end to some point in the abdomen, from a local peritonitis caused by infectious invasion through its wall. Infection is more apt to pass out of the distal end of Meckel's diverticulum than from any other portion, on account of the liability of the mucosa at the distal end to suffer injury, and because its infection is more liable to tarry there and the fæcal circulation is slower from physical reasons; and also we often notice a short distance from the end of the diverticulum a constricted neck. This narrowing of the diverticular lumen is very liable to obstruct the outlet. It then produces a closed mucous cavity, a condition of distinct menace, as it is in appendicitis. The omentum majus becomes fixed or adherent, in different localities of the abdomen by infectious invasions through the gut wall or from the tubal ends. However, we note that local peritonitis is nearly always a secondary disease. Tuberculous peritonitis perhaps comes under the same category of infectious invasion from the gut lumen, but it is more widely spread than ordinary or common adult peritonitis. Again, the origin of tuberculous peritonitis is very significant when one notes that in most of the cases the tubercles are most common on the peritoneum of the small intestines, i.e., the business portion of the digestive tract. The germs pass through the small bowel wall when freed by the digestive process. The cause of typhoid fever is the accidental perforation of the bowel, which, however, frequently heals and leaves an irregular, small, glistening peritoneal cicatrix. In the consideration of the effect of peritonitic adhesions upon the digestive tract we must take into account the subject of mobility of organs. The digestive viscera have all degrees of mobility, besides a more essential characteristic expressed in the idea of rhythm. A widely mobile viscus with a high peristalsis is compromised when either mobility or peristalsis is checked by peritonitic adhesions. If mobility or peristalsis is destroyed the organ is dislocated. Any abdominal viscus is dislocated when it is permanently fixed.

Rhythm is one of the means by which the digestive tract accomplishes its end. It is the method of introducing new food on fresh mucosa and finally of disposing of the débris. The vertical colons are fixed in man; normally there are no vertical meso-cola, so that it matters little if many adhesions are found about them, unless the colonic lumen be compromised, since at the time of the peritonitic deposit the colon gained sufficient rhythm or motion while the peritonitic exudates were soft and pliable to enable it to accomplish its ends of slight digestion and essential expulsion. The transverse colon and sigmoid flexure appear to adapt themselves to considerable peritonitic adhesions, for they are merely fæcal receptacles, to be emptied periodically. But there is one feature that neither of them, more especially the sigmoid, will agreeably accommodate themselves to, and that is when the bowel is drawn out to an acute angle by a peritonitic band. I have proved by secondary laparotomy that, if the highest point of the sigmoid flexure be fixed to the cut

ends of the Fallopian tubes, such a condition will sometimes make a patient an invalid until released. It then requires excessive peristalsis to force the faecal current past the acute sigmoid bend. But probably more than all else the peritonitic band creates irritability, excessive peristalsis at the seat of the adhesions. The liver may be entirely surrounded by adhesions without complaint from the patient. The mobility of the liver is but little, within the range of respiration only, and its rhythm is so limited, though definite, that it adapts itself to the surrounding adhesions. While the exudates are soft or fresh the liver by its rhythm produces sufficient space to accomplish its necessary functions, so that we can exclude the idea that merely peritonitic adhesions ever do much damage to the digestive tract, either by producing pain or by compromising digestive lumina. The spleen is capable of considerable mobility, yet confining it by adhesions does little damage, so far as is yet known. The rhythm of the spleen is very limited, so that peritonitic adhesions compromise the organ in a very small degree either to impair digestion or to produce pain. Over ninety per cent. of peritonitic adhesions are found around the adult spleen, and if impairment of digestion arose from parasplenic peritonitic adhesions it would long ago have been demonstrated. The uterus is so closely bound up in function with the tubes and ovaries that one cannot be considered without the other. Peritonitic adhesions dislocate the uterus because they permanently fix it. They produce pain and unbalance the function of the uterus and disturb its nutrition. Perhaps the chief pain in peritonitic adhesions in the genitals are those which check the rhythmical peristalsis of the Fallopian tubes. We know this to be a fact, for with women possessing considerable peritonitic adhesions about the tubes a vaginal examination will frequently arouse tubal colic lasting from one to three hours, of occasionally intense degree. We know that peritonitic adhesions about the pelvic organs induce pain both previous and subsequent to laparotomies. It is such a patent daily experience with a gynecologist to know that the peritonitic adhesions create pain both before and after vaginal hysterectomy, that it is amusing to see in a journal article, as we do occasionally, that the writer has discovered that peritonitic adhesions create pain, while no reasons are laid down as the cause of the pain, nor is it stated which organs are especially compromised by the adhesions.

For ten years I have closely watched the subjects of peritonitic adhesions, and my conclusions in regard to what induces the disturbances are that if a viscus with a long pedicle, *i.e.*, a highly mobile viscus with high peristalsis, becomes fixed at its most distal point by peritonitic adhesions it will induce pain. Dr. Lucy Waite and I have reoperated on ten or twelve patients for peritonitic adhesions formed subsequent to laparotomy. The patients who suffered the most were two in whom the most distal point of the sigmoid loop became fixed by peritonitic adhesions to the cut end of the Fallopian tube. These patients suffered very much from colic, indigestion, and neurosis before we would again put them to the risk of a second laparotomy. After the second operations every patient improved, and some gained fifteen to twenty-five pounds in weight within a few months. In other cases a loop of small intestine with an elongated pedicle, in other words a long mesenterium, was found fixed to the cut ends of the tubes, the uterus, bladder, or perhaps to a very mobile loop of the sigmoid or transverse colon; *i.e.*, some highly mobile viscus with a high peristalsis was checked in its natural movements. This is found in our abdominal work to be the distinction between peritonitic adhesions which disturb the patient and those which

do not. Sometimes one may do fifteen or twenty autopsies and find in over half the cases some fixed organ, *i.e.*, one with a short mesentery, as the cæcum, liver, or even the spleen, immovably fixed in solid peritonitic adhesions, but not the slightest complaint was recorded from the patient during life. If we do not make a definite distinction as to whom operations are applicable for peritonitic adhesions, many young surgeons will be led into error. For, if a surgeon should operate in a case of supposed appendicitis and simply find the cæcum and appendix buried in peritonitic adhesions, he might think the operation justifiable. But it is certainly not justifiable to operate for the peritonitic adhesions about the cæcum, as they occur there in over seventy per cent. of adults; furthermore, the adhesions are no sign that appendicitis ever existed. No one denies that pain in the right iliac fossa may demand an operation. If so, it is more likely to be due to the fact that some inflammation has fixed the appendix to a point at the long or longest range of action of the psoas muscle, and the motion of the muscle induces irritation in the appendix and consequent appendicular colic. I have operated on just such cases, in which if a patient was quiet, *i.e.*, did not walk, he was just as comfortable as any one, but let him exercise the psoas and he was in pain, an invalid. Now at the operation of such patients we find the appendix, having a small rupture or perforation which is a year or more old, with a few peritonitic adhesions, but it is fixed solidly to some point on the anterior surface of the psoas muscle, where walking or exercise will stir up the old point of adhesions.

A short summary of conclusions may be drawn up in regard to the effect of peritonitic adhesions on a subject:

1. Peritonitic adhesions may induce pain, neurosis, and indigestion, either before or after an abdominal section.
2. Peritonitic adhesions seldom or never give pain when surrounding fixed organs, *i.e.*, those with short mesenterial supports and limited peristalsis, as the cæcum and liver.
3. The pain in adhesions either previous or subsequent to operation is due to the fixation of mobile viscera and to the checking of active peristalsis or visceral rhythm.
4. The effect of peritonitic adhesions on viscera are dislocations and compromises of their lumina.
5. The viscera of great mobility and high peristalsis are the loops of small intestine, the sigmoid flexure, the Fallopian tubes, and the bladder.
6. The peritonitic adhesions have the most damaging effect in cases in which a peritonitic band becomes fixed to the point of the widest range of motion of any organ, as about the middle of the sigmoid, inducing an acute angle at the top of the bladder, or the cut end or normal end of the Fallopian tube.
7. The peritonitic bands may be found at any point where the peritonitis has existed, but is usually at a point of peritoneal abrasion, at the cut ends of the Fallopian tubes, or in the locality of an inabsorbable ligature.
8. In laparotomies all adhesions around highly mobile and highly peristaltic viscera, as the bladder, sigmoid, Fallopian tubes, and the loops of small intestines should be broken up. So far as I have observed, the transverse colon is less affected by peritonitic adhesions than any other mobile viscus. I have seen the extension of fourteen inches of the transverse colon in an inguinal hernia and the two limbs of the colon were absolutely adherent, like a double-barrelled gun, yet no record of the patient's complaints appeared. But the matter may be accounted for by the fact that in the vast majority of cases the

peritonitic adhesions of the transverse colon are located about the hepatic and splenic flexures, where the colon is the most fixed, which is the very reason that the peritonitic adhesions exist.

9. Patients with peritonitic adhesions before but especially after laparotomy complain of periodic colic and periodic dragging pain. It is exacerbated by taking hot food or drinks. It is rarely made worse by moderate exercise. In short, anything which increases peristalsis makes colicky, dragging, bearing-down pain. Just before or at stool the pain is annoying and occasionally continues some time after. In the cases of peritonitic adhesions about the bladder, the pain is exacerbated at the time of evacuations and for some time later. Should a diarrhoea start, the pain of peristalsis is severe.

10. Pain from peritonitic adhesions about the gall bladder may arise from two causes: (a) the peritonitic bands may drag the top or fundus of the gall bladder so that it will produce a sharp bend or kink in the neck or outlet ducts. Dr. Lucy Waite and I had just such a case. The peritonitic bands had dragged on the fundus of the gall bladder and added something over four inches to its length. We released the gall bladder, elevating the fundus, relieving its bend or kink, and curing the patient. (b) As the gall bladder empties, pain from dragging on the surrounding adhesions may arise; also, as the adjacent colon may rapidly distend and contract, this may produce dragging pain from this effect on the peritonitic adhesions adjacent to the gall bladder.

11. The viscera which come within the clinical and surgical range of peritonitic bands are those of wide mobility and high peristalsis.

12. The reason that so many patients recover from peritonitic bands without requiring subsequent interference is because the active mobile peristaltic viscera make room and space for their own function while the exudate is still soft, pliable, and mouldable to the environments.

About seventy-five per cent. of laparotomies are followed by peritonitic adhesions or bands. Unless there be some continued source of infection, like the mouth of a Fallopian tube, normal or amputated, ulceration of mucosa, stone in the urinary or gall bladders, which sustains infectious invasion, peritonitic adhesion will grow less; very slowly, however, until the bands become organized with a steady blood or nourishing supply, when they may persist forever.

13. The final persistent effect of peritonitic adhesions on active mobile, peristaltic viscera are pain, indigestion, and neurosis.

ACROMEGALY.

By H. H. DINKE, M.D.,

ST. CHARLES, MO.

TEN years have elapsed now since that careful and a painstaking observer, Pierre Marie, first recognized in strange complex of morbid symptoms a new clinical entity and aptly termed it acromegaly. Since then the clinical histories of quite a number of cases have been accurately recorded, and exhaustive reports of more than a dozen post-mortem findings in cases succumbing to this disease have been made, but they have failed to throw much additional light on the subject, and our conceptions of the pathology and etiology of this rare disease remain varied and indefinite. Dr. William R. Parker, of Stricklandgate, Kendall, England, who has given the subject of acromegaly, myxoedema, cretinism, and kindred diseases much attention, and who has had extraordinary opportunities for the accurate study of these maladies, in a letter of recent date writes as follows: "A few months ago I collected

all the information about acromegaly that had been published in the *British Medical Journal* for the last nine years or so, and found that it amounted to nothing. Cases were described minutely, and a few illustrations were given and accounts of post-mortem examinations, in which the pituitary gland was usually found enlarged. Some few had imagined they could observe some improvement by treatment with pituitary extract, and one or two imagined thyroid extract had done good. But no marked or obvious improvement ever occurred. For the severe headache, trephining sometimes worked wonders by relieving intracranial pressure. I do not know of any recent information about the subject of any value. I imagine we shall be on its track before long, and find it curable, but the goal is not attained yet." In spite of these discouraging facts, or possibly on account of them, it would seem important that all cases should be carefully recorded, the clinical histories as well as the results of autopsies, as such reports will contribute to a better understanding of the true nature of the disease. The recital of this case may gain additional interest from the circumstance that our patient has been treated uninterruptedly for the past five months with animal extracts and that an effort has been made accurately to note all changes in the physical as well as mental condition resulting therefrom.

The family history of our patient is negative as to any cachexia or faulty nervous inheritance. The father died at the age of sixty-six years of "asthma;" the mother died of rheumatism at the age of sixty-three years. She has one brother and three sisters living and perfectly well; none dead. No one in her family was ever afflicted as she is. She is the mother of one son, aged twenty-four years, in good health; and she has lost two children by diseases incident to childhood. She is a woman of excellent habits, and there is no history of any venereal disease. Up to the time of the appearance of her present trouble she had always enjoyed fairly good health and had never been very sick. Her present illness commenced about fifteen years ago, but the beginning was so gradual and insidious that neither she nor her relatives can state accurately just when the trouble set in. Her hands, feet, and face began to swell gradually, but her attention at first was particularly drawn to her hands and feet. The swelling of the extremities was accompanied by lancinating pains suggestive of rheumatism. In fact the disease was thought to be rheumatism and she was treated for such until Dr. J. H. Stumberg, of this city, recognized it as a case of acromegaly. The patient remains under the treatment of Dr. Stumberg, and it is through his kindness that I am permitted to place this case on record. Our patient is now fifty-one years of age and was born in this country. She is five feet five inches in height, and weighs one hundred and sixty-seven pounds. She displays all the classical symptoms of acromegaly; the hands and feet are enormous, the head and face are large and broad, the lower jaw is massive and projecting.

The head is large and covered by an abundant growth of coarse hair. The forehead is retreating and the superciliary ridges are very prominent. The nose is much increased in size, in length as well as in width. There is considerable exophthalmia, but she can move her eyeballs readily in all directions, and the pupils react well to light stimulus. The ears are very large, stiff, and thick, and project from the head. The lips are extraordinarily thick and everted, the lower one more so than the upper one. The tongue is broad and flat and so large that it completely fills the oral cavity, and it is almost impossible to depress the tongue sufficiently to see the condition of the throat. The tongue and oral cavity are covered by a thick but pale mucous membrane, having deep and irregular furrows.

The alveolar processes are broad and the teeth bad. The lower jaw is massive and the teeth of the lower jaw project in front of the upper jaw. The scalp and the skin of the face are very fair and greasy in appearance, and soft and spongy to the touch. It is evident that the enlargement of the face and head is at the expense of the soft parts as well as of the bones and cartilages. The head is slightly bent forward, but there is no marked cervico-dorsal kyphosis; the neck is short and measures thirteen inches in circumference. As far as we are enabled to determine by palpation, the thyroid gland is absent. The clavicles, scapulæ, and ribs appear to be larger than usual. The chest is normal in form. Palpation and percussion reveal nothing abnormal; no adventitious sounds can be heard. The heart, too, is normal; we are unable to detect any abnormal murmurs, but its pulsations are somewhat accelerated. The shoulder and elbow joints are normal in size. The hands are greatly enlarged, probably more so in width than in length. The fingers are broad, thick, and stumpy; the nails short, thick, and striated. This enormous increase in size of the hands does not extend up very

Aged 28 Years.

high, for at the junction of the lower with the middle third of the forearm the circumference is only seven and a half inches, whereas at the wrists it is nine inches. As far as we are able to determine, the abdominal organs are healthy. There does not seem to be an increase in the size of the thighs, but the knee-joints are considerably enlarged. The legs also partake somewhat of this increase; the feet, however, are simply enormous. Patient states that she used to wear No. 4 shoes, but is now compelled to wear No. 7½ shoes. The feet are flat, broad, and thick, and much increased in length. A thick cushion of soft tissues surrounds the os calcis and the outer side of both feet. The toes are very broad and stumpy, with thick cushions on the plantar surface of the last phalanges, which press the tips of the toes up and cause the nails to stand almost erect. It is evident that the increase in size of the feet is more the result of an hypertrophy of the soft parts than that of the bony tissue. The skin is white, soft, and doughy, and marked by deep furrows over the entire body, but most markedly so about the face and extremities. The voice is coarse and speech thick. Patellar reflexes are lessened on both sides. The tactile sense

is not perceptibly impaired. The eyesight is bad; patient is unable to see objects distinctly at even short distances. Tinnitus aurium is distressing, but the hearing is good. Taste and smell are not affected. Her mind is clear and she answers readily and intelligently all questions addressed to her. Her memory is very defective; there is no stupor, nor does she suffer attacks of somnolence. She is inclined to be depressed in spirits, and keenly feels a sense of general weakness. Headache, though present at times, has never been a prominent symptom. Patient's appetite is normal, but she has an extraordinary thirst. She sweats freely upon the slightest exertion and passes large quantities of urine, over half a gallon per day. Examination of the urine does not show presence of albumin or sugar. There are no disturbances of digestion. Temperature, 98° F.; pulse, 85. The hands and feet are usually cold to the touch. The pains in her hands and feet, starting at the knee and elbows and extending downward, continue to be the most distressing symptoms and render it impossible for the patient to sleep during the earlier hours of the night.

The accompanying photographs show singularly well the ravages of the strange disease. The first photograph presents a rather attractive face with pleasing features; the second photograph shows the same face, but disease has cruelly and ruthlessly effaced all traces of former beauty and impressed upon it indelibly its own individuality. The accompanying measurements will serve to show accurately the amount of deformity, and the extent of enlargement of the affected parts:

Measurements.	Beginning of Treatment.		Five Months Later.	
	Right.	Left.	Right.	Left.
	Inches.	Inches.	Inches.	Inches.
Length of hand, wrist to tip of middle finger.	7¾	7½	7¾	7½
Circumference of hand at knuckles.	11½	11	11	11
Circumference of metacarpus with thumb.	9¼	9	9	9
Circumference of thumb at first phalanx.	4½	4	3¾	3¾
Circumference of thumb at last phalanx.	3½	3½	3	3
Circumference of wrist.	9	9	7	7
Circumference of forearm at juncture of lower and middle third.	7½	7¼	7¼	7¼
Length of foot, heel to great toe.	10	9½	10	9½
Circumference of foot at ball of great toe.	9¼	9¼	9¼	9
Circumference of foot at instep.	11	10½	10½	10¼
Circumference of foot across instep and heel.	13½	13½	13	13
Circumference of foot at ankle.	10½	10½	10½	10
Circumference of leg at knee.	16½	16	15¾	15¼
Length of nose (root to tip).	3			
Distance between angle of jaw and symphysis.	5¼			
Circumference of neck.	13			
Circumference of chest at nipples, expiration.	35			
Circumference of chest at nipples, inspiration.	38			
Circumference of abdomen.	29			

We decided to give our patient the benefit of treatment with animal extracts. During the first two months she took one-half grain of thyroid extract three times a day. One grain of this extract represents ten grains of the fresh gland. During the third and fourth month desiccated pituitary bodies were given, about one and a half grains three times a day. During the last month a combination of both extracts was administered, four grains of desiccated pituitary bodies and one-half grain of thyroid extract a day. By comparing the measurements at the beginning of treatment and five months later, it will at once be seen that there is a decided decrease in size. The fingers

and the wrists in particular are much thinner than they were, and the shoes that fitted snugly at the beginning of treatment are much too large now and feel like loose slippers. Her general condition, too, has improved. Her memory seems to be better, and she is not so much at a loss for words as she was. She can walk much better, and for greater distances. She notices, however, that the extremities temporarily swell whenever she exercises too much. The pains in her extremities have left her almost altogether, and there is an increased freedom of movement of the hands and feet. The hair is softer, the skin a little firmer, less wrinkled, and more natural. The lips and tongue are perhaps a little thinner, but speech remains thick. The mucous lining of the mouth is less furrowed and more healthy in color. The thirst is not extraordinary now; she does not sweat nearly so readily, and she voids less urine. Her bowels are no longer constipated, but have become regular. (I have noticed this to occur in patients to whom I have given thyroid extract to reduce fat. These patients not infrequently are suffering from chronic constipation, and thyroid extract not only effects a loss of weight but also relieves the chronic constipation.) Our patient has lost about fifteen pounds in weight during these five months. The feeling of general languor is not nearly so annoying, and she can sleep now the entire night. The general condition of our patient, therefore, is unquestionably improved, but the unmistakable marks of acromegaly are nearly as plain now as they were at the beginning of treatment. Patient believes that the thyroids benefit her most.

It might not be without interest to inquire what led to the employment of animal extracts in acromegaly. The experimental researches of Schiff, Horsley, and Murray resulted in establishing the function of the thyroid body and demonstrated how important that organ is to the growth and development of the organism. Stimulated by these brilliant results, the function of other ductless glands and the internal secretion of the glands having efferent ducts have been carefully studied, and enough is already known to justify the belief that these glands secrete substances *sui generis*, which are carried by the blood to the most distant parts and which are indispensable to the proper nutrition of all the tissues of the body. In other words, that the glands of the body are practically the centres governing normal metabolism would seem to have been established. It is well known now that myxœdema is a disease of the thyroid gland resulting from an arrest of function of that organ. Any one who has had an opportunity of seeing and watching a case of myxœdema and a case of acromegaly cannot help but recognize the striking resemblance of many of the symptoms of these strange affections. But the similarity of many of the symptoms is evidently not the only tie of relationship. There is every reason to believe that in acromegaly the pituitary body is principally involved, as it was first declared to be by Marie; all the facts at hand go to show that acromegaly is either a disease of the pituitary body alone, or of the pituitary body and other glandular structures histologically and physiologically kindred.

In the twelve autopsies recorded¹ this gland was found enlarged and disorganized in eleven cases; in one case, however,² no particular changes were observed. Then, too, it should be stated here that there are two cases on record which militate against the assumption that the pituitary body is the site of this disease. In one case³ a large aneurism of the blood-vessels at the base of the brain had entirely obliterated

this gland; in another case,¹ at autopsy the pituitary body was found greatly enlarged. In neither case, however, were symptoms of acromegaly present during life. It should be remembered, however, that symptoms of acromegaly develop very slowly and very gradually, and it might be possible that in these latter cases death occurred before the symptom-complex of acromegaly could develop. The post-mortem findings in the great majority of cases, therefore, point unmistakably to the pituitary body as the principal if not the sole site of the disease; then, too, the symptoms of intracranial pressure, such as headache, tinnitus aurium, defective vision, etc., though differing in intensity and degree, are prominent in all cases during life. Histologists have shown that the structure of the pituitary body is almost analogous to that of the thyroid gland, and experiments on lower animals by Hofmeister, Vasalle, and Sacchi have demonstrated that after the removal of the thyroid the pituitary body enlarges, and after the ablation of the pituitary body a compensatory enlargement of the thyroid gland takes place. Myxœdema and acromegaly, therefore, are close ties, and there is every reason to believe that leontiasis ossium, elephantiasis, and gigantism sustain a close relationship to both. All

Aged 51 Years.

these affections show evidence of grave nutritive disorders, and the lesions of diseases resulting from trophic disturbances are to be sought for in the glandular tissues of the body. Up to within recent years the treatment of acromegaly has been wholly symptomatic and altogether unsatisfactory. In bad cases, in which symptoms of intracranial pressure become distressing and unbearable, trephining has been done with satisfactory results, and this surgical treatment of acromegaly deserves consideration. The treatment of acromegaly by animal extracts is new. Dr. Richard C. Cabot² has succeeded in collecting the details of nine cases in which thyroid extract was exhibited, and ten cases in which pituitary bodies were administered. Quite a number of these cases were benefited by both these animal extracts, which leads Dr. Cabot to advise the simultaneous use of both. The results of the

treatment with these animal extracts, singly and combined, have been recorded in the above. There is probably no remedy which will completely efface the ravages of the disease, and in our case the remedies have been used for too short a time to permit us to arrive at positive conclusions. In a general way, however, it may be asserted that a number of the most distressing symptoms, such as pain, helplessness, etc., are either much relieved or entirely removed; that the patient's physical as well as mental condition is greatly improved by this treatment, and that the results obtained by it are much more satisfactory than those following the older remedies.

THE NEED OF ABDOMINAL SECTION IN CERTAIN CASES TO AID THE GENERAL PRACTITIONER TO DIAGNOSE OBSCURE ABDOMINAL DISEASES.¹

By J. H. CARSTENS, M.D.,

DETROIT, MICH.,

CHIEF OF STAFF AND GYNECOLOGIST TO HARPER HOSPITAL, PROFESSOR OF OBSTETRICS AND CLINICAL GYNECOLOGY IN THE DETROIT COLLEGE OF MEDICINE, EX-PRESIDENT OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

WHAT surgical crimes have not been committed by the reckless and inexperienced as the result of the statement made by an eminent abdominal surgeon, "If you don't know what is the trouble within the abdomen, open it and find out," or words to that effect! Such a statement was made in an entirely different sense in which it was accepted at the time by the reckless.

It seems to me that we often find growths and tumors in the abdomen which we cannot diagnose with certainty, but after we open the abdomen we can generally tell what they are. All tumors and growths of whatever kind require surgical interference and a positive diagnosis is not necessary. If it is a case of pus tube or ovarian tumor, or if we mistake a cyst for a fibroid, or make any other mistakes, as long as there is palpable morbid condition, operation is the proper thing. It does not make very much difference whether it is the one kind of tumor or the other, as long as the surgeon is prepared to meet all emergencies which may arise.

The term exploratory cœliotomy is used a great deal in the same sense. We generally mean that there is some morbid condition within the abdomen which we diagnose, but we are not positive whether it can be removed, or if the removal is justifiable. We cannot positively tell whether it is malignant, involving vital organs, or whether it is a benign growth which can be removed and which we know will not recur. We make an exploratory abdominal section for the purpose of diagnosing the exact condition and removing the growth if possible, but if we find that the risk is too great and that it would recur in a short time, even if removed, we close up the abdomen and let the patient live as long as possible.

But there is another class of cases, not too common and still frequent enough, in which it is utterly impossible for the general practitioner or any specialist to make a proper diagnosis. There is no tumor, growth, or other manifest condition. All our means of precision cannot help us; neither chemical analysis of different fluids, nor instruments of precision, nor the latest fad, the Roentgen x-rays, will help us to diagnose the trouble. The patient simply becomes gradually weaker and weaker. All our medication, careful diet, change of climate, and surroundings do not help. Sometimes, even in acute cases, with the onset sudden and rapidly fatal, the symptoms are so mixed

and obscured that the diagnosis is not made until post-mortem investigation. In this kind of cases, it seems to me, when the usual plan of treatment is of no avail—the physician sees the patient gradually slipping away from him—that abdominal section is indicated, first, for diagnostic purposes, and, secondly, also with a view to curing the patient. And when I make this suggestion I do it with a tremble on my lip, because it will give any tyro an excuse to open the abdomen for the most trivial things and refer to me as his authority. If I say that such practice should be limited to those who have had experience and have facilities, I may be accused of being afraid that some young man may become a rival. Therefore, those of us who have made hundreds of abdominal sections, and who start every new case with a certain tremor and fear that it may be complicated and difficult and that the patient's life may be endangered, are placed in a peculiar position.

If we say to the general practitioner that this is, as a rule, without danger, that we can diagnose the case and even submit the patient to an operation at the same time, if necessary, and thus save him, we spur on the ambitions of the inexperienced and the conscienceless to reckless deeds. If we qualify the above suggestion by saying that such operations should be performed only in thoroughly equipped hospitals, surrounded with every facility to meet every emergency, and that the operation should be performed only by those who have experience and manual dexterity, we are accused of trying to have a monopoly and not giving those who are to come after us a chance to get the experience.

This is all wrong. Whoever wants to make this a life work should prepare himself properly for it by assisting at many operations, and should live in a locality where he can expect to do a good many operations every year. An operation or two of this kind a year will increase no one's reputation, nor would it pay from the financial standpoint; often it would not pay even for the instruments and paraphernalia required.

All we claim, then, in advocating abdominal section for diagnostic purposes, is that it should be done by one of experience and in a place where every facility is at hand. Then the danger will be so very little that the family physician can conscientiously urge it upon his patient, and the patient will gladly submit to it in order that a clear understanding of his case may be arrived at, so that the proper treatment, be it surgical or medical, can be instituted.

First, in reference to acute cases, everything in the way of functional disorders of the bowels, excited by indiscretion in eating, cholera morbus, cholera infantum, etc., must be excluded: all these can be readily diagnosed. But if the case presents itself with persistent vomiting, there is grave suspicion that it is due to obstruction and requires surgical interference. Also cases with severe excruciating pain in the region of the liver strongly point to gall stones, even if jaundice does not exist; in fact, jaundice is so rarely found with gall stones that the profession has been led astray for years by the old text-books emphasizing jaundice as a marked symptom. So renal calculi or suppurating kidney may cause occlusion of the ureter and can only be diagnosed inferentially, except by an abdominal section. Of course, the marked symptoms of appendicitis, I think, are so well known now that every practitioner can diagnose the disease and also knows that prompt surgical interference, as a rule, is required.

Secondly, however, our principal aid can be given to the general practitioner in chronic cases of trouble of some kind within the abdomen. While no swelling or growth can be detected, the patient is an invalid.

¹ A paper read at a meeting of the Northern Tri-State Medical Society at Angola, Indiana, July 21, 1896.

even if not in danger; he does not enjoy life, and in some cases it can be readily seen that he is gradually becoming weaker and weaker.

In all cases of this kind an exploratory abdominal section will clear up the diagnosis, and, if necessary, can be made into an operation if something is found requiring surgical interference. The technique of the operation can be settled in each individual case only according to the seat of trouble especially indicated. In the large majority of cases the trouble is located on the right side in the regions of the appendix, gall bladder, or kidney. An incision made on the right outer edge of the rectus about opposite the umbilicus will allow exploration with the finger to be made around the cæcum, the gall bladder, and the kidney, and then the incision can be extended either upward or downward. Sometimes the left outer edge of the rectus is chosen; rarely, I think, the median line.

It is hardly necessary to mention that all the pelvic diseases of women are excluded from this paper, because they can be readily diagnosed by conjoined examination by anybody with even limited experience.

I do not report any cases, simply because I do not want to take up your time, but I can mention any number of obscure cases promptly explained and often relieved by abdominal section.

The danger of abdominal section is very slight, while the gain is immense. Accidents occasionally occur, but the mortality should be less than one per cent. The vast majority of such patients can be saved, either by prompt operation or by proper medication.

In conclusion I would say that abdominal section for diagnostic purposes in a well-equipped hospital is indicated:

(A) In acute cases with severe symptoms which threaten life if not promptly removed.

(B) In chronic cases in which treatment has been of no avail and the patient continues to be more or less of an invalid, or steadily becomes worse.

Progress of Medical Science.

Contamination of Liquid Eye Medicines.—Dr. Clough (*Journal of Medicine and Science*, October, 1896) says: "A fruitful source of contamination of liquid eye medicines is the common rubber-bulb dropper. Many a solution over which much care has been exercised to render it stable soon becomes worthless through these little miscreants. Their mischief lies in the fact that many of them—the white variety in particular—are coated with a flour-like film, which becomes detached the instant any fluid touches it and diffuses itself, in an insoluble state, throughout the contents of the bottle in which it is used. Hence, care should be taken that the pharmacist either dispense droppers free from such objection, or else obviate the difficulty by careful cleaning before inserting into the bottle.

A New Aseptic Method of Closing Wounds without Sutures.—The great difficulty often experienced in closing wounds where sutures are impracticable or where they are liable to slough out from too great tension has been overcome in a great measure. The use of adhesive plasters instead of sutures is not thoroughly aseptic, and to overcome this defect Dr. Schürmayer uses pieces of fine platinum wire having hooked ends. These wires span the wound, and can be rendered aseptic by flaming. At either end they are hooked into strips of adhesive plaster, that in case of a limb encircle it, so that with the wire they entirely surround it. The ends of the adhesive strips are folded upon themselves to prevent their adhering, and

the hooked ends of the wire are passed through punctures in this double thickness. Aseptic gauze is laid on the skin beneath the ends of the wire to prevent infection of the wound from the adhesive plaster. The great advantages of this method are that the tension is applied at a distance from the margin of the wound; that the wires alone come in contact and may be perfectly sterilized; they can be easily removed, either singly or all together during the dressing and then replaced; there is no strain upon the edges of the wound during their removal, and coaptation of the margins of the wound can be secured as easily and perfectly as by the use of sutures.—*Centralblatt für Chirurgie*.

Anterior Colpotomy.—At a late meeting of the Obstetrical Society of London, as reported in the *British Medical Journal*, Dr. John Phillips read a paper on this subject. He considered that to Dührssen belonged the credit of calling attention to this operation. Any one who had performed either vaginal hysterectomy or fixation could not but be struck by the ease with which the pelvic organs could be examined through the opening in the anterior vaginal cul-de-sac. Full details of the operation as carried out by Dührssen, Mackenrodt, and the author were given, with histories of four cases. In the first of these vaginal fixation only was originally intended. The author considered the advantages of this method to be: (1) No hernia or cicatrix and less liability of the formation of adhesions with the omentum and intestines. (2) Greater simplicity of operation, greater rapidity of performance. (3) Post-operation sickness is much less and the convalescence shorter. (4) No bleeding of any consequence, except occasionally from the vaginal flaps. (5) No drainage tube required. The disadvantages, on the other hand, were: (1) Much greater difficulty in making the vagina antiseptic, especially if there be any fetid uterine discharge. (2) Greater risk of wounding the bladder, ureters, and coils of intestine. (3) If the swelling is adherent in the left and posterior quarter of the pelvis, the rectum may be lacerated. A list of cases in which this operation seemed indicated was given. With regard to recommending the operation, the author wished it to be borne in mind, first, that the peritoneal cavity was opened, with its possibly grave after-results; and, secondly, that removal of the ovaries and tubes, whether by vagina or abdomen, must always be looked upon as a mutilation, and hence the same care and anxious thought should be exercised as before resorting to abdominal section.

Postoperative Intestinal Obstruction.—Dr. Adenot recognizes the following varieties of post-operative intestinal obstruction: 1. Occlusion caused by adherence of the intestine to raw surfaces, intraperitoneal drains, and inflamed organs. 2. Occlusions due to bands. 3. Those due to anomalous position of the intestines. 4. Those due to an exaggeration of the normal left subcostal angle of the colon. 5. Spasmodic occlusion. 6. Occlusions due to inefficient operative procedures. According to him there are three marked symptoms of post-operative intestinal obstruction: 1. Persistent absence of the passage of flatus. 2. Nausea and vomiting. 3. Painful point in abdomen. As regards treatment, one should not delay too long. While it is legitimate to try mild purgation, insertion of rectal tube, etc., the amount of such treatment should be abridged proportionally to the severity of the symptoms and clearness of diagnosis. The period of operation will be from three to five days, according as the vomiting is urgent and there is absence of stools or passage of flatus. The abdomen should be opened largely. Work quickly

and have good assistants. Examine the cæcum; if it is not distended, the occlusion is located higher up in the small intestine. If it is distended, explore the sigmoid flexure. One should always follow a definite plan: first ascertain the extent of the occlusion, then its location, and lastly the cause. Examine the pedicles, raw surfaces, angles of the intestine, and drainage apparatus. Examine the colic flexure of the left side. If the obstacle cannot be found, evisceration must be performed. Recourse should not be had to this grave procedure too readily, notwithstanding that it has succeeded in the hands of Jaboulay and Pollosson. Sometimes an artificial anus is necessary, but it is not an operation of choice.—*Revue de Chirurgie*.

Healed Wound of Heart.—At the London Clinical Society, Mr. W. G. Spencer recently showed a specimen of healed wound of the heart. The patient had been stabbed in four places, and was admitted pulseless and unconscious. Infusion of saline fluid, etc., was employed, and he went on well for a week. Then hemorrhage occurred, and Mr. Spencer passed his finger through the wound in the second left intercostal space, and touched a large vessel with low tension and a whirling current with each systole. The wound was firmly plugged. The plugging had to be renewed again and again, on account of fresh bleeding and the plug becoming extruded. By the twenty-seventh day the plug was all pushed out, and only a superficial wound remained. This healed in six weeks from the accident, and nothing abnormal was heard in the chest, except a faint murmur, as in anæmia. The patient continued weak and anæmic, but attended a long trial, and eventually sank exhausted seventy-nine days after the injury. At the post-mortem, the scar in the left intercostal space was seen to correspond with another in the pericardium, and this again with a linear depressed scar, five millimetres long, on the surface of the right ventricle. Then opposite to this, on the endocardium, was a fine bluish line. This was thought to be the scar of a firmly healed perforation of the ventricle, and was just below the pulmonary valves. There was no sign of any other vessel being wounded, and no clot inside or outside the heart or great vessels. The only question raised was whether the weapon had actually penetrated the endocardium (the scar on which was very fine) and the hemorrhage came from a branch of the coronary. The question of suturing was mentioned, but Mr. Spencer said it was difficult to fix the direction of the wound.

Pregnancy Diagnosed by the Urine.—Dr. William E. Parke, following Dr. William D. Gray, of Richmond, states in the *American Gynecological and Obstetrical Journal* that he can make a positive diagnosis of pregnancy within twenty days after conception, by certain changes in the microscopical appearance of the urinary phosphates. The normal triple phosphate is stellate and markedly feathery. Soon after conception the feathery parts begin to disintegrate, take on the crystals, approach to normal, and at term are normal. In preparing the urine for examination Dr. Gray takes about one inch in a test tube and adds about one-third as much of Tyson's magnesian fluid. This will throw down the triple phosphates in fifteen or twenty minutes and furnish the necessary material for examination. Tyson's fluid consists of one part each of the muriate of ammonium, aqua ammonia, and sulphate of magnesium, and eight parts of distilled water. When conception occurs the triple phosphates lose their feathery appearance, the change beginning at the tip and progressing toward the base. One side only may be affected, or both, leaving only the shaft and perhaps a few fragments adhering. The shaft assumes a beaded or jointed appearance. These

changes are most marked in the early months of pregnancy. Dr. Gray draws the following conclusions: 1. The change occurs in a very large percentage of pregnant women. 2. This change is not equally pronounced in the urine at the same period of gestation in different women nor at consecutive examinations of the urine of the same woman. 3. When recognized it forms strongly presumptive evidence of pregnancy. This sign is recognizable very early. (Dr. Gray, in a personal letter, states that he has made many diagnosis as early as ten days after conception.) It is therefore of the greatest value when other signs are of the least value, or not present at all. 4. A diagnosis of probable pregnancy can be made without a physical examination or without exciting the suspicion of the patient.

Treatment of Suppurating Buboës by the Injection of Iodoform Ointment.—Dr. Otis' method, given in the *Journal of Cutaneous and Genito-Urinary Diseases*, 1896, vol. xi., pp. 174-176, is as follows: "The skin for some eight or ten inches about the affected area was rendered thoroughly aseptic by scrubbing with green soap, washed with sulphuric ether, and then with bichloride (1 to 1,000). A narrow bistoury was then inserted into the abscess cavity, and the contents were gently but thoroughly squeezed out, the cavity was irrigated with bichloride (1 to 1,000), and immediately filled to moderate distention with warm iodoform ointment (ten per cent. iodoform and vaseline), care being taken not to use a sufficient degree of heat to liberate free iodine. The syringe used for introducing the ointment was the ordinary cone-pointed, glass clap syringe. The plunger being removed, the barrel was warmed in the flame of an alcohol lamp, filled with ointment by means of a spatula, and on finishing the injection, at the instant of withdrawing the syringe from the wound, a compress wet with cold bichloride solution was applied, which instantly solidified the ointment at the orifice, preventing the escape of that in the abscess cavity. A large compress of sterilized gauze was then applied by means of a firm spica; the patient was told to return in four days, when, if all was well, the dressing was reapplied, but if any evidence of inflammatory action was found the wound was thoroughly irrigated and cleansed and the injection repeated." Out of sixteen cases, Dr. Otis reports nine cured in six days, three in twelve days, one in fourteen days, one in twenty-three days. He claims the following advantages for this method: "1. That it is simple and safe. 2. In suitable cases cure, as a rule, seems more rapid than by any other method. 3. The patient is not prevented from going about during treatment. 4. The first gland being rendered thoroughly aseptic renders it less likely that other glands in the chain will become infected (?). 5. It leaves no telltale scar. 6. It in no way interferes with any subsequent surgical procedure, should such be deemed advisable." Dr. Otis concludes by saying that his experience has demonstrated that this method is available only in those cases of infection by the staphylococcus in which there is an appreciable pus cavity, and thus a storage place for ointment until absorption can take place. In diffuse phlegmons, in which no pus cavity existed, the method was found to be absolutely useless. He calls attention to the fact that by this method patients are able to resume their duties without any discomfort on the day following the operation, and that, if secondary suppuration does occur, the inconvenience is slight compared to that at first. He says there is good chance of failure unless two cardinal points are observed: 1st, Absolute cleansing of the cavity of all traces of pus; and 2d, the injection of ointment into it in quantity barely sufficient to produce moderate distention.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 28, 1896.

THE RELATION BETWEEN EXTERNAL HERNIAS AND GASTRO-INTESTINAL DISORDERS.

THE symptoms of incarcerated hernia are at once so pronounced and so characteristic as not readily to escape discernment and proper interpretation at the hands of even the unskilled. Reducible hernias, on the other hand, often give rise to symptoms whose real origin is likely to be overlooked unless their nature is thoroughly understood and their source looked for. The relation between these two sets of events is discussed in an intelligent and interesting manner by Docent Schütz, of the University of Vienna, in the *Wiener klinische Wochenschrift*, 1896, No. 27, p. 595. A reducible hernia, he points out, is often responsible for disturbances not limited to the site of abnormal protrusion, but which may also involve remote portions of the gastro-intestinal tract, and from which relief can be secured by means of operation or a properly-fitting truss. Thus, one of the commonest symptoms of inguinal hernia is pain, usually colicky in character or of the nature of gastralgia. It occurs, as a rule, some time after meals, as well as in the train of active physical exercise or much walking, and is at times of great intensity. Not rarely the pain is dull, occurring independently of meals or at varying intervals after eating, and being referred to different parts of the abdomen. In association with this symptom, or independently, there occurs the group of phenomena included in the designation "dyspepsia"—impairment of appetite, constipation, flatulence, eructation, nausea, etc. In some cases neurotic symptoms also are present. These concurrent manifestations are to be attributed to mechanical influences, such as traction or pressure, or to reflex disturbances. The causative condition may appear insignificant, or the hernial protrusion may be inadequately supported, or, finally, violent physical exercise may act as the excitant.

Hernias of the linea alba are responsible sometimes for the most varied gastro-intestinal disorders; but they are often overlooked by reason of their small size. In their treatment the use of a bandage will usually fail, and resort must be had to a radical operation. A statistical study by Schütz of one hundred cases of this kind, shows that the disorder occurs variously between once in fifty and once in four hundred cases; in patients between seventeen and seventy years of age,

though most frequently between thirty and forty; and more commonly in men than in women, in the proportion of eighty-seven to thirteen. Trauma, great muscular activity, including the contractions of parturition, and the act of vomiting are named among the causes; but in most cases no cause can be ascertained. Among the causes assigned for this condition are: (1) Imperfect apposition of the walls of the abdominal cavity during embryonal life; (2) congenital weakness of the fascia of the linea alba, with hereditary predisposition; (3) the protrusion of a subserous lipoma through the fascia of the linea alba, with the secondary protrusion of the peritoneum; (4) violence, resulting in rupture, in greater or less degree, of the abdominal wall in the linea alba. As a rule, the herniæ are situated above the umbilicus and usually to the right side of the median line. They vary from the size of a pea to that of an apple. At times they are multiple; and sometimes they are associated with other forms of hernia in other situations.

The most common symptom to which these hernias of the linea alba give rise is gastric disturbance without distinguishing characteristics. As a rule, there also occur paroxysms of pain in relation with the taking of food. At times the pain radiates from the situation of the hernia, is aggravated by increased intra-abdominal pressure—as from coughing, vomiting, sneezing, etc.—or by any form of active physical exercise, and is relieved by the recumbent posture. Pronounced symptoms of incarceration are rare. The hernial swelling is usually tender and the pain is increased by pressure. The physical examination is best made in the erect posture or with the body of the patient inclined somewhat forward.

Besides the hernias of the linea alba others of similar origin and symptomatology may occur at some distance from the median line—usually in the mammary line. Finally, umbilical hernias may give rise to the phenomena that have been detailed.

THE EXTINCTION OF THE DEGENERATE.

SOME confusion of ideas might be avoided regarding the tendency of atypical qualities to result in sterility, if it were borne in mind that what we inherit is our bodily constitution, a constitution which varies according to the known and the unknown laws of heredity, and that our various tendencies or susceptibilities to external impressions depend upon such bodily inheritance. A variation of type, whether by way of exaggeration or depression of certain qualities or by malformation, may not be permanent; but if the attempt to return to the original form fails by extinction, it may be due, not to sterility, strictly speaking, but to shortening of life to below the age of reproduction. Indeed, it would seem that the laws of heredity governing fecundity and sterility are as distinct as those governing the number of the fingers, the color of the hair, or other characteristics, and that when these laws are appealed to for the regulation of the number of individuals the object is accomplished in quite a different manner, if not for a different purpose, from what

is observed when life is shortened. It may be assumed that the individual born into the world even in the most miserable physical condition has an ancestry reaching as far back as that of the most perfect specimen of his type; and the only questions are how far back does his frailty extend among his progenitors, and how far down may he be able to transmit it before return will take place to the original type or life in the descendants become so shortened that there will not be time for further reproduction?

Sterility may be inherited and recur in certain members of a family, while other members have full power to perpetuate their kind. It would seem to be by inflicting sterility that nature prevents the perpetuation of the offspring of too strong a cross-breed, while marked or long-continued interference with the laws of health is more likely to result in so shortening life that the stock will die out for want of time to mature and reproduce, rather than from inability and indisposition to procreate if age would permit.

THE "WIZARD" CURE.

A CERTAIN proportion of every collection of human creatures is upon the lookout for miracles. Common-place does not meet their requirements. They will gladly accept all that is beyond the power of human ken, but that which has a common-sense basis and is understandable does not interest them.

Thus one is not at all surprised to find that almost everything is expected of the newly discovered rays which still must be denominated by the symbol of an unknown quantity.

We not only rely upon their power to penetrate the hitherto impenetrable and establish the diagnosis, but once having pointed out the cause we expect them to supply the cure as well. The announcement made by Mr. Edison that there was some hope of restoration of sight to the blind by the application of Roentgen rays has naturally brought forth applications from all parts and from all conditions of sightless sufferers. Undoubtedly there will be those among them who will be capable of being made to see. Sight has been restored on many occasions by means which must seem miraculous to those who are ignorant of the matter. When, however, the various tissues of the globe which make sight possible have been destroyed, it would seem as futile to dream of restoration of sight as it would be to hope for a reflection of one's image in the empty frame from which the mirror had been broken and removed.

There is a merchant who is said to be a millionaire somewhere in lower Broadway who has received considerable newspaper notoriety and advertisement by his repeated offer through the newspapers of a million dollars to any one who will restore his sight.

The medical profession has been the recipient of numerous slurring reflections which have grown out of this repeated offer of so princely a sum. It is now announced that the gentleman will place himself in Mr. Edison's hands, after an experimental trial of the rays have been made upon his "proxy."

It is greatly to be desired that success attend this effort. Not that Mr. Edison should receive a million dollars, since he has more than he has need for already, but that this tantalizing sum should not longer be made to dangle before the eyes of impecunious doctors, who, though willing, honest, and perhaps able, are powerless to aid, because the would-be patient demands some miraculous cure which will not take him from his counting-house desk for even a single day. May the "Wizard" with his magic tube supply the ray of light and remove the million-dollar offer from the public press.

UNFAIRNESS IN APPOINTMENTS.

A LAW has recently been promulgated by the minister of education of Germany forbidding the appointment to the position of assistant at any German university of other than graduates of a German university. It is much to be regretted that politics, with its cry upon the European continent of "Russia for the Russians," "France for the French," and "Germany for the Germans," should find a re-echo in the ranks of education. It has been a signal advantage to many of the Americans going abroad to be able, even in exceptional cases, to obtain such positions as an assistant at some of the German medical clinics. Would it not be a good time, now that the States of New York and Pennsylvania have so fixed the time required for study and the passing of a State examination in such manner as to make the value of a diploma given here second to none, to suggest reciprocity between France, Germany, and England, and the States mentioned? The recent movement in France, by which the foreigner was to be excluded from receiving a diploma granting him the right to practise in France, is a second and more forcible argument in favor of our making some endeavor to gain for the two worthy States New York and Pennsylvania some special advantage justified by the praiseworthy course these States have pursued.

OUR HEALTH RESORTS.

THAT this is in many respects a great and remarkable country goes without saying. Among other things which add to our greatness are to be numbered the natural resources which can be utilized in health production. It was not to be presumed, therefore, that in writing up the "Winter Health Resorts," Dr. McKay should touch upon all places worthy of notice, and many excellent stations were omitted in his article which appeared in the *MEDICAL RECORD* of October 31st. Among the many good words and commendations which this article has received from our subscribers, there have been a few complaints because of such omissions. Among them is one from Dr. C. F. McGahan, observer of the winter bureau at Aiken, S. C. This is a winter resort with a mean winter temperature of 51.89° F., and a mean relative humidity of 58.73 per cent. Rainfall about twenty inches; altitude, five hundred and sixty-five feet. These figures vary somewhat from those given by Dr. McKay, and

we are glad to present the authoritative statement of one connected with the United States signal service.

Another communication comes from Dr. Charles A. Powers, of Denver, Col., who considers that the State which should be most prominent in the category of winter resorts has been omitted.

"Probably the population of Colorado," he says, "presents a greater percentage of people who have come here for purposes of health than does any other State in the Union. As a resort for pulmonary invalids it offers the greatest advantages—proper elevation, a dry, clear, sunny atmosphere. The winters, taken as a whole, are very delightful; the tonic and bracing air makes tuberculous patients desire to be out of doors. Such cities as Denver, Colorado Springs, and Glenwood Springs offer the very best of accommodations, with all that this implies in the matter of suitable food and the like; and people in all walks of life find here that which their taste demands or their means command."

Dr. Powers' opinion is that his adopted State was unintentionally omitted. We cannot say how this may have been, but it occurs to us that the author may have considered Denver and its neighboring resorts too well known to need comment.

For the peace of mind of those who recognize the good qualities of any given region as a health station, we need but say that, while we are always pleased to hear from them, the author of "Winter Resorts" disclaimed any intention of naming them all or of telling all there was to tell of the good features of those mentioned.

News of the Week.

"**The Courier Record of Medicine**," whose editor, Dr. Brooks, recently died in Dallas, will be continued under the management of his son.

Dr. Fort Mobbed.—Rio de Janeiro was recently the scene of a manifestation against Dr. Fort, who was revisiting the city in which he had successfully practised for some years after graduating in Paris. Upon returning to France he had published his impressions of Brazilians and had commented adversely upon their system of medical instruction and upon the zeal with which the students worked. To show the French physician that they still possessed certain kinds of zeal at least, some thousand of them visited the hotel at which he was stopping, with the avowed purpose of lynching this calumniator of their fair land. Not succeeding in laying violent hands upon the object of their ire, an effigy was procured and a funeral procession organized, with catafalque, burning tapers, funeral dirges, and terminating in a cremation upon a public square. We shall keep an eye upon French journals to see what Dr. Fort will have to say upon his return this time about Brazilian zeal.

International Medical Congress.—Section on surgery: Acting upon the advice of Dr. E. Braatz (Königsberg), the surgical section of the XII. International Medical Congress has decided, in view of the ap-

proaching congress, to collect international statistics on narcosis for the current year (1896). For this purpose the managers of the said section apply to all their colleagues, and earnestly request them to give answers to the following questions: 1. Number of narcoses from January 1, 1896, to January 1, 1897. 2. What narcotics were administered. 3. Number of fatal cases. The secretary of the surgical section, F. Rein (Moscow, Malaja Dmitrovka, house Scheschkov), will be glad to receive such information, and, if possible, not later than July 1, 1897.

Section of nervous and mental diseases: The following themes will form part of the programme: Neuro-Pathology: 1, Pathology of the nerve cell (finest structure and its pathological changes); 2, Pathological anatomy and pathogenesis of syringo-myelia; 3, Pathogenesis and treatment of tabes dorsalis. Psychiatry: 1, Obsessions and fixed ideas; 2, Pathogenesis of general paralysis of the insane and delimitation of this disease from its cognate forms; 3, hypnotism and suggestion in their reference to mental diseases and medical jurisprudence. The question of the surgical treatment of the brain and spinal-cord diseases will, moreover, be discussed in joint session with the surgical section.

Jefferson Medical College.—At a clinical meeting of the Philadelphia chapter of the alumni association of Jefferson Medical College, on November 10th, Dr. J. H. W. Chestnut read a paper on "Intestinal Obstruction." Following the meeting, the new laboratories of the department of pathology and bacteriology were thrown open for inspection, and a reception was tendered to Dr. H. F. Harris, the new associate in pathology.

A Thought-Weighing Machine.—The cerebrum is the organ of the will and it is known that in the exercise of its function there is an increased supply of blood to that part. Professor Mosso, an Italian physiologist, has invented a thought-weighing machine, consisting of delicate balances so contrived that they weigh the varying amount of blood in the brain. The activity of the brain is in direct proportion to the amount of blood therein. According to a local newspaper report, the machine is so delicately constructed that it readily detects the difference in the exertion required to read Greek above that necessary to read Latin. Every youngster is ready to believe in the machine.

Schuylkill County (Pa.) Medical Society. At a meeting of the Schuylkill County Medical Society, held at Pottsville, Pa., on November 10th, Dr. C. Lenker, of Schuylkill Haven, read a paper on "Chorea," and the following officers were elected for the ensuing year: *President*, Dr. A. F. Bronson, of Girardville; *Vice-President*, Dr. H. Bowman, of Mahanoy City; *Secretary*, Dr. Cable, of Tamaqua; *Treasurer*, Dr. D. Taggart, of Frackville; *Censor*, Dr. G. H. Halberstadt, of Pottsville. Seventeen delegates to the Medical Society of the State of Pennsylvania and nine to the American Medical Association also were elected.

Twelfth International Medical Congress.—The American national committee of the Twelfth International Congress, which is to meet at Moscow, Russia, from August 19 to 26, 1897, consists, according to the directions of the general committee at Moscow, of the following gentlemen: J. S. Billings, M.D., New York; Frank P. Foster, M.D., New York; S. Weir Mitchell, M.D., Philadelphia; Charles A. L. Reed, M.D., Cincinnati; George B. Shattuck, M.D., Boston; F. J. Shepherd, M.D., Montreal; George F. Shrady, M.D., New York; W. S. Thayer, M.D., Baltimore, and the chairman, A. Jacobi, M.D., 110 West Thirty-fourth Street, New York. The chairman begs to invite the attention of the medical profession of the United States and Canada to the fact that the professional gentlemen in charge of the congress are anxious to make it a success both from a scientific and a social point of view. Their difficulties are unusually grave; but it is not their fault that the congress had to wait for governmental permission to meet in their country, or that a special ukase was required for the admission into Russia of Jewish medical men on equal terms with their Greek, Catholic, Protestant, agnostic, and Mohammedan colleagues; or that the famous and meritorious secretary-general was—it appears because of his liberalism—ousted both from his place and from his professorship. They should not be held responsible for the political semi-barbarism of the country in which they live and to whose laws they have to submit. Their position in the world of science and their endeavor to make the twelfth congress equal to its most famous predecessors will prove an incentive to American physicians to sustain, both by their presence and their contributions, the Russian committee in its exertions to make the next congress equal to its predecessors. Such information as will be received from time to time will be published in the medical journals immediately after its arrival.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending November 21, 1896. November 16th.—Surgeon A. F. Magruder detached from the marine barracks, Washington, and placed on the retired list. Passed Assistant Surgeon J. S. Sayre placed on retired list November 16th. November 18th.—Medical Director H. M. Wells detached from the naval laboratory, New York, ordered home, and placed on waiting orders. Medical Director T. C. Walton detached from the naval academy December 15th and ordered to the naval laboratory. Surgeon C. T. Hibbett detached from the *Independence*, ordered home, and granted three months' leave. Passed Assistant Surgeon F. W. Olcott detached from the *Enterprise* November 27th and ordered to the *Independence*. Passed Assistant Surgeon W. F. Arnold detached from special duty and ordered to the *Enterprise* November 27th. Passed Assistant Surgeon J. M. Moore detached from the *Texas* December 7th and ordered to the *Castine* December 8th. Passed Assistant Surgeon L. H. Stone detached from the *Castine*, December 8th, ordered home, and placed on waiting orders. Assistant Sur-

geon S. B. Palmer detached from the *Vermont* December 7th and ordered to the *Texas*. Passed Assistant Surgeon P. Leach promoted to surgeon from November 15th, and Passed Assistant Surgeon T. C. Craig promoted to surgeon from October 14th.

Prof. Edmund Lesser, of Berne, has been appointed director of the Charité clinic for dermatology and syphilis in Berlin, a post hitherto occupied by Professor Lewin who died on November 2d at the age of seventy-six years.

A New Medical Monthly, the *Scottish Medical and Surgical Journal*, will appear in January, under the direction of Professors Simpson and Annandale (Edinburgh), Professor Stephenson (Aberdeen), and others, and will be edited by Dr. William Russell.

Obituary Notes.—DR. JAMES GRAHAM, a widely known physician of Philadelphia, died on November 12th, of pneumonia, after an illness of nine days. Dr. Graham was born in 1846 and was a graduate of Jefferson Medical College. During the war of the rebellion he served with the United States army, being connected especially with the army transports.—DR. LOUIS W. HILDENBRAND died at Philadelphia on November 13th, at the age of forty-seven years. He was graduated from Jefferson Medical College in 1874.—DR. LUIS F. SASS, seventy-six years old, a well-known physician of this city, died at his home, No. 56 West Thirty-ninth Street, early Monday morning from complications due to old age. Dr. Sass was a native of Havana, Cuba, but had lived in this city for forty years. In his fifty years of practice he made a reputation as a specialist for the nose and throat. He was the recipient of many honorary degrees in this country, in Europe, and in Cuba. He was a member of the County Medical Society.—SIR BENJAMIN WARD RICHARDSON, the celebrated English physician and author, died on November 21st. Death was due to apoplexy, from which he never rallied. He was sixty-eight years of age. The late Sir Benjamin W. Richardson, in 1865, conducted an experimental research on the nature of the poisons of the spreading contagious diseases, which ended in the detection of a special poisonous product, common in these poisons, to which he gave the name of septime. In 1866 he discovered the application of ether spray for the local abolition of pain in surgical operations. He introduced methylene bichloride as a general anæsthetic, and discovered the controlling influence of nitrite of amyl over tetanus and other spasmodic affections. Dr. Richardson's principal contributions to medical and scientific literature have been directed to the advancement of medical practice by the experimental method. The study of disease by synthesis, the restoration of life after various forms of apparent death, the effects of electricity on animal life, methods of killing animals without the infliction of pain, the maintenance of life in factitious atmospheres, the investigation of the theory of a nervous atmosphere or ether, were among the subjects he treated of in lectures and essays. In later years his researches were directed to the study of diseases incident to modern civilization.

Clinical Department.

THE WOODBRIDGE TREATMENT OF TYPHOID FEVER.

By CHARLES E. NAMMACK, M.D.,

ASSISTANT PHYSICIAN TO BELLEVUE HOSPITAL, VISITING PHYSICIAN TO
GOUVERNEUR HOSPITAL, NEW YORK.

FIFTEEN years' experience in treating typhoid fever, in hospitals and in private practice, has convinced the writer that the Brand method of tubbing is far and away the best treatment of that disease. But the number of the cases that can or will be submitted to the Brand method, either in cities or in the country, is small by comparison with the total number of cases of typhoid fever that occur in the United States. There are many obvious reasons for this state of affairs, and the general practitioner will eagerly welcome any plan of treatment less cumbersome and expensive than the Brand bath. Dr. W. Gilman Thompson has recently computed that the average cost of a Brand bath in private practice is two and a half dollars, and since some of his reported cases required more than one hundred and twenty-five baths, it will be easily seen that a workingman's chance of receiving the benefits of tubbing consists chiefly in his getting into a hospital. Many families are unwilling to send their sick ones to a hospital, and many medical practitioners must live from the fees collected in workingmen's homes. Any one who will read the papers of Dr. Woodbridge must be impressed with their evident earnestness and sincerity, even though one cannot accept the statements that "typhoid fever can always be aborted," or "that death is a wholly unnecessary consequence of the disease if proper treatment is instituted sufficiently early."¹ The weak point in the Woodbridge treatment would seem to be that it rests upon no biological fact in the disease, but upon the symptomatic grounds of intestinal evacuation and intestinal antiseptics. But good things have come to us in medicine, ere this, upon purely empirical grounds; and, with a view of testing this new aspirant for therapeutical honors, the writer, upon assuming the fall service of one of the medical divisions of Bellevue Hospital, requested the house staff to put all new cases of typhoid fever admitted at once upon the Woodbridge treatment, and to follow the details of the originator implicitly, except that patients suffering from hyperpyrexia (rectal temperature exceeding 104° F.) were not to be denied the benefit of the tub bath. It may seem that this was half-hearted and unfair to the Woodbridge treatment; but he must have the faith of a little child (and such are not of this earthly kingdom) in any new procedure whose conscience would allow him to deprive a typhoid high-temperature case of the results of a Brand bath when practicable. During the progress of the test, Dr. Woodbridge visited New York and was invited to examine the cases. A study of the charts did not show that the usual course of typhoid fever was in any way modified by the treatment instituted. One case, which gave us great hope that a specific had been found, was shown by the serum diagnosis test of Widal² not to have been a case of typhoid fever. All the cases were submitted to this test by Dr. Alexander Lambert, bacteriologist to the New York board of health, at the time of Dr. Woodbridge's visit, and the results demonstrated by him in the laboratory.

The writer sincerely regrets that his hope that the treatment of the poor man's typhoid fever had been

found is still deferred. Looking back to 1878, he can see marked progress since the days of large doses of quinine and the use of the Kibbe cot, through the period of the antipyretic heart-depressing coal-tar derivatives, to the magnificent results of the Brand method of tubbing and rubbing, which does many good things for the typhoid patient in addition to reducing his temperature. Looking forward along biological lines, he cherishes the conviction that the serum diagnosis of the present will soon be followed by the successful serum therapy of the future.¹

42 EAST TWENTY-NINTH STREET.

NOTE ON THE EFFERVESCENCE OF URINE WITH NITROSO-NITRIC ACID.

By J. B. NICHOLS, M.D.,

CLINICAL ASSISTANT, UNITED STATES SOLDIERS' HOME, WASHINGTON, D. C.

ON adding to urine a considerable proportion of the impure yellow nitric acid of commerce, a well-marked effervescence occurs. A similar evolution of gas is sometimes noticeable in carrying out the test for albumin with heat and impure nitric acid. The phenomenon is also well marked when the urine is underlaid with the acid, as in Heller's contact test for albumin; in this case minute bubbles of gas may be seen rising in the fluid, while larger bubbles slowly collect on the sides of the tube. A similar evolution of gas, but less in degree, occurs even with colorless nitric acid sold as pure. Other acids (hydrochloric, sulphuric, acetic) do not produce this reaction.

The fact that nitrous acid is capable of effecting the decomposition of urea, in an identical manner with the hypobromites, has been long known, and was utilized as a means of quantitative estimation of urea by Millon, Draper, and others, before the hypobromite method came into vogue. It is to this action of the small amounts of nitrous acid contained in commercial nitric acid upon the urea, uric acid, etc., of the urine, resulting in the evolution of nitrogen and carbon dioxide, that the phenomenon under consideration is doubtless to be attributed. The reaction would be as follows:

Experiments bearing on the subject corroborate this supposition as to the cause of the reaction. Solutions of urea and of uric acid reacted with impure nitric and the other acids employed precisely like the urine, while with solutions of the chief mineral constituents of the urine no formation of gas occurred. Treatment with nitroso-nitric acid containing larger proportions of nitrous acid (produced by dissolving mercury or copper in nitric acid) caused the same effervescence with urine and urea solutions, but much more vigorously.

It is important, for purposes of qualitative analysis, that this evolution of gas from urea should not be confounded with the effervescence arising from the addition of acids to carbonates, to which the reaction under consideration is apt to be attributed. The distinction can be easily made by testing with other acids, as hydrochloric or acetic, which cause effervescence with carbonates but not with urea.

Another practical point suggested is the advisability of using pure nitric acid in making the contact test for albumin, in order to reduce to a minimum the accumulation of gas bubbles on the side of the glass, which tend to obstruct the view of the contact reactions.

RECURRENT SCARLATINA.

BY E. L. DRAKE, M.D.,

PHILADELPHIA, PA.

I wish to report a case in which the patient had two distinct attacks of scarlatina, exfoliation of the epidermis occurring after each attack. The patient, a little girl, aged six and one-half years, a foreigner by birth, was taken sick on July 14, 1896. The mother gave a history of vomiting, and explained that the child "felt hot" and was very restless. When I first saw the case, on the third day of the disease, there was a small patch of exudate on both tonsils, fever, and a typical scarlatinous rash. A culture made from the exudate failed to show the presence of the Klebs-Loeffler bacillus, and by the fifth day the temperature, which never was above 101° F., had returned to the normal. The skin began to exfoliate in good-sized patches, and the child was about ready to be discharged, when, on the morning of August 29th, she vomited twice. She was put to bed, and by evening her temperature had gone up to 101° F., and a red punctiform rash was noticed over the clavicles. The next morning a highly characteristic scarlatinous rash was noticed, covering the whole body. There was also a small spot of exudate upon the right tonsil, and a beautiful demonstration of the so-called strawberry tongue. The temperature was normal by the eighth day of the second attack, and she at once started to shed the new coat of skin which she had received shortly before. This last desquamation was much finer in character than the first, and it was not until October 20th that the skin had regained its smooth character. The patient developed no complications, and was discharged on the above date.

STRANGULATED HERNIA IN A CHILD TWO MONTHS OLD, WITH OPERATION AND RECOVERY.

BY S. NELSON IRWIN, M.D.,

NEW YORK.

THE profession at large is by no means agreed as to what method for the radical cure of hernia is the best, and the question is one of great interest to the surgeon. It is not my intention to enter into the subject of the "radical cure of hernia," but simply to give some details in a case which, from the extreme youth of the patient operated on, may be of interest.

By kind permission of Dr. J. A. Breakell, whose practice I have been attending to during the summer, I am permitted to give the following account:

On September 18th Mrs. B— came to my office with her infant (male), two months and a few days old. The child was crying bitterly, and was evidently suffering great pain. The mother stated that it had kept her awake all night, and there had been much vomiting. Temperature normal; pulse, 120. Examination revealed a tumor on the right side, well down in the scrotum, about the size of a pigeon's egg, pressure upon which increased the pain very much. I had my doubts as to its being a hernia, and examined it carefully for translucency, which was present with a dark spot in the centre. I now came to the conclusion that the child had a strangulated hernia, and proceeded to reduce it, but without result. After several attempts, which caused much crying and annoyance, I decided that an operation was the only means whereby the tumor could be replaced in the abdominal cavity; and so informed the parents, who readily consented. The operation was performed at their home that evening. The little patient was placed on the table and put under chloroform anæsthesia. The usual incision was

made by Dr. C. F. Adams, who divided the superimposed tissue, layer by layer, until the sac was reached. Considerable fluid escaped, bringing the gut plainly into view, very much congested and maintaining a stubborn resistance to reduction.

Upon closer examination, a little piece of gut, about one and one-half inches, was discovered protruding from the bowel proper. This proved to be the vermiform appendix. Its appearance suggested removal, not merely because it was that troublesome piece of visceral anatomy, but on account of its always getting in the way in attempts to reduce the hernia, which, indeed, was not an easy matter, for, after several attempts to replace the tumor, the opening at the internal ring had to be enlarged, when it was replaced with ease. Here a complication arose—our little patient ceased to breathe. The operation was suspended, and our united efforts were directed toward resuscitation. By inverting the child and the performance of artificial respiration, after about ten minutes' hard work, we were rewarded with signs of returning animation. Our little soldier was once more put under the anæsthetic, the operation resumed, and completed rapidly as follows: By the use of a deep catgut suture the internal ring was transfixed; the suture was carried from the skin without, down through the ring and back again, and tied externally, thereby acting as an external suture as well. The canal was closed by interrupted sutures, drainage being left at the lower angle, the wound dressed with iodoform gauze, and the mother directed to administer one teaspoonful of the subjoined mixture every third hour:

R Tr. opii camphoratæ ʒij.
Elixir, simp. ʒij.

I was to call at nine o'clock that evening, but was telephoned for long before that time. On my arrival I found the child crying as bitterly as when first seen by me in the early part of the day. To make sure, I examined the patient and found the dressing was as when first applied. To insure rest I gave one drop of deodorized tincture of opium (Squibb's); at the end of half an hour two more drops were given, and, at the expiration of the hour, two more—making five drops in all. Then the little patient fell asleep. Naturally I felt very anxious about the little one during the night, for it had undergone a critical operation, a severe shock, and had taken a large dose of opium. When I examined the eyes before leaving, the pupils appeared much contracted, and the breathing was indicative of more than natural respiration, showing that the child was fully under the influence of the narcotic, which secured for it a good night's rest. Next morning on removing the dressing the wound appeared clean and healthy-looking, with signs of union by first intention. Temperature normal; pulse, 120. I called again in the evening and found pulse and temperature normal. On the third day, when dressing, I discovered a little pus exuding from the sides of the deep suture, which disappeared after the wound was syringed with H₂O₂ and dressed as before. The case proceeded to complete recovery without a single interruption.

Conclusion: Here was a child, only a little over two months old, with a tumor well down in the scrotum, surrounded with fluid and showing translucency. I might have drawn off the fluid, thereby reducing the size of the tumor, lessening the tension, and so relieving the child of pain. But would this have aided in the reduction of the hernia? I am convinced that in this case (in which my colleagues, Dr. D. J. Moss and Dr. C. F. Adams, to whom I return thanks, tried also in vain to reduce the hernia, and all agreed that the fluid could play no part in the reduction) we had no alternative but the performance of the foregoing operation, which proved so gratifying in its results.

It is worthy of mention that I attended the child's mother at its birth, which was a normal cephalic presentation, although the forceps were used for delivery. There was no visible anatomical defect at that time.

HERPES ZOSTER.

By CALISTA V. LUTHER, M.D.,

NEWARK, N. J.

I HAVE been very much interested in the discussion on herpes zoster in the *MEDICAL RECORD* of late. I have had no experience with blisters, but I have long been dissatisfied with the routine treatment of this troublesome disease, and my experience has led me to feel that most cases run their course uninfluenced by medication.

For more than a year I have been treating all my cases with the application of heat followed instantly by cold, and the results have been exceedingly satisfactory to me. I apply water as hot as can be borne for a few seconds, and follow by very cold water, or, better still, by frictions of ice until there is slight aching of the part. The hot water increases the itching, but the cold instantly relieves it, often for some hours. I order the applications to be made three times a day, oftener if demanded by the itching. They not only relieve this troublesome symptom; they abort the disease. When this treatment is applied to fresh patches, the vesicular stage is never reached, and no case of mine during the last year has lasted over a week.

A CASE OF RACHITIC PARALYSIS.

By LOUIS ROSENWASSER, M.D.,

NEW YORK.

ON July 6, 1896, I was called to see J. G.—, aged three years, male, and was told by the mother that the child had been coughing for some time, was in high fever, and had had a convulsion the night before. On examination I found dulness over the left apex behind, bronchial breathing, and subcrepitan râles. Temperature, 104.6° F.; pulse, 140; respiration, 50; and marked nasal breathing. I therefore made the diagnosis of broncho-pneumonia, and treated the child with the usual remedies, with a good but slow recovery.

When the child was in a fairly good condition, the mother asked if I would not give him something to strengthen him, as he was too weak to walk.

On closer inquiry, I learned that the child had never walked since birth, and that he cut his first tooth at eleven months. On examination I found the epiphyses thickened, a large square head, forehead covered with sweat, and the peculiar beading of the ribs. The legs were thin and flabby, but the patellar reflex was good. I then recognized that I had to deal with a case of rachitic paralysis. I put the child on a proper diet and ordered him to be a good deal in the air. I prescribed syrup of iodide of iron and Thompson's solution of phosphorus, ten drops t.i.d. The child is now able to walk and much improved in his general condition.

540 FIFTH STREET.

Calomel in Heart Disease.—Dr. Maldaresco (*Therap. Woch.*) has reported very favorable results from a course of calomel, followed by the iodide of potassium. He first gives one and one-half grains every two hours for six doses daily, and keeps this up for two or three days, when the dose may be increased to two or three grains for a few days longer, before the iodide is begun.

Therapeutic Hints.

Epileptics have at times shown decided improvement under drop doses of a one-per-cent. solution of nitroglycerin, three times daily after meals.—*CAMPBELL*.

Vulvar Papillomata.—

R Collodion elastic..... 5 gm.
Acid, salicylic..... 2 gm.

Apply a few drops to eight or ten lesions at each sitting. The next day treat the same number of new ones, and again cauterize the original, continuing in this way until all are cured.—*MERCIÈRE*.

Citrate of Silver has been found by Werter (*Berlin. klin. Woch.*, No. 37) to give excellent results in some fifty instances of acute blennorrhagia. A solution, 1 to 8,000, is employed at first, the strength being subsequently increased. It is reported non-irritating to the mucous surface, and its action is not limited to the superficial layers.

Consumption.—The colder the atmospheric air the patient breathes the better; the more oxygen it contains, bulk for bulk, the more it acts as an antiseptic; the more it expands when it has been inspired, and, in expanding, dilates the air cells, the more it tends to cool the overheated lung tissues, rendering them less favorable for the multiplication of bacilli.—*PLAYTER*.

The Prevention of Consumption.—Dr. B. W. Richardson, in *Asclepiad*, makes some suggestions which will prove beneficial to those having a tendency toward pulmonary tuberculosis. Dr. Richardson says that pure air for breathing is the first requisite for the prevention of consumption, and that a uniform climate and as much active out-door exercise as possible are essential. Out-door occupation is preventive. Amusements should favor muscular development and sustain healthy respiration. The dress of the consumptive should secure uniform warmth, and the hours of rest should be carefully regulated by the sunlight. Cleanliness, in the broadest sense of the word, is of special moment. The diet of consumptives should be ample, and every precaution should be taken to prevent colds.

Treatment of Constipation.—Dr. T. Lauder Brunton (*The Lancet*, 1896, p. 1,483) says that he regards this symptom as the reaction of a healthy organism to unfavorable surroundings, viz.: too soft food, too little water, or too little exercise. For the first, he advises bread of the whole grain or with more or less bran, vegetables in abundance, either cooked or raw, as tomatoes or celery. Fruits are beneficial, as melons, apples, oranges, and figs. If stewed prunes are ineffectual, a few senna leaves tied in a bag and cooked with the prunes will produce good results. Sugars are useful laxatives. Orange marmalade, which contains vegetable salts, sugar, and the hard skin of the orange in small pieces, is a valuable addition to the breakfast. If insufficiency of water is the cause of constipation, a tumblerful of hot or cold water should be drunk on rising in the morning and on going to bed. Bottled waters should be substituted for waters from a chalky soil. The habit of evacuating the bowels at a certain time should be formed. Exercise is of advantage; massage, rubbing the bowels in the direction taken by the hands of a watch, is also useful. In women suffering from ovarian or uterine trouble, exercise may be harmful. When the floor of the perineum is lax, it may be necessary to press the faecal mass along in somewhat the same way in which the accoucheur

advances the child's head. Leaning forward to an acute angle causes a stretching of the floor of the pelvis and affords support to the fecal mass, as it is forced backward by the action of the abdominal muscles. In some cases hydropathic treatment is useful—wet compresses to the abdomen two or three times daily and sitz baths, cold in summer and with the chill taken off in winter.

Vomiting of Appendicitis.—

R Menthol..... gr. viij.
Cognac..... 3 iss.
Laudanum..... 3 v.

M. S. Take from ten to twenty drops several times a day, in a little sweetened water.

—PICK, *Revue Internationale de Médecine et de Chirurgie*.

Cocaine is not soluble in vaseline or lard, but is readily so in olive or castor oil.—SAGE.

Ozone is of assistance in pertussis. It diminishes the number and intensity of the paroxysms, shortens the entire duration, and improves the general health.—LABLE AND OUDIN.

Hot-Water Bag over the heart in threatened heart failure.

To Induce Labor.—Inject within the cervix five grams of glycerin.—KOSSMANN.

Galactifuge after Bandaging the Breast.—

R Atropinæ sulph..... gr. ʒi.
Magnesii sulph..... iij.
Infus. gentian..... viij.

M. S. Tablespoonful every two hours.

—BLOOM.

Post-Operative Sequelæ of Gynecological and Abdominal Surgery.—Dr. Byron Robinson (*Denver Medical Times*, October, 1896) gives the following as of common occurrence: 1. Pain. 2. Suppurating ligature. 3. Fæcal fistula. 4. Hemorrhages. 5. Peritoneal adhesions. 6. Hernia. 7. Neurosis. 8. Development of fat and hair. 9. Atrophy of the genitals. 10. A decrease in sexual desire. 11. Renal and pulmonary disturbances. This is quite an array of defects, but every abdominal surgeon of considerable experience has seen almost every one follow his work. Some are unavoidable and the results of life processes.

Krause Skin Transplantation in Plastic Surgery of the Face.—Dr. John F. Erdmann writes in the *American Medico-Surgical Bulletin*, October 24, 1896, as follows: "The advantages of this method of Krause are readily observed. The area repaired is covered by skin of the same character as that over the rest of the body. There is no scar or cicatrix, as very frequently follows after the Thiersch method. The new tissue resists destructive conditions far better than that in cases of the Thiersch method. The area grafted is covered by a soft, cushiony structure. The flap does not bind the underlying tissues, as in some cases of Thiersch grafting. There is no likelihood of the great keloid development, as seen occasionally after the Thiersch method. Hairy areas can be covered by hairy flaps, in which the hair again grows. An objection to the method might be offered in cases in which a large area is to be covered, owing to the fact that it is desirable to have but one flap. This can be readily overcome by taking several flaps from various areas of corresponding thickness and applying their edges with great care to one another, as will be observed was done in the case reported in this paper, although in this instance the second flap was due to an error in measurement, and not to the size of the area to be covered."

Irritability may be an indication of heart disease, of gout, or of an impending headache. Bromides relieve the irritable nerve centres.—LAUDER BRUNTON.

Epididymitis.—

R Potass. bitart..... 3 iv.
Podophyllin..... gr. ij.
Make twelve powders and give one every two hours.

—YOUNKIN.

Milk Diet in albuminuria of pregnancy, deficient elimination, and threatened eclampsia may materially decrease the danger of the last-named affection.—QUEIREL.

Ulcer of the Cornea.—Touch with tincture of iodine and wash off the excess with formaldehyde solution, 1 to 1,000.—VEASEY.

Boric Acid, so valuable in cystitis, may cause digestive disturbances, in which case it may be given best an hour before food and at 10 P.M., making four daily doses.—SLOCUM.

Syphilis.—Dr. Briquet advises the use of iodide of sodium when the potassium salt is not well borne. Ammonium iodide is often very serviceable in the tertiary stage.

Dysmenorrhœa.—Caffeine, bromide of potassium, and gelsemium make a combination of great value if given a few days before the period.—TALLEY.

Hysterical Aphonia.—Ethyl chloride suddenly applied to the nape of the neck, freezing a patch the size of a quarter.—KEBBELL.

Mucous Membranes can be made anæsthetic by oil of cinnamon (1 to 500).—*Therapeutic Gazette*.

Tapeworm.—Salicylic acid eight grains every hour until five or six doses have been taken, followed by a full dose of castor oil.—*Times and Register*.

Emetics.—Syrup of ipecac should be discarded as slow and uncertain. The wine made from fluid extract can be depended upon. Antimony as an emetic should be banished from infantile therapeutics.—*Pediatrics*.

Quinine in Pertussis.—Two out of twenty-seven patients could not retain the drug. The others were remarkably benefited. After five days the attack was ended. Dose, one centigram for each month of age and ten for each year.—FISCHER.

Uterine Hemorrhage following abortion and attended with subinvolution:

R Fluid extract of ergot (Squibb's)..... 3 ij.
Fluid extract of viburnum prunifolium..... 3 ij.
Tincture of cinnamon..... Enough to make 3 ij.

M. Dose: Teaspoonful in hot water from two to six times a day.

—EGBERT, *Philadelphia Polyclinic*, October 31, 1896.

Ipecac in proper dose is a vasomotor stimulant, causing constriction of the arterioles and capillaries, especially of mucous membranes. It acts in the same way to relieve headache of the congestive variety. In glycosuria it may reduce the excretion of sugar, and, generally speaking, it is a tonic to mucous membranes and glandular cells.—ADOLPHUS.

Osmic-Acid injections in neuralgia, the needle being inserted perpendicularly and deeply into the muscles:

R Osmic acid..... 1
Distilled water..... 6
Glycerin..... 4

Keep well corked. Inject the equivalent of one-sixth grain opposite the most painful part.—FRANCK.

Society Reports.

SECOND PAN-AMERICAN MEDICAL CONGRESS.

Held in Mexico City, November 16, 17, 18, and 19, 1896.

(Special Report to the MEDICAL RECORD.)

Monday, November 16th—First Day.

SECTION ON GENERAL MEDICINE.

The Roentgen Rays in Thoracic Aneurism.—DR. WILLIAM PEPPER, of Philadelphia, read a paper in illustration of the value of the x -rays in the diagnosis of thoracic aneurism. He recounted the histories of several cases and exhibited the skiagraphs of the patients, in which the outlines of the aortic swelling were very clearly shown. In one case (possibly of tuberculous adenitis), in which the symptoms suggested an aneurism, the skiagraph showed no enlargement of the aorta. The arrest of the x -rays by an aneurismal tumor was owing to the blood and probably to the iron contained in it. It had been asserted that tuberculous deposits were also impervious to the rays, but this was still a matter of some uncertainty. In the case reported the symptoms were probably due to pressure by an enlarged tuberculous gland, yet there was no shadow in the skiagraph indicating the presence of such enlargement. In the cases in which aneurism existed, the diagnosis had already been made, but the picture made by the Roentgen rays confirmed this diagnosis, and instances might readily be imagined, especially of commencing aneurism, in which certainty could not be obtained from the objective signs alone. It was to be remembered also, the speaker said, that our application of the Roentgen rays was but in its infancy. A year ago the suggestion that we might see the bones or internal organs of a living man would have been received with derision; and yet, only a few evenings ago, the speaker had put a healthy young man, wearing all his clothes but his coat, between a tube of special construction and the fluoroscopic screen, and in twenty seconds he could see clearly not only the ribs but the heart pulsating, and the latter was so distinct that it was possible to tell the ventricles from the auricles. The possibilities of this discovery were almost beyond the power of our imagination.

The Urine in Yellow Fever.—DR. MANUEL RUIZ CASABÓ, of Havana, read a paper on the physico-chemical characters of the urine in yellow fever. He had devoted especial attention to a comparative study of the characters of the urine in yellow fever and other diseases, taking advantage of the opportunities afforded by the large number of cases of yellow fever now in the city of Havana and also utilizing the resources at his disposal as director of the section of urology in the bacteriological laboratory of the University of Havana. After a general review of the chemical properties of normal urine, and the microscopical appearances of the sediment in various semi-normal and pathological conditions, he described the appearances of this fluid in cases of yellow fever. These appearances were not uniform but varied considerably with the individual, yet there were certain characteristics which seemed peculiar to yellow fever and which were always found in cases of this disease, although modified by the individual peculiarities. The paper was largely made up of carefully prepared statistical tables giving the results of the examination of the urine in a large number of cases.

DRS. E. ACOSTA and J. M. DÁVALOS, of Havana, followed with another paper on the same subject, of

which the following is a brief abstract: The bacteriological laboratory was established in Havana in 1887, and since that time many experiments in this field have been undertaken, a great number of cases of infectious diseases existing in that city having been studied in the light of the new science developed, if not discovered, by the immortal Pasteur. Among these diseases yellow fever is the one that has most engaged the attention of scientific men in the island, because it is the one that carries off most victims, and which offers the greatest obstacle to the prosperity and wealth of Cuba. The authors of this paper have for a long time given special attention to the study of this disease, and have now undertaken that of the urine of yellow-fever patients. They studied the toxic power of the urine, and carried out more than one hundred experiments on rabbits. From these experiments they arrived at the following conclusions: 1. The urine of yellow-fever patients contains toxins which are separated by the diseased system, and which perhaps pertain to the agent that produces the disease. 2. The toxic power of the urine reveals the actual condition of the patient, so much so that the toxic power is in inverse ratio to the gravity of the disease. This is explained by the fact that when there is less toxin in the patient's system he improves, because the evil principle is carried off by the urine, while, on the other hand, when the urine is not toxic, the toxin accumulates in the patient's body and increases the gravity of the disease. 3. The urea has nothing whatever to do with the prognosis of yellow fever, as the labors of Bouchard have so demonstrated it with respect to different diseases, and as has been privately proved by the authors of this paper with respect to yellow fever. From the urinary analyses that have been made, they have found that serious cases might eliminate a good deal of urea, while others of less gravity might store it up in great quantities within the system.

Rabbits which were inoculated with urine charged with urea were a longer time in dying after an intravenous injection of yellow-fever virus than others which were injected with urine containing little urea.

The authors claimed that yellow-fever patients die through poisoning by the toxins of the germ which produces the disease, and never from uramia.

Biological Characteristics of the Blood in Yellow Fever.—DR. THOMÁS VICENTE CORONADO, of Havana, presented an exhaustive paper with this title. Having been for many years accustomed to make careful examinations of the blood in order to arrive at a clinical diagnosis of malaria, and having later on carried out some comparative studies between the blood of malarial patients and that of healthy people, he determined to take the first opportunity to extend these studies to the blood of persons attacked by yellow fever. The sudden entry into Cuba within a short period of time of more than one hundred and fifty thousand men who were not acclimated, and who came from Spain for the purpose of fulfilling their military duties, gave new strength to the disease and greatly disseminated the yellow-fever germ from one end of the island to the other, and the great number of cases, both in Europeans as well as in native-born Cubans who had not obtained immunity through a previous attack of this terrible scourge, afforded him a vast field in which to carry on his studies in hæmatology. The technique for collecting the blood and preserving it in good condition for study is very simple, and similar to that which the speaker employed in examination of malarial blood. A finger of the hand, in a thoroughly clean and aseptic condition, is pricked with a common needle, or with a lancet which has been passed through an alcohol flame. The blood is collected in small glass vessels having a long sharp

neck, which can be broken with the nail and closed, after filling, with the flame of a match. The blood which has been collected in this manner can be preserved in good condition for one or many days.

The examination in a natural condition can be made by putting a part of the blood on a cover glass, and then inverting this over the slide. The permanent preparations must be made by the method of double staining with eosin and methylene blue.

Both in the serious cases of yellow-fever infection, in which a fatal result took place a few hours after the extraction of the blood, as well as in the commoner mild cases and in a very large number of observations, the investigations gave surprisingly negative results.

In fact, the speaker said, he had been surprised to find that the blood of the yellow-fever patient which had been taken one or two hours before his death, as well as that which had been drawn when the disease was much less advanced and also during convalescence, should present all the features of normal blood; that is to say, similar to that of a healthy and robust man, full of life and without any pathological stain. It is therefore evident that the blood is not the seat of the disease in that terrible form of the infection which is called black vomit, and which in not a few cases carries off its victim with the same violence as cholera, or poisoning by vegetable or mineral substances. A direct observation, however, shows the normal red globules increased in number, while in connection with these we perceive numerous leucocytes, full of phagocytic life. These facts, which appear extremely singular, Dr. Coronado firmly believed, would shortly carry us to the solution of problems connected with the pathology first, and afterward with the etiology of yellow fever.

The author believed, contrary to the general impression, that the Cubans or natives suffer like Europeans from true yellow fever whenever they have not obtained immunity through a previous attack.

Cantharidal Blisters in Acute Pulmonary Affections.—DR. JOSÉ DE LA CERNA, of Calimaya, Mexico, read this paper. Acute diseases of the chest, he said, are frequent in the Valley of Toluca, and play an important part in the statistics of mortality. The use of blisters is general, both because the public has become accustomed to them, as well as because many physicians prescribe them; but the speaker did not approve of their use.

At the time when pneumonia was considered a local disease, in which inflammation played an important part, the action of a blister could be supposed to be beneficial, although it was not proved.

In pneumonia we are not dealing with a local inflammatory process, but with a disease of which the pathogenic agent is known. A blister is almost always applied for the purpose of easing the pain and diminishing the congestion, but, seeing that pneumonia is a general disease, it should not be treated by attacking one of its symptoms, and still less by the employment of cantharides. In pneumonia renal congestion is constant; we are acquainted with the functions of the kidneys in the expulsion of the toxins produced by the economy, and consequently we recognize the importance of preserving the renal integrity. A blister increases this congestion and diminishes the quantity of urine, and, as in pneumonia one of the indications is active diuresis, the result is that we obtain the contrary effect to what is desired.

In pleurisy a blister exercises no effect on the effusion during the acute period.

The following were the conclusions of the author: Pneumonia and pleurisy being of a general and infectious character, and the defects of the blister being known, it ought to be left out in their treatment.

If it is applied, it should never be during the acute period, but toward the end, when the *restitutio ad integrum* is difficult, provided the kidneys are known to be sound. It ought to be kept on for from four to six hours, and while the epidermis rises hot drinks should be taken. Antisepsis of the skin should also be carefully looked after.

Spontaneous Rupture of the Aorta.—DR. J. LLAMBÍAS, of Buenos Ayres, Argentina, read a paper on this accident, in which he endeavored to demonstrate the anatomical cause of spontaneous rupture, since he believed that it was not sufficiently explained by the existence of chronic endarteritis. He cited a number of authors who had sought to explain the nature of the accident, but held that their explanations were unsatisfactory, since they were not applicable to all cases. Dr. Llambías held that the original lesion which was the actual occasion of the rupture consisted in an alteration in the circulation in the vasa vasorum resulting in an endarteritis of these minute vessels. Although we cannot demonstrate it, the author regarded it as probable that this endarteritis arose from systemic causes. Its existence was demonstrated by thrombosis in the vasa vasorum, and thus was caused a necrosis of the area supplied by the occluded vessels.

A paper on "International Medicine," by DR. JOHN W. TRADER, was read by DR. T. D. WHEATLEY.

SECTION ON GENERAL AND ORTHOPÆDIC SURGERY.

Tuberculosis of the Knee.—DR. ANGEL CONTRERAS, of Puebla, Mexico, reported a case of tuberculosis of the right knee, in a boy six years of age, in which a cure was obtained by arthrectomy after the method of Albertin, of Lyons. The diagnosis of the tuberculous nature of the affection was made from the clinical symptoms and was confirmed by microscopical examination. There were no signs of tuberculosis in any other part of the body. The operation was performed on August 17, 1895, the limb being immediately after immobilized in a plaster-of-Paris dressing. During the first three days there was a slight elevation of temperature, but after this there was no fever.

The antiseptic dressing was renewed on the 20th of the same month, and afterward on the 31st, being left without moving during the whole month of September. During the months of October and November, it was found necessary to change the dressing several times, as eczema had developed in the operated member and a fistulous path was found, caused by a small carious focus. On November 29th this carious part was scraped, and during the month of December the wound was completely closed, and perfect ankylosis obtained of the femur with the tibia. During the first months of the present year the patient was visited again, and the permanence of the cure was confirmed: the patient was found to have preserved his leg straight with only a slight shortening and limp. A photograph of the patient as cured was shown.

The object of publishing this case, Dr. Contreras said, was to stimulate surgeons to perform an operation which can radically cure such a common disease and one of such a serious character as tuberculosis in the knee, and to show that the treatment by means of the atypical arthrotomy is preferable to that by revulsion and immobilization, as well as to antiseptic and other injections, or to typical resection.

Laryngeal Operations.—DR. GEORGE W. CRILE, of Cleveland, O., presented a communication entitled "Researches into the Technique of Laryngeal Operations, with a Report of Four Successful Total Extirpations." The first part of the paper was devoted to a recital of the results of a series of experiments. Even slight contact, the author said, with the mucous

membrane upon and about the region of the vocal cords causes sometimes partial but more frequently complete arrest of respiration; pressure or dragging on the larynx causes in addition a considerable, sometimes very great, slowing of the heart beat and correspondingly considerable or very great fall in blood pressure, in several cases almost to zero. On section of the inferior laryngeal nerves the phenomena are not changed; on section of the superior laryngeal nerves the phenomena are abolished. Atropine in physiological doses abolishes the heart phenomena but does not prevent the respiratory alterations or arrest. Cocaine hypodermatically also guards the heart but not the respiration. Cocaine locally applied abolishes completely both the effect upon the heart and the respiration. These results having been obtained by graphic record on twenty dogs under full ether narcosis, we may conclude, Dr. Crile said, that the phenomena are due to reflex action caused by mechanical irritation of the peripheral terminals of the superior laryngeal nerves, and that cocaine locally applied paralyzes the same even under full anæsthesia. The local application of cocaine in certain laryngeal operations is indicated.

In the second part of the paper the author dealt with clinical observations and the conclusions derived from them. Carcinoma, he said, probably cannot penetrate cartilage. The most frequent point of attack is the region of the vocal cord, consequently causing early symptoms. When suspected a specimen should be early secured and submitted to a competent pathologist, and, if proven cancer, an early and radical operation should be performed. Early operations should be extremely promising as to their results.

In neglected cases, usually ulcerating and foul, suffering from septic broncho-pneumonia caused by the discharges or by entrance of food, subjects of most intense suffering, a radical operation, while it may not cure, will give a respite and prove to be merciful and humane. The testimony of patients themselves on this point is emphatic. By the technique described, the pulmonary tract may be safely guarded, the operating-time may be lessened, the patient will obtain as long a time of freedom from recurrence as after the most favored capital operation, and, better than all, the high mortality will be very greatly reduced. In the four cases of total extirpation of the larynx, reported by Dr. Crile, the patients all made a good recovery.

Fracture of the Clavicle.—DR. A. D. SPOHN, of Corpus Christi, Tex., exhibited a new form of apparatus for use in the treatment of fracture of the clavicle, to retain the ends of the divided bone in coaptation and to prevent deformity.

A paper on "Gastro-Enterotomy" was read by DR. E. B. SMITH, of Detroit, Mich.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Uterine Fibroids Complicated with Pregnancy.—DR. A. VANDERVEER, of Albany, N. Y., presented a communication with this title. Although cases of this kind are not numerous, he said, yet the method of treatment now employed, thanks to recent progress in abdominal surgery, gives very satisfactory results, at least as regards the life of the mother. The subperitoneal, pedunculated, or sessile fibroids usually give but little trouble upon the occurrence of pregnancy, but danger exists in the case of those which are so situated as to interfere with the cavity of the uterus or obstruct the outlet of the pelvis. Whenever the tumor is so located as not to be likely to interfere with delivery, or its growth is so gradual as to admit of postponement of the operation until after the viability of the child, our duty is clearly to wait. Myomectomy

in the interest of the child is justified in cases in which dystocia would probably occur; at or near term, when dystocia threatens, suprapubic hysterectomy is probably the safest course to pursue. In such cases the loss of the mothers ought not to exceed ten per cent., and the children ought nearly all to be saved. Dr. Vanderveer then reported two cases illustrating this complication of pregnancy in aggravated form, and emphasizing the necessity of thoroughness when operation is called for. In such grave cases delay, in the hope that absorption will occur or that a living child may be delivered (as we sometimes see in cases of uterine cancer), is hardly ever justifiable. We should operate and should remove the appendages with the uterus, for suppuration and sepsis may follow an attempt to perform a Cæsarean operation. The speaker said that his remarks did not apply in the main to small tumors, but only to large and rapidly growing ones, in which cases the mortality, when operation was not done, is very high. They do not admit of myomectomy, and a uterus with large fibroids, with cystic degeneration going on, will not admit of the patient going to full term, and demands prompt surgical interference. Even though abortion may occur, still the uterus is septic, and this is one cause of the great mortality in such cases.

Dystocia in Mexico.—DR. J. IGNACIO CAPETILLO, of Mexico City, read a paper on this subject. Dystocia from maternal causes was comparatively rare in Mexico, and especially so was that from narrowed pelvis in consequence of rickets or osteomalacia. Dystocia sometimes was caused in the native (Indian) women by reason of the greater narrowness of the vulva and rigidity of the perineum in them as compared with women of Spanish blood. Dystocia sometimes occurs in consequence of the premature rupture of the bag of waters, resulting from the common use of the Montanea fomentosa, or "zoapatl." Placenta prævia and procidentia of the cord are rather common causes of dystocia, as shown by the statistics of the Maternity Hospital in Mexico City.

The Management and Surgical Treatment of Ectopic Pregnancy.—DR. AUGUSTUS P. CLARKE, of Cambridge, Mass., followed with a paper with this title, based chiefly upon the results of his own experience and observation. He divided the treatment into several classes. In those cases in which the foetal sac is situated in the abdominal cavity there will not usually be an immediate urgency for surgical measures. In cases of ectopic pregnancy seen at a very early period the application of the galvanic or faradic current may be effective in destroying the fetus and thus enabling absorption of the remains to take place. The liability of the supervention of shock, hemorrhage, or sepsis, from rupture of the sac or of some of the larger arterial branches, especially after the third month of gestation, is so great that precautions should always be taken to have everything in readiness for making an abdominal section. Cases in which rupture has occurred and the child continues to develop should be treated as circumstances demand. If gestation has not gone beyond the third month, removal by coeliotomy should be advised. When the pregnancy has passed much beyond the sixth month it may under proper precautions be allowed to continue until the end of the eighth month. In those really desperate cases of rupture of the sac or of blood-vessels, immediate coeliotomy should be regarded as our chief reliance. This precaution should be adopted whether the hemorrhage is the result of a primary rupture or is a sequel to the yielding of a partially restored vascular tissue. The nearer the gestation has reached the close of its term, the greater will be the probability of saving the life of the child. The immediate removal of the placenta in such cases is often attended with ex-

treme danger; for this reason the sac may sometimes be sutured to the peritoneum, and the placental mass, before its removal, may be given time to undergo contraction and become loosened from its attachment. If it is deemed wise to effect immediate removal of the placenta it can best be done after clamping and tying the ovarian and uterine arteries; should the foetal sac then be found too firmly adherent to allow its safe removal, suture of its edges to the parietal peritoneum and the employment of drainage will be required. In those cases in which the foetation is intraparietal the liberation of the child can be most safely effected, so far as the mother is concerned, by resort to hysterectomy. In some cases closure of the rent by aseptic animal sutures and the stitching of the opening to the abdominal wound might prove sufficient for overcoming the hemorrhage. Cases that sometimes give rise to most alarming symptoms are those in which the foetation takes place in some portion of the Fallopian tube. Hemorrhage from rupture of the sac or from the yielding of the vessels near the fimbriated extremity of the tube can best be controlled by suturing the ruptured vessels through an abdominal incision.

The Ambulant Treatment of Certain Forms of Pelvic Disease.—DR. EMMA B. CULBERTSON, of Boston, Mass., presented a communication in which she said that the frequent occurrence of pelvic disease among women of the laboring classes has of late been more fully recognized than formerly, so that now more accurate diagnosis, leading to more efficient treatment, great relief from suffering, and frequently entire cure can be secured while the patients continue their usual occupations.

It was to emphasize this fact, to make a plea for more optimistic views of ambulant gynecology, that the speaker presented the following statistics. These were taken from the records of but one institution and covered but one year, though similar results, she believed, would be derived from the tabulation of the dispensary service of the past twenty years.

The cases treated in the gynecological department of the New England Hospital Dispensary during the year ending September 30, 1896, were classified as follows: Occupation: Housewives, charwomen, domestics, shop girls, seamstresses, and factory girls. Diseases: Malposition, inflamed adnexa, neoplasms, endometritis, subinvolution, and venereal disease.

To all of these patients a stay in the hospital would have meant serious interference with their daily work. The problem therefore was to effect good results in spite of the fact that rest, care, good food, and freedom from anxiety could not be secured. Fortunately, however, we observe in the majority of such cases a marked toleration of treatment. Measures that could be employed only with the greatest precaution among women of the leisure classes become routine treatment in the dispensary clinics. It would seem, Dr. Culbertson said, as though constant muscular activity must exert some derivative influence upon the pelvic viscera. The speaker then described the technique of various methods of treatment, showing instruments, tampons, etc., referring also to the general treatment employed in conjunction with local measures.

Potassium Iodide in Passive Metrorrhagia.—DR. ANTONIO MACÍAS, of Guanajuato, Mexico, read a paper on the use of iodide of potassium as an indirect hæmostatic in passive hemorrhage of the uterus of asthenic character. He said that this drug was often employed to restore the equilibrium of the circulation in pathological conditions characterized by passive hyperæmia, and he had merely extended the use of the remedy to the treatment of passive hemorrhage in general, but especially to that occurring from the body of the uterus in cases not calling for operative interfer-

ence. His treatment was based upon the results of the extensive studies of the physiological action of potassium iodide made by Germain Sée. These were summarized as follows: potassium iodide presents two phases in its biological action: one is the excitement which is characterized by tachycardia, an elevated pressure, and vasoconstriction. We afterward have another phase, of vasodilatation and low pressure. It is, therefore, a drug whose action is similar to that of digitalis; it first produces a strengthening of the heart and increases the blood pressure. Once this is increased, the circulation becomes more active in the coronary arteries and in the arterial system; thus potassium iodide nourishes the heart and is the regulator of the pulmonary and systemic circulation. As the drug acts on the muscular fibres of the vessels, it regulates the local circulation which is passively disturbed. In fact iodide of potassium is a stimulant to the muscles of the cardiovascular system.

Applying these principles to cases of passive hemorrhage of the uterus (considering this as an exaggerated hyperæmia with extravasation) and in view of the favorable clinical results obtained, the speaker said that we might formulate the following theory: Potassium iodide is a cardio-vascular muscular excitant which reduces venous tension in the uterus, whether simple (hyperæmia) or accompanied by extravasation (hemorrhage). It relieves congestion and acts thus indirectly as a hæmostatic. Its action is certain, powerful, and lasting, and it is not poisonous. It resembles in its action that of the normal blood, which is the physiological stimulant of the circulatory system. The remedy should be given in moderate doses. The indications for its use are all forms of passive hemorrhage from the uterus, whether from general or local causes or that which occurs in women staying at great altitudes.

Other papers read were on "The Treatment of Face Presentations," by DR. JOSÉ TORRES ANZORENA; "A Contribution to the Surgery of the Female Perineum," by DR. EDWARD J. ILL, of Newark, N. J.; "Etiology of Eclampsia," by DR. CLARK, of Chicago; and "The Therapeutic Value of Rest," by DR. SARAH H. STEVENSON.

Tuesday, November 17th—Second Day.

SECTION ON GENERAL MEDICINE.

Pseudo-Hermaphroditism.—DR. IGNACIO ORTIZ Y CÓRDOBA, of Guernavaca, Mexico, presented an individual, Maria Hernandez by name, who was a pseudo-hermaphrodite, and gave in detail an accurate study of the anatomical, physiological, and moral peculiarities. The condition was one of perineo-scrotal hypospadias. The sexual apparatus was masculine, some of the parts being apparently missing, others imperfectly developed, but the exact condition of all the organs of generation could not be determined with absolute certainty. The physical functions were those of a male. During coitus, which could be but imperfectly performed, there was an ejaculation of a liquid which was seen under the microscope to contain spermatozoa in small number. The character and habits of the individual were distinctly feminine, yet sexually the subject was attracted toward women and not toward persons of the other sex. The author reviewed at some length the literature of similar cases and also discussed the classification as proposed by Pozzi, of Paris, and concluded with some considerations bearing upon the medico-legal relations of this and other like cases. In addition to the presentation of the individual, the report was accompanied by photographs and microscopical preparations.

Hæmology of Tuberculosis.—DR. A. M. HOLMES,

of Denver, Col., presented a communication on "The Diagnosis of Tuberculosis by Means of a Microscopical Study of the Blood," of which the following are the conclusions: 1. The diagnosis of tuberculosis from the morphological appearance of the blood rests upon the hypothesis that each individual has a biological prototype in the leucocytes of his own blood. 2. Leucocytes are independent organisms with functions analogous to those of the larger organism. 3. These pass through various stages of growth and decay. 4. Disintegration of leucocytes may occur at any age. 5. The leucocytes are tissue formers. 6. As are the leucocytes so is the individual. 7. Tuberculosis is a disease characterized by tissue disintegration. 8. In tuberculous blood there is abundant cell-disintegration, premature development, premature decay, and a greater or less deviation from the normal average of the various types of cells. 9. If there is a marked disintegration in the leucocytes, it is with certainty that we can predict a similar condition in the larger organism. 10. Tuberculosis possesses a combination of blood appearances from which a diagnosis may be made earlier than by any other means that we now possess. 11. These changes may be recognized by appropriate microchemical stains and a high magnification. 12. They can be recognized even before the disease manifests itself in the individual. 13. They are sufficiently marked in tuberculous individuals, or even in those with a strong tuberculous predisposition, to enable a diagnosis being made from the blood alone, without knowledge of the history or physical condition of the patient. 14. Thus far, no other pathological condition has been found which presents similar blood appearances. 15. An early diagnosis would enable many to avail themselves of favorable climatic changes, and thereby delay or even prevent the destructive results which would otherwise inevitably follow.

DR. JAMES K. CROOK, of New York, read a paper on the use of creosote in the treatment of pulmonary diseases.

SECTION ON GENERAL AND ORTHOPEDIC SURGERY.

Linear Electrolysis in Stricture.—DR. J. A. FORT, of Montevideo, Uruguay, read a paper with this title in which he described at length his method of treatment of obstinate stricture of the male urethra by means of linear electrolysis. The method is the same as that described in a monograph published by the author when residing in Paris. Special instruments devised by Dr. Fort for use in this operation were also exhibited.

Intestinal Anastomosis.—DR. J. FRANK, of Chicago, performed an experiment upon a large dog in the San Andrés Hospital, demonstrating the application of his new device for anastomosing of the intestine. The dog being etherized, its abdomen was opened and about four inches of the small intestine were resected. The divided ends of intestine were then united by means of the bone buttons united by a piece of rubber drainage tube. The operation was completed in fourteen minutes, but Dr. Frank said that he had done it with ease in eight minutes, a longer time being occupied at this operation because of the necessity which he was under of explaining to his audience the details of each step in the operation. The button employed and the method of performing the operation are familiar to the readers of the MEDICAL RECORD, having been fully described by the author in a recent issue.

The method was discussed and favorably commented upon by Sir William Hingston, of Montreal, Dr. Ramon Macías, of Mexico City, and others.

DR. EDWIN BENTLEY, of Little Rock, Ark., read a paper entitled "The Claims of General Surgeons."

SECTION ON OBSTETRICS AND GYNECOLOGY.

Hydatidiform Mole.—DR. J. IGNACIO CAPETILLO, of Mexico City, reported a case of hydatidiform mole which had been accompanied by considerable hemorrhage from the uterus. The woman had been examined by a number of physicians at different times and all had pronounced the case one of placenta prævia. The true diagnosis was not arrived at until the mole had been extracted.

Puerperal Septicæmia.—DR. MANUEL BARREIRO, of Mexico City, read a paper on puerperal infection. The routine practice in all cases of childbirth in the Maternity Hospital of Mexico is to administer a laxative on the day following delivery, and each day thereafter, until the end of the puerperal period, to give tepid antiseptic vaginal injections. Should the temperature rise, an intra-uterine injection is prescribed with a weak pressure (not exceeding twenty inches). If, after the lapse of two days, the temperature continues high, prolonged douches are administered during two hours. Continuous irrigation is both dangerous and inefficacious. If, on the third or fourth day, the temperature does not fall to the normal, it then becomes necessary to curette without loss of time. Both before and after this operation perfect asepsis must be maintained. Excessive loss of blood is a very serious complication and militates against the success of the operation. The objections which have been brought forward against this operation are of no value, clinically speaking; its advantages are indisputable, especially when the infection arises from the existence of placental remains, as it does in the majority of cases, in the author's opinion. The most convenient antiseptic is generally iodine, on account of its volatile character, and of its power to enter thoroughly into the tissues; but in special cases we obtain better results with corrosive sublimate, permanganate of potassium, or oxygenated water. A general tonic treatment ought to be well attended to, as well as the administration of strychnine hypodermically.

Should success not be obtained after a first curettage, this can be repeated a second and even a third time, and in these cases, should it be found necessary, the practitioner can have recourse to catheterization and refrigeration of the uterus.

The clinical comparison of this method with others in common use has firmly convinced the author that curettage is an operation that can be executed without danger, and, if done in due time, is superior to any other of the means that are now known.

DR. GONSALEZ DE LA VEGA, of Mexico City, followed with a paper on the same subject, entitled "Observations on the Classical Treatment of Puerperal Septicæmia." Although, he said, orrhotomy has been found efficacious in the treatment of puerperal septicæmia, it is, however, not the only method worthy of our careful consideration. The reasons why orrhotomy cannot always be relied upon are: Firstly, because the antistreptococcus serum employed can combat only those septicæmias which are produced by the streptococcus; secondly, because the serum acts on the toxic products already absorbed, and it is always a good plan to destroy the causes of this toxic absorption. Local antiseptic treatment consequently and also chiefly merits attention.

Before undertaking any treatment, the physician ought to determine which is the starting-point of the infection, and not at once make intra-uterine applications that may be useless or even injurious through some act of commission or omission. In order to discover this source and utilize all the means for diagnosis, it ought to be searched for, according to a determinate plan, from the exterior to the interior, and in

many cases it will be found necessary to make use of the speculum.

When it is clearly demonstrated that the infection is extra-uterine only, no injection or curettage should be resorted to. Even should the disease have gone beyond the third day of fever, the septicaemia can still be combated without resorting to curettage when its source is extra-uterine.

In those rare cases in which it may be impossible to diagnose the focus of infection, the applications must be both extra- and intra-uterine. When some lesion is found in the canal, intra-uterine injections must be practised through the speculum, in order to avoid the carrying of the septic products of the vagina to the uterus by means of the instrument.

Dr. de la Vega then reported four cases illustrating the points brought out in his paper. The first case was one of puerperal septicaemia resulting from a lacerated cervix. The treatment was a purely antiseptic one and resulted successfully after some days. In the second case septicaemia occurred and persisted, in spite of antiseptic injections, for thirteen days. At the end of this period a very careful examination was instituted, and resulted in the discovery of a slight tear of the perineum. When this was repaired the temperature rapidly fell to the normal, and the patient recovered. The third case was one in which septicaemia had existed before the patient was seen by Dr. de la Vega. A cure speedily followed the use of antiseptic vaginal douches. The fourth case was one of considerable obstinacy. Antiseptic injections, both vaginal and intra-uterine, were employed for a time without result, and then curettage was resorted to. This also failed, and then the author performed a trachelorrhaphy under strict antiseptis, with the result that the temperature quickly fell and the patient made a good recovery.

DR. HENRY SCHWARTZ, of St. Louis, Mo., read a paper on the same subject, under the title of "Antiseptic Obstetrics and the Antitoxin Treatment of Puerperal Infection."

DR. RAFAEL NORMA, of Tulancingo, Mexico, also presented a communication on this subject.

DR. J. FRANK, of Chicago, said that there was no absolute therapeutic rule which it was possible to establish as embracing all cases of puerperal septicaemia, and each case was a law unto itself and should be treated according to the individual indications. In many cases curettage was called for, and he did not agree with those who condemned the use of the curette, for he believed it had a definite place in uterine surgery.

DR. E. A. SPOHN, of Corpus Christi, Tex., was strongly opposed to the use of the curette in these cases, regarding it as a dangerous instrument, the employment of which, unless possibly in certain extreme and very exceptional cases, was unjustifiable.

Third General Session—Thursday, November 19th.

The closing session was held in the chamber of deputies on Thursday evening. After the reading of the treasurer's report, DR. PORFIRIO PARRA delivered an address in which he reviewed the progress made in medical science of recent years, referring to Pasteur, Lister, Koch, and other leaders in the triumphant march. He rejoiced that Mexico had had the honor of receiving this representative body of American physicians.

DR. REED reported that the executive committee had, in response to the invitation of Dr. Costa Ortiz, decided upon Caracas as the place of meeting of the third congress, in December, 1899.

Addresses were then made by the delegates from each government, represented as follows: DRs. LA

CHAPELLE, Canada; LEE, Colombia; CORONADO, Cuba; YELA, Guatemala; DE BAYLE, Nicaragua; ORTIZ, Venezuela; LA VISTA, Peru and Ecuador; and CALNECK, Costa Rica.

The latter said he was born in Canada, educated in the United States, and practised in Costa Rica; and he was therefore well fitted to speak of Pan-Americanism, a spirit which should animate and bind together all the people of the western hemisphere. To know thoroughly and appreciate the Spanish Americans, one should live among them and meet them in their hospitable homes and in the bosom of their families, where the charming traits of their character find fullest expression.

DR. REED, on behalf of the members from the United States, gave voice to the friendly sentiments and gratitude of his associates. "We came here," he said, "feeling somewhat as strangers, but go home feeling as brothers. Your cordial, your generous hospitality, your splendid entertainments, and your distinguished attentions have won our affections and shall abide in our memories. We return to our homes in the North, and in the fullest meaning of the word we feel as if we are leaving part of our hearts in the glorious and beautiful land of the Montezumas."

The closing address was by DR. GREGORIA MENDIZABAL, and at its termination MINISTER BARANDA declared the second Pan-American medical congress closed.

Surgical Suggestions.

Aortic Regurgitation with Mitral Stenosis.—

R Tr. strophanthus,
Tr. nucis vomicae,
Tr. digitalis.....āā p. æ.
M. S. grt. xx. to xxx. i. i. d.

—W. H. THOMSON.

Blood Stains.—Dr. Blenkiser in the *Scalpel* says that surgical instruments, sponges, the hands of the operator, and blood-stained articles may be readily cleansed by washing them in a tepid solution of tartaric acid and rinsing in water without soap.

The Cure of Crying Babies.—In a New York nursery, as soon as a child begins to cry, the nurse catches it up, holds it gently, and places her hand over its nose and mouth, so that it cannot breathe. The crying ceases directly, and the child is allowed to breathe freely again. Should it a second time attempt to scream, the same simple and effectual method is applied. This is repeated until the baby imagines that the painful stoppage of the breath is caused by its own effort to scream, and so is careful to keep quiet. —*Argus.*

Trichocephalus Dispar.—Dr. Moosebrugger (*Cor. Med. Press and Cir.*, vol. lxii, No. 2,991) reports three instances of children, aged respectively one, three, and three and one-half years, who were affected with trichocephalus dispar, and suffered severely from hemorrhage of the bowels, diarrhoea, and great prostration. One of the children died from intercurrent croup. Post-mortem examination gave evidence of severe catarrh of the large intestines, with two small ulcers in the descending colon and a recent cicatrix in the transverse colon. In the colon eight hundred and eighty-nine specimens of the entozoon were found. In the other two cases large quantities of the ova were found in the faeces—in one, eighty-eight hundred and seventy-eight were estimated to exist in one cubic centimetre. Dr. Moosebrugger concludes, from the favorable results obtained, that the presence of this parasite is not so fatal as is commonly supposed.

A Sudden Decline in temperature during typhoid fever is a warning of hemorrhage from the bowels.—*The Medical Summary.*

Indications for Nephrectomy.—Dr. Kuester gives the following indications for operation: 1. Tumors of the kidney. 2. Tuberculosis of the kidneys; experience has shown that renal tuberculosis occurs very often primarily and unilaterally; it affects the genitals and the lower urinary passages more frequently than some other parts of the body. Severe persistent catarrh of the urinary bladder is one of the first symptoms which tuberculosis of the kidney presents; in cases of this kind nephrectomy gives excellent results, and complete recovery ensues. 3. Suppurating kidney caused by metastatic processes and foreign bodies, especially calculi. 4. Renal hæmophilia. 5. Movable kidney. 6. Injury to the kidney. 7. Calculous diseases of the kidney. 8. Uretero-abdominal fistula.

Small Ovarian Tumors.—Dr. Davenport (*Boston Medical and Surgical Journal*, October 8, 1896) gives the following propositions as helpful in diagnosing small ovarian tumors: 1. Small pelvic tumors are usually accompanied by well-marked symptoms. 2. Pain is usually present, but its seat does not have any constant relation to the kind of tumor or its location. 3. Menstrual disturbances are the rule, and by far the most frequent abnormality is menorrhagia or metrorrhagia, or both. 4. There seems to be a direct causal connection between severe uterine hemorrhage and cystic ovaries which are closely adherent to the uterus. 5. Uterine hemorrhage associated with a pelvic tumor which is uninfluenced by intra-uterine treatment (curetting or electricity) is more likely to be due to an ovarian tumor than to a fibroid. 6. Reflex symptoms are comparatively rare, and occur in the later stages of the disease.

Peritoneal Wounds.—Dr. L. McLane Tiffany (*American Journal of the Medical Sciences*) reports four cases of wounds of the peritoneal cavity and thinks the following propositions are justified: 1. A penetrating wound of the peritoneal cavity is not accompanied by symptoms commensurate with the extent of the injury. 2. Many fatal lesions may be present, yet give rise to no marked symptoms. 3. Fatal lesions may exist, yet shock be wanting. 4. The wound of entrance should be enlarged, and, if the missile have entered the abdomen, a section is called for. 5. Operation is proper soon after the injury, before the peritoneal membrane has become infected or much blood lost. 6. Flushing the open peritoneal cavity with hot water or hot normal salt solution is an excellent stimulant to the heart. 7. The abdominal wound should be closed when practicable, drainage being provided for.

Puerperal Self-Infection.—Dr. Charles Jewett (*American Gynecological and Obstetrical Journal*) read a paper on this subject before the New York Medical Society in which he draws the following conclusions: There is no clinical proof that puerperal infection can occur from normal vaginal secretions. All childbed infection in women previously healthy is by contact. Prophylactic vaginal disinfection as a routine measure is unnecessary, and even in skilled hands is probably injurious. Its general adoption in private practice could scarcely fail to be mischievous. In healthy puerperæ delivered aseptically post-partum douching is also contraindicated. These rules must hold good in the simpler cases of manual or instrumental interference in which the uterus is not invaded. A purulent vaginal secretion exposes the woman to puerperal infection. In the presence of such discharges at the beginning of labor the vagina should be rendered as

nearly sterile as possible. Concentrated antiseptic solutions should not be used, and the process should be conducted with the least possible mechanical injury to the mucous surfaces. In case of highly infectious secretions the preliminary disinfection should be followed by douching at intervals of two or three hours during the labor. Sterilized glycerin or other suitable material may be used to restore the proper lubrication of the birth canal. The safest and most efficient means for correcting vicious secretions is a mild antiseptic douche, repeated once or more daily for several days during the last weeks of pregnancy. It is the duty of the obstetrician to know before labor the amount and character of the vaginal discharge. Clinically, the amount of the discharge, its gross appearance, and that of the mucous and adjacent cutaneous surfaces, usually furnish a sufficient guide to the treatment. Probable unclean contact within twenty-four or forty-eight hours before labor is an indication for prophylactic disinfection.

Prevention of Hernia after Abdominal Section.

—Dr. Emory Lanphear says: "From a rather extensive series of experiments, as well as from observation of a number of cases upon which I have had to operate for hernia following abdominal section, I am of the opinion that rupture, subsequent to operation, is almost invariably due to faulty suturing. For this reason, I always close the peritoneum separately and carefully with catgut stitches, unless there is the utmost need of rapidity in completing the operation. If the two cut margins of the peritoneum be brought into close apposition, so there is no little hole through which the omentum can force itself, and if over this the muscular tissues be carefully sutured, there is but trifling danger of post operative hernia. In a large number of sections I have never had a rupture follow such closure. In introducing the stitches of silkworm gut through the skin, muscle, and fascia, it is best to catch up the raphe formed in suturing the peritoneum, including it in about every other one of the sutures, thus preventing the formation of pockets, which favor the development of hernia. Another point—I always make the incision a little to one side of the median line, through the rectus muscle, as I believe union will be more prompt and strong in the vascular muscular tissues than in the non-vascular structures of the linea alba. The sutures should be left as late as the tenth day before removal, in ordinary cases; longer in extraordinary ones."

General Rules for the Treatment of Hydatids of the Liver.

—Dr. Frank (*American Journal of the Medical Sciences*, October, 1896) suggests the following rules: "1. An incision over the most prominent portion of the presenting mass, be this high or low; or, if no tumor can be discovered, the area of hardening and increasing dulness should be our guide for incision. 2. Examine for adhesions: if they be complete, our work is simplified; if not, we must sew the peritoneum all around the mass so as to shut off the abdominal cavity. 3. Introduction of the aspirator. This needs no explanation; but it is well to bear in mind that we do not always obtain the characteristic fluid, as at times the fluid may be too consistent to enter the needle. 4. We must wait for three, four, or five days for adhesions to become firm before opening the cyst. 5. When the cyst is opened a large opening should be made and the largest-sized rubber-drain introduced. 6. The dressings must be made under strict antiseptic precautions, as there is a possible danger of secondary infection. 7. The cyst-cavity should be washed out with sterilized water for the first week, after this with carbolic-acid solution, iodine solution, peroxide of hydrogen, boric acid, creosote, or any of the antiseptic

solutions. The point on which there has been more diversity of opinion than any other is: When there are no adhesions, should the operation be made in one or two sittings? Most authors advise two operations, claiming that there is too much danger of allowing the hydatid fluid to enter into the peritoneal cavity, which would perhaps result fatally, or it might form a nucleus for another cyst. With care an operation of this kind can be performed in one sitting, as my first case will show; but the best plan is, if time will permit, first to sew the peritoneum to the sac and wait four or five days for the adhesions to become firm, as was done in my second case."

Indications for Mastoid Operations in Acute Purulent Otitis Media.—Dr. Knapp (*Arch. of Otolaryngology*, xxiv., 3 and 4) concludes from his observations that: 1. There is in acute otitis media no symptom which by itself constitutes a sufficient indication for mastoid operation. Neither is there any one symptom which contraindicates it, with the exception, perhaps, of deep coma. The most important symptoms are local pain, spontaneous and on pressure, headache, rise or fall of temperature, dizziness, nausea, vomiting, stupor, aphasia, hemianopsia, optic neuritis, paralysis, and coma. Choked disc from otitic brain disease may disappear with either operative or spontaneous recovery of the patient. 2. The indication for operating is derived from the *ensemble* of the symptoms and the course of the disease. 3. Even if the patient does well and seems cured, he should not be lost sight of for weeks or months, for acute purulent mastoiditis is a treacherous disease. 4. Whatever the symptoms be, we should, as a rule, begin the operation by opening the antrum, and then be guided by the conditions coming into view.

The Limits of Vaginal as Compared with Abdominal Exploratory Section.—Dr. Henry C. Coe (*New York Polyclinic*, June, 1896) gives the conditions which lead him to select the abdominal method of explorations: "1. In the case of neoplasms or obscure enlargements which are situated in the abdominal cavity, or have risen above the pelvic brim, especially if they are more or less adherent. 2. In ascites of doubtful origin, more particularly when tuberculous or malignant disease is suspected. 3. In cases of disease of the adnexa in which the latter are situated near or above the pelvic brim, as established by bimanual palpation. 4. In cases in which the history and symptoms point to general intestinal adhesions, and, above all, when appendical complications are suspected. 5. In ectopic gestation before rupture, when the sac is high up, at the side or in front of the uterus, instead of in Douglas' pouch. 6. In cases of intractable pelvic and abdominal pain of obscure origin, including the so-called neuroses. On the other hand explorative vaginal section should be preferred: 1. In all cases in which the presence of pus within the pelvis is suspected, as in pyosalpinx, pelvic abscess proper, suppurating dermoids and cysto-adenomata, and hematocele. 2. In the case of small intrapelvic tumors situated in the pouch of Douglas, or at least readily accessible from below. Impacted ovarian cysts, dermoids, and fibroids belong to this category. 3. Adherent adnexa situated in the true pelvis. 4. Unruptured ectopic sacs in the same locality. 5. Circumscribed exudates and indurations in the broad ligaments or behind the uterus, especially when associated with displacement and fixation of the latter organ."

Treatment of Prolapse of the Rectum by Torsion.—This procedure is based on that proposed by Gersung for urethrocele in women and which Vreden has used for rectal prolapse. A circular incision is

made around the anus half a centimetre outside of the limit of pigmented skin. The rectum is separated from the surrounding tissues to the level of the levator ani. All prolapsed parts are replaced, twisted to an angle of 180°, so that the external opening will permit only the passage of a single finger, and fixed in this position by silk sutures. Union takes place quickly, and recovery is rapid and complete. The author, having used this method in two cases, explains the favorable results of this simple and almost bloodless operation by (1) the tension caused by twisting all the layers of the rectal wall; (2) the even diminution in calibre of the lower portion of the rectum from the level of the levator and by its spiral direction, which prevents the recurrence of prolapse.—*Gazette des Hôpitaux*.

Cancer of the Cervix.—Early hysterectomy even in doubtful cases, since microscopic findings are not infallible.—CORDIER.

Adhesive Affections of the Ear.—Inject liquid vaseline through the Eustachian tube into the tympanic cavity.—DELSTANCHE.

Acute Otitis.—For the earache of this affection, apply dry heat. At no time should the canal be mopped, swabbed, or syringed.—BURNETT.

Ice Bandages are useful in traumatism of the external ear; in inflammatory processes of the auricular canal; in chronic suppuration, when sensitiveness, etc., develops over the mastoid.—BOEKE.

Corneal Ulcer.—Formalin solution, 1 to 200 to 1 to 500, for touching the ulcer once daily. As a general collyrium, 1 to 1,000 to 1 to 2,000.—BURNETT.

To Prevent Hemorrhage.—An hour before operation a pint of water containing an ounce of chloride of calcium was injected into the rectum (to increase the coagulability of the blood). During the operation Wright's fibrin-ferment solution was applied to the freshly cut surfaces.—WATSON CHEYNE.

A Perfect Needle should be adapted for use by the surgeon's fingers without needle holder, excepting for work in deep cavities. The point must be sharp and the eye large enough to be readily threaded. Glover's needles present the best pattern. The trocar-like point should occupy about one-third the length of the needle, and its greatest diameter should be near its middle portion.—JOHN B. ROBERTS.

Massage in fracture of the clavicle is recommended by Dr. Dagrou (*Jour. de Méd. et de Chir.*). Fractures of the extremities of the bone are more amenable to massage, as they present less deformity than the median variety. Manipulation must not encroach upon the fragments themselves. The arm is fixed in an ordinary sling, which, after the fifteenth day, can be put on outside of the clothing. Consolidation occurs from the eighteenth to the twenty-fifth day.

Suppositories for Acute Localized Prostatitis.—

R Iodoform,
Extract of hyoscyamus.....ãã gr. ss.
Cacao butter..... gr. xlv.

—GUÉPIN, *Journal des Praticiens*, August 15, 1896.

Gleet.—The following injection is for daily use in post-gonorrhœal discharges:

R Mercuric chloride,
Zinc sulphate gr. xij.
Boric acid 3 i.
Distilled water 3 vi.

—NEILSON, *Philadelphia Polyclinic*.

Injury at the Elbow-Joint.—Be very guarded in your prognosis in cases of injury at the elbow. A fracture into this joint treated with the most far-seeing precautions may be followed by more or less stiffness and disability. Begin passive motion as early as possible, delaying only long enough to allow the first pain and reaction from the injury to subside. In most cases this will allow some manipulation of the joint by the end of the first week.—*International Journal of Surgery*.

Corneal Opacities.—Electrolysis, the kathode being applied to the eye by means of a small silver rod with rounded end. An ordinary sponge anode may be applied to the opposite cheek. A pressure of from one and one-half to three volts is sufficient. This should be at one-fourth milliampère, and one-half should never be exceeded. The eye is cocaineized and the silver rod is rubbed lightly over the opacity for about one minute.—*STEVENSON, Canada Lancet*, November.

The Etiology and Treatment of Venereal Buboës.
—Dr. Perry, after collecting statistics on the above subject, draws the following conclusions in the *American Journal of the Medical Sciences*, November, 1896:
1. That buboës are probably caused by the absorption of chemical poisons, the result of the action of the micro-organisms in the chancroid, and not to the entrance of the micro-organisms themselves into the lymphatics.
2. That the benzoate of mercury yields such satisfactory results that it should be employed in the treatment of non-suppurating buboës, and excision reserved for those cases in which benzoate has failed.
3. The injection of iodoform ointment should be used in the treatment of all freely suppurating buboës, since statistics show that it yields much more satisfactory results than the other methods of treatment applicable to this variety.
4. Incision and curettage should be used in a few cases in which the skin has been destroyed and the ulcer presents an unhealthy granulating surface.
5. Excision should be reserved for cases that have not yielded to other treatment, and for those in which there are several foci of suppuration.

Malignant Disease of the Body of the Uterus.
—Dr. F. B. Jessett writes, in the *Medical Press and Circular*, October 21st, upon operation in the above condition, giving the results in seventy-five cases. He says: "In ordinary cases, in which the uterus can be completely drawn through the vulva, its removal is a simple matter, but in my experience these cases are like angels' visits, few and far between. The lessons to be derived, then, may be summed up: 1. In all cases of women suffering from leucorrhœal discharge, do not hesitate to insist upon a vaginal examination. 2. If on examination a discharge is seen escaping from the os in a woman at or past the menopause, which discharge is occasionally slightly colored and offensive, dilate the canal and curette the cavity of the uterus for microscopic examination. 3. If the report is unfavorable, at once urge total extirpation of the organ. 4. Even in advanced cases, so long as the uterus is movable, I am convinced that much relief can be afforded and life prolonged by vaginal hysterectomy. To my mind, the man who will limit the operation only to those cases in which he can pull the uterus well down through the vulva is certainly not doing the best that can be done for his patient. One might just as reasonably argue that because a carcinomatous breast is somewhat fixed on the glands affected, the surgeon should not remove it. What surgeon would hesitate to do this? Moreover, in a somewhat large experience in the post-mortem room, I found the lumbar and sacral glands free from infection in many cases in which the disease was far advanced."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE COMING ELECTION—LONDON WATER—"DAVID LEWIS TRUST" AND HOSPITALS—SOCIETIES—DWARFISM—CANCER OF TONGUE—BIGELOW'S OPERATION—THE LATE SURGEON-GENERAL MUNRO—DIPHTHERIA—GLASGOW UNIVERSITY—IRISH ACADEMY—SIR WILLIAM MACCORMACK.

LONDON, November 6, 1896.

As the election of three members to the general medical council draws near, the signs of activity increase. Our usually apathetic profession has been stirred in various quarters, and the friends of the several candidates are exerting themselves more than at previous elections. Alas, there are too many candidates—no less than eleven for three vacancies. Many votes must be lost by this division, but it is certainly a better sign than allowing a walkover. Several meetings of practitioners have been held during the week to hear the views of candidates, and have been well attended. The most important meeting was on Tuesday at the Medical Society's rooms, and was in support of Mr. Rivington, who has been brought forward by the societies of members and fellows of the Royal College of Surgeons. These two organizations have agreed to support Mr. Rivington, and, as this college has more than twelve thousand on its roll, he ought to have a good place on the poll, although he came forward late. The college is ruled by a council of twenty-four, elected by fellows, and Mr. Rivington has always supported the claim of members to some voice in their affairs. He is also opposed to the creation of an inferior order of practitioners as midwives, and this is a crucial question for the rank and file. It will probably dominate the contest. Dr. Rentoul, who made such sacrifices to defeat legislation which would have established midwives in a position independent of medical men, loses no opportunity of ventilating the question. He is also a candidate, and if the general practitioners fail to carry him for one of the vacancies they may have cause for bitter repentance.

The water supply of London seems a more serious question than for some time was supposed. There is no longer any doubt that the filtration sometimes fails. The county council has decided to continue the investigation, and the revelations already made are likely to urge on legislation. The previous work of the analysts has been shown to be defective. Organisms many times larger than pathogenic bacilli have been found in the water as delivered. Of course, when large ones pass the filter beds, smaller ones will find the road clear. Bacilli coli communis have been found, so that sewage pollution may be confidently asserted to have occurred at intervals. The companies deserve no consideration, for they have made enormous profits out of their monopolies and often failed to fulfil their contracts. They have gained by a one-sided arrangement, and the time has come for Londoners to control their own supply.

The "David Lewis trust" arises out of the will of a wealthy Jew, who left some £300,000 to two of his friends. To one of these friends he also addressed a letter, suggesting the use of the money for the benefit of the people of Liverpool and Manchester. The two friends accordingly determined to act on this suggestion, although the will gave them the money absolutely, and they associated with themselves leading Manchester and Liverpool gentlemen to form the "David Lewis trust." Hospitals were early to benefit. The Northern Hospital of Liverpool was in need of a better building, and gladly accepted £60,000 from the

trust, on condition of associating the name of the deceased benefactor. So it became the David Lewis Northern Hospital, and on October 19th the foundation stone of the new building was laid by the Countess of Derby, in the presence of some twelve hundred citizens.

Manchester was offered a similar benefit. The trustees proposed to give £70,000 to St. Mary's and the Southern Hospital, which were to be amalgamated, the name of St. Mary's being retained, coupled with that of David Lewis. The proposal did not seem to suit some of the parties, or their mutual jealousies were allowed to prevail. At length the trustees fixed a date up to which their offer would hold good, and after which they would proceed to devote the money to other purposes. That date has expired, and now some of those concerned are crying out for an extension of time. Owens College was to have some connection with the hospital, and it is said jealousy of this has caused the breakdown. There are many hospitals which would jump at the chance of being renamed on such terms.

The opening meeting of the Medical and Chirurgical Society was signalized by a paper describing a case of "Mixed Premature and Immature Development." Mr. H. Gilford was the author, and he had ransacked the literature of the subject. A similar case, recorded by Mr. Hutchinson, appears in the Transactions of the Society, 1886. The interest of the case lies in its relation to dwarfism and giantism. While the patient was clearly a dwarf, there were parts that were more than fully developed, and Mr. Gilford was led by this case to the study of dwarfism and giantism. He sees a close relationship between these deviations in nutrition, and suggests the term *micromegaly* as descriptive of his case and others allied to it. He thinks it not impossible that the cause of *acromegaly* operating before birth may bring about *micromegaly*; for many giants have evidently owed their proportions to the former. May the one be the congenital condition of the other, or are the two opposite states? Mr. Hutchinson holds that this subject and his own were dwarfs, though they presented premature senile changes, but he had not noticed premature development of the intellectual faculties. Dr. Norman Moore said, if disease such as syphilis could be excluded, the state might be analogous to that seen in some *amphibia*, which may remain for a long time in the larval stage and may suddenly pass to the adult or even senile stage.

At the last meeting of the Medical Society of London, Dr. Jennings read notes of thirty patients taken in at the Cancer Hospital, supposed to be suffering from cancer of the tongue, and pointed out some of the conditions that are difficult to differentiate. Of the thirty admitted, twenty appear to have been afflicted undoubtedly with cancer. Smoking, he considered, if slight, could not be regarded as a cause, but would aggravate the growth. Syphilis as a predisposing or exciting cause seemed to him beyond doubt.

Mr. P. J. Freyer read a paper on the best methods of removing large calculi from the bladder. Out of three hundred cases of all ages, he had only had to cut seven times, the other two hundred and ninety-three cases being treated by litholapaxy. One year he treated one hundred and six cases, with only one death. Of forty-nine cases of large stones, *i.e.*, of two-ounce weight or upward, thirty-one had been cured by Bigelow's method. When a stone is so large that the lithotrite will not lock, he advises "chipping" it by grasping it on one side and screwing home the instrument. He related one case in which he had removed a stone of six and one-half ounces by litholapaxy. He attributed much importance to the rapidity with

which a stone could be removed by Bigelow's operation.

Surgeon-General William Munro, C.B., died on October 30th, in the seventy-third year of his age. He retired in 1881, after thirty-seven years in the army medical service. He served through the Kaffir war of 1846-47. In the Crimea he took part in the battles of Alma, Balaklava, and the fall of Sebastopol. In the Indian mutiny he was present at many engagements and in the relief of Lucknow. In 1863 he was chief medical officer in the operations in the Umbeylah Pass. His C.B. followed in 1865. He was the author of several works, of which the best known are "Reminiscences of Military Services with the Ninety-third Sutherland Highlanders" and "Records of Service and Campaigning in Many Lands."

The deaths from diphtheria in the last four weeks have been 52, 66, 57, 64.

Mr. Chamberlain has been elected by the students lord rector of the University of Glasgow. Some of the students carried their excitement to the verge of riot, and several had to be arrested.

The annual meeting of the Academy of Medicine of Ireland took place on Friday, when a secretary was elected in place of Mr. Thompson, who has become the president of the Irish College of Surgeons.

Sir William MacCormack does not progress as rapidly as was expected. The lung, I hear, is clearing gradually, but there is great weakness.

• GIVE THE FULL NAME.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Having been engaged lately in a literary work involving considerable consultation of papers and verifying of references, I have realized, as any one must under the circumstances, the extra labor necessitated by a practice which has always been more or less general with authors, of mentioning only the surname of writers and investigators referred to. Any one who has had experience cannot fail to have been struck with the large number of persons of the same surname who are contributors to medical literature, so that a reference to Dr. Sydenham's or Dr. Jones' views or to Dr. Ranklin's papers gives a very imperfect idea of the individuality of the author. Take, for example, the name Hoffmann. The student will find in the surgeon-general's catalogue this surname more than one hundred times, and of these many Hoffmanns quite a number are authors of voluminous and important papers; so that to be told that Hoffmann believed thus and so is of little assistance to the reader who desires to look up his views and papers. Again, to take a name to which modern medical literature often refers—Laveran. At least two Laverans, both French army surgeons, have written papers of importance. The Laveran whose name is so identified with the malaria plasmodium is A. Laveran, while Louis Laveran is a very different person. Yet writers quote only "Laveran." It is needless to multiply instances. They will occur to any one. My object in asking publicity for this letter is to beg writers to adopt the practice of giving the full name of the authority quoted. This, of course, involves a little trouble at first to hunt up the Christian name, but, as years roll on and we all are thus explicit in indicating authorities quoted, it will become easier and easier, while the amount of labor saved to those looking up references will be immeasurable. Especially important is it that the editors of the various handbooks and annuals, which are now filling such a useful niche in medical literature, should

¹ Unfortunately even the surgeon-general's catalogue has not the full Christian name.

adopt the practice of using the full name, for it is from suggestions in such books that writers often want to look up references.

JAMES TYSON, M.D.

October 30, 1896.

CONGENITAL TEETH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: After reading the article by Dr. E. S. McKee, in your issue of October 17th, on congenital inferior incisors, it impressed me that the condition was of such rare occurrence that it deserved mention; hence these short notes on the following case:

On January 11, 1895, I was called to confine Mrs. M—, a multipara. After a somewhat tedious labor twins were born—a boy and a girl. The boy weighed four pounds six ounces, the girl four pounds eight ounces. They were both poorly nourished, the skin falling in loose folds over the whole of the body, of a brown-yellow color, almost simulating jaundice. The fontanelles were large, rachitic to all appearance. But the abnormality that at once impressed the mother and the rest of the family as a most deplorable ill omen was the discovery of an upper incisor tooth in the girl and two lower ones in the boy. The teeth were all loose, being held, as it appeared, only by a depression in the gum, the teeth being free from the alveolar process. The girl lost her tooth in the first twenty-four hours—what became of it no one knew. The boy retained both of his until the second week, when, being greatly in the way of his nursing, I removed them with my fingers. The gums after the extraction did not bleed. Both children died in their fifth month, of the same ailment—splenic anæmia. Numerous microscopical examinations of the blood were made. The spleens were so enlarged as almost to occupy two-thirds of their respective abdominal cavities. No necropsy was permitted.

A. S. WAISS, M.D.

3,000 ST. CHARLES AVENUE, NEW ORLEANS, LA.

THE IMMORALITY IN CANADA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Regarding the truthfulness of the statements made in the *Dominion Medical Monthly* on bicycle riding which you quoted under the above caption in the editorial columns of the MEDICAL RECORD, November 7th, one hundred per cent. of the reputable physicians and probably ninety-nine per cent. of the unethical ones in Toronto, and for that matter throughout all Canada, will agree in saying that if ever the dimensions of a libel, as to its absolute falseness, vileness, and harmfulness, can be measured, these statements made in the *Dominion Medical Monthly* will easily, in height, depth, length, and breadth, transcendently excel all the exhibits of libels ever presented by either medical or lay press. The editorials in the MEDICAL RECORD have three cardinal virtues. They educate, arouse, and delight. If your caustic comments on your contemporary of the *Dominion Medical Monthly* do not contain much of the first and last elements, they contain more than *quantum sufficit* of the second.

The facts, Mr. Editor, are that lady bicyclists in Toronto, as no doubt they do elsewhere, sit erect and ride very gracefully, and that the use of the bicycle has the slightest tendency injuriously to affect morals by sensuous erethisms or orgasms is most conclusively refuted by the fact that an ever increasing number of clergymen's, teachers', and physicians' wives are riding them and allowing their daughters to do so. The consensus of medical opinion as recently obtained by

a reporter for one of our dailies is that, barring those suffering from certain diseased conditions, bicycling furnishes, for women especially, a useful, healthy, invigorating, and very enjoyable recreation.

It may be added in conclusion, and out of respect for reputable Canadian medical journalism, that this very article had passed unnoticed into oblivion and would doubtless have remained in "hades" had not the MEDICAL RECORD resurrected it and exposed its heinousness.

JOHN HUNTER, M.D.

116 DOVERCOURT ROAD, TORONTO.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 21, 1896:

	Cases.	Deaths.
Tuberculosis.....	153	85
Typhoid fever.....	38	6
Scarlet fever.....	112	5
Cerebro-spinal meningitis.....	2	1
Measles.....	67	21
Diphtheria.....	230	25
Small-pox.....	0	0

Hallucinations of Vision.—Facts relating to hallucinations of vision in those from whom the eyeballs have been removed or in whom the globes are congenitally absent are sought by Dr. Thomas M. Stewart, and any communications bearing upon the question will be acknowledged with thanks if sent through the MEDICAL RECORD or addressed directly to 704 Elm Street, Cincinnati, O.

Ethics.—The code governing Paris societies says: "It is good confraternity to accept the consulting physician desired by the family, no matter what his age, his grade, or his situation, providing his personal honor and regular professional standing are not in dispute."

We Need the Same.—In Germany a law is said to exist which holds the newspaper as well as the advertiser responsible for assertions made. If a promise to cure is held out and the remedy fails, prosecution is liable to follow.

Acute Urethritis.—At the out-patient department of Roosevelt Hospital we use as a routine practice the internal administration of five grains of salol every three hours, and we think that it does good.—MOUNTON.

What X-Rays Will Do.—A fond mother reported that with their aid a coin which her son had swallowed had been distinctly located in his sarcophagus.

Formaldehyde solution in alcohol has been praised by Rosenberg (*Deutsche med. Woch.*) as a disinfectant. The vapor given off is said to be especially valuable for the disinfection of rooms. In pertussis and phthisis it is claimed to give relief from attacks of embarrassed respiration. Meat, eggs, and other articles of food exposed to the vapor and then covered with a thin layer of the solution will keep for months free from putrefactive changes, but their value as food cannot be said to be improved by the process.

Microscopists and Pathologists are entitled to a fee when their examinations aid in the conduct of a case. It is a consultation, and the consultant should not be expected to give valuable opinions, arrived at

through hard and specially skilled labor, just for the fun there is in it.

Medical Students.—Munich has 1,502, Vienna 1,370, and Berlin 1,118.—*Universitäts Kalender*.

A Double Hymen.—A curious case is recorded in the *Comptes Rendus de la Société Médicale de Tambor*, 1895, which concerned a young peasant woman who, accompanied by her husband, presented herself at the consultation of Dr. Olénine and gave the following history: She had always been in excellent health; began menstruating at the age of fifteen, since which time she had always been regular. During the nine months of her married life coitus had never been satisfactorily accomplished, though frequently attempted, despite extreme pain in the effort. Examination revealed a thickened fleshy hymen with an opening at its upper part. At one or two centimetres beyond this, and situated in the inferior third of the vagina, was a second membrane with a small central orifice. This completely closed the calibre of the vagina, but by a crucial incision of both inner and outer barriers, in the words of the report, the woman was *rendue à la vie conjugale*.

Meat Diet.—The annual consumption of flesh for each inhabitant of the United States is 120 pounds; Great Britain, 105 pounds; France, 74 pounds; Germany, 69 pounds.

Poisoning by Plumbo-Solvent Water Supplies.—A special report to the local government board of Great Britain, made by Inspector W. H. Power, gives the results of an original investigation concerning the effects of moorland waters, in respect of their plumbosolvent ability. The results go to confirm the microbic theory of lead solution. The investigation is not yet ended, but the chief propositions, as contained in the *Glasgow Sanitary Journal*, are these: 1. The lead-dissolving property of moorland waters is associated with acidity. Moorland waters that are acid invariably possess ability to dissolve lead. At the same time they may, or may not, erode this metal. Many moorland waters which dissolve lead to a considerable extent possess, in regard to this metal, no conspicuous erosive power. Other moorland waters both dissolve and erode lead in a very decided fashion. Moorland-peat waters are all, it would seem, not far removed from possession of one or the other property, or of both properties. 2. There was indication also of close relation between amount of acidity and vigor of solvent action on lead. But the correlation does not amount to complete parallelism. Different waters of equal acidity did not necessarily possess equal power of dissolving lead. 3. In certain circumstances moorland waters are found to increase in acidity, and therefore in lead-dissolving potency. This is true of waters on peat soil. 4. Peat soil, from various gathering-grounds, was found to be, when moist, invariably acid. 5. When divorced from the peat, the moorland waters did not increase in acidity. 6. When "sterile (neutral) peat-essence" was added to freshly collected samples of acid moorland water, the result was bacterial growth and, in most cases, acid reaction in the peat-essence. 7. When the acid water was added to the peat-essence (sterile and neutral), the result was bacterial growth and, in most cases, acid reaction in the peat-essence. 8. Thus the water must have contained bacteria that, by acting on some substance in the peat, were capable of increasing the acidity of the mixture. 9. These bacteria are derived from the peat. 10. To separate samples of distilled water that was neutral in its reaction and which did not dissolve lead, there were added small amounts in each instance of moist peat soil from different selected gathering-grounds. As a result, every sample of distilled water

developed in a short while acid reaction and was found to have acquired ability to dissolve lead. 11. To separate samples of sterile peat decoction which did not dissolve lead, there were added minute amounts in each instance of moist peat soil from different gathering-grounds. As a result the samples of peat decoction always developed bacterial growth, and at the same time were usually found to possess acid reaction and ability to dissolve lead. 12. Of the microbes discovered in the above peat decoctions only two, named provisionally "O" and "Q," were found to make sterile peat decoction acid, and to confer on it the ability to dissolve lead. 13. Lastly, moist peat soil from a variety of gathering-grounds yielded two microbes identical with "O" and "Q," which, when inoculated into sterile peat decoction, multiplied therein with considerable vigor, produced in the medium acid reaction, and conferred on it ability to dissolve lead. These brilliant results will now be applied to the vast areas selected. The distribution of lead poisoning will be noted and verified. Doubtless many peculiarities, otherwise unexplained, will now fall into their place as natural deductions from the life history of these microbes. And thus, surely a sufficiently startling conclusion, lead poisoning by moorland waters almost leaps into the circle of infectious diseases.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

HUMAN ANATOMY, GENERAL AND DESCRIPTIVE, FOR THE USE OF STUDENTS. By John Cleland, M.D., and John Yule Mackay, M.D. 8vo, 833 pages. Illustrated. The Macmillan Company, New York. Price, \$6.50.

THE SERUM TEST OF WIDAL AND THE POSSIBILITY OF ITS APPLICATION WITHOUT MICROSCOPIC EXAMINATION, WITH A REPORT OF CASES AND DEMONSTRATION OF METHOD.

By CHARLES LYMAN GREENE, M.D.,

INSTRUCTOR IN PHYSICAL DIAGNOSIS AND CLINICAL MEDICINE IN THE UNIVERSITY OF MINNESOTA; VISITING PHYSICIAN TO THE CITY AND COUNTY HOSPITAL, UNIVERSITY FREE DISPENSARY, ETC., ST. PAUL, MINN.

THE great importance of the serum test of Widal for the diagnosis of typhoid fever must serve as my excuse for appearing on the programmes of two successive meetings of this society.

In a former report I stated that with such evidence as we then had it would appear quite possible that we had at last found the long sought pathognomonic sign of typhoid fever, and in the light of a more extended personal experience I desire to express the opinion that the test is absolutely pathognomonic, whether performed with fresh or with dried blood. In support of this view I shall cite a series of cases, make a brief reference to the recent contributions to this most interesting discovery, and call attention to the fact, not hitherto mentioned, that even macroscopic methods may suffice for its application.

As has been the case with most important advances in bacteriology and serum diagnosis and therapy, we are able to trace the test of Widal through several successive steps and must give credit to Pfeiffer, Gruber, Grünbaum, and Durham for important preliminary observations, and to Dr. Wyatt Johnson, of Montreal, for the first application of this method to board-of-health work, and for having, independently of Widal and without knowledge of the latter's prior announcement, shown that equally good results were obtained if dried blood were used instead of the fresh serum.

Pfeiffer in May, 1894, found that cholera vibrios, mixed with the serum of an immune animal and injected into the peritoneal cavity of a guinea-pig, lost their motility and underwent a peculiar change in physical characteristics. In November, 1894, he found that typhoid bacilli underwent similar changes, and he also found that the blood serum of a typhoid-fever patient would produce the same results. Gruber in 1895 found that if the serum of an immune animal were added to a bouillon culture the bacilli became agglutinated and lost their mobility. No use was made of these discoveries, however, save as a means of identifying the bacillus, and to Widal belongs the credit of transposing these findings and adapting them to the needs of clinical diagnosis by studying the effect of the blood serum of a typhoid patient upon the pure culture of the bacillus typhosus.

He first reported his clinical results on June 26, 1896, and later suggested the use of dried blood instead of the fresh serum, when the latter could not easily be procured. The present status of the test justifies the following statements:

(a) That the blood or blood serum, and very frequently the urine, of a typhoid patient, by virtue of a

specific antitoxin, causes, when added to an emulsion of the pure culture of Eberth's bacillus in hanging drop or ordinary cover-glass preparations, a characteristic loss of motility with agglutination and grouping of the bacilli.

(b) That this reaction may and generally does occur as early as the fourth or fifth day and is variable on the eighth or ninth, lasting generally throughout convalescence and very often for many months after complete recovery. (Widal thinks for years in some cases.)

(c) That the antitoxin of a typhoid patient acts thus only upon the bacillus of typhoid. (This has been denied as to the colon bacillus, but the denial is immaterial from a clinical standpoint.)

(d) That the blood serum or urine of patients suffering from diseases other than typhoid does not so affect the typhoid bacilli.

(e) That dried blood retains the antitoxin unchanged and may be used when the fresh blood or serum is unobtainable. The antitoxin remains unchanged in dried specimens for weeks and probably for several months.

(f) That the test is therefore pathognomonic of typhoid and easily applicable to the use of public laboratories.

The fact that no adverse reports have appeared attests the simplicity and reliability of the test. Its application requires only the possession of a moderately high-power lens, $\frac{1}{4}$ - $\frac{1}{6}$ objective (an immersion objective is not necessary), a tube containing the pure culture, such as may be easily obtained from a public laboratory, and such a rudimentary knowledge of bacteriological technique as will serve to prevent the contamination of the pure culture used and permit proper reinoculation of fresh culture tubes from time to time (about every two weeks). For such as do not possess these facilities the public laboratories should offer a means of ready assistance. The practitioner would then need only to sterilize the skin of his patient's finger or ear, draw a drop or two of blood, transfer it to a cover glass, visiting card, or any other similar object, and send it closely sealed to the laboratory.

Dr. Harry P. Ritchie, senior house physician, and myself have made the following tests at the City Hospital with results as stated below, using indifferently fresh and dried blood. We have not found it necessary to use the serum alone. We have so far experienced no difficulty in the application of the test, and have had frequent occasion to note its great differential value in doubtful cases.

Cases Tested.—1. Mary F., typhoid. Widal's reaction on fourth day. Diazo marked. Spleen (?). Rose spots. Temperature, 101–104° F.

2. Rinbolt S., typhoid. Widal's test marked. Diazo marked. Seventh day, temperature, 102–103.5° F. Spleen enlarged. Rose spots.

3. Andrew P., typhoid. Widal's present November 6th. Diazo present November 7th. Tenth day, rose spots. Enlarged spleen.

4. George F., typhoid. Widal's marked. Diazo marked. Second week of a relapse, rose spots. Enlarged spleen.

5. Jacob C., typhoid. Widal's marked. Diazo marked. Middle of second week, (ambulatory) temperature, 104-106° F. Spleen enormous. Rose spots. Pulmonary stasis. Albuminuria.

6. W. J. M., typhoid. Test of Widal made on twenty-fourth day after admission. Temperature nearly normal. Reaction present.

7. J. N., typhoid. Test on fortieth day. Temperature normal. Reaction present.

8. F. D., typhoid. Test on forty-sixth day. Temperature normal. Reaction marked.

9. A. G., typhoid. Test on sixteenth day after admission. Reaction marked.

10. J. J., typhoid (mild). Test on twenty-fourth day. Reaction present.

11. R. Y., typhoid. Test on twenty-eighth day. Reaction marked.

12. Mrs. C., typhoid. Test on thirtieth day. Reaction marked.

13. M. P., typhoid (mild). Test on twentieth day. Reaction present.

14. Lizzie, typhoid. Test on sixtieth day. Reaction present.

15. M. G., typhoid. Test on thirty-eighth day. Reaction present.

16. L. F., typhoid. Test on twenty-first day. Reaction marked.

16½. A. G., typhoid. Test on seventy-second day. Reaction. (Case No. 7.)

17. D. D., ulcerative endocarditis. No reaction.

18. Laura, ulcerative endocarditis. No reaction.

19. G. T., broncho-pneumonia. No reaction.

20. Mrs. B., lobar pneumonia. No reaction.

21. F. S., lobar pneumonia. Widal's test, November 3d, negative. Diazo, November 2d, negative. Duration of disease four days. Typical typhoid tongue and countenance. Temperature, 104.4° F. Spleen not palpable.

22. Mrs. H., pyloric stenosis. No reaction.

23. Mrs. S., septicæmia (abortion). No reaction.

24. Diphtheria. No reaction.

25. Diphtheria. No reaction.

26. E. W., gonorrhæal bubo with fever. No reaction.

27. Phthisis. No reaction.

28. Phthisis. No reaction.

29. Phthisis. No reaction.

30. Tuberculous pleurisy. No reaction.

31. Erysipelas. No reaction.

32. Mr. B., erysipelas. Widal's test negative. Duration of disease, three days. Temperature, 104° F.

33. Holtum J., alveolar abscess. Widal's negative, November 5th. Diazo negative, November 5th. Duration of disease five days. Temperature, 102.8° F. Spleen not enlarged. Sent in to hospital as typhoid.

34. D. C. T., gastro-enteritis. Widal's negative, October 31st. Diazo negative, October 31st. Duration of disease, five to six days: prodromata about ten days. Diarrhœa gave good preliminary history of typhoid. Temperature, 103-104° F.; in three days came to normal. Spleen enlarged (?) (not palpable).

35. Altin G., gastro-enteritis. Widal's, November 15th, negative. Diazo, November 10th, negative. Duration of disease, five days. Temperature, 100° F. Spleen not palpable.

The total number of typhoid cases tested is not large (sixteen), but they are representative, and, being ward cases, were carefully studied and thoroughly proven.

You will note the presence of the reaction on the fourth day, its persistence until the seventy-second, and the fact that in no disease other than typhoid has any reaction been obtained. If it be not present on the seventh or eighth day of fever, you are not dealing with typhoid.

I have here the dried blood of typhoid which has been kept for ten days and will endeavor to demonstrate the test, using as control the blood of pulmonary tuberculosis and some from my own finger.

I first place upon a slide a large drop of distilled water, sterilize my loop, and take from the culture tube a bit of the pure culture, using every precaution to prevent contamination of the growth. This bit of the pure culture is stirred very thoroughly into the distilled water and another drop of distilled water is placed upon the dried blood, which is thoroughly moistened, a drop transferred to the emulsion of bacilli and distilled water already prepared, and the whole thoroughly mixed. The cover glass is dropped on and the specimen is ready for examination.

If the reaction be absent, as will be the case in the slide prepared from the normal blood or that from the case of tuberculosis, we shall find the bacilli in rapid motion and not grouped, nor will they show any tendency to group within fifteen minutes. On the other hand we shall find in our typhoid-blood mount that motion is rapidly lost and grouping well under way in five or ten minutes. This going on until after a variable period, the bacilli appear like islets in a sea, and the slide viewed with the naked eye will present the peculiar appearance described below.

The time required is very variable. Oftentimes grouping is well under way before the field can be brought into focus, and at other times five or ten minutes may elapse before it is well marked, and a half hour or more be required for its completion.

The method described is simple but sufficient, and the use of hanging drops, definite amounts of a bouillon culture, etc., seem to be unnecessary for clinical work. Nor does it seem to me necessary to wait for a complete cessation of motion throughout the whole field, inasmuch as decided grouping has not been observed in any other disease.

A bouillon culture is preferable as being more easily and thoroughly mixed with the blood, and in using it one need not place any distilled water on the slide. Here a fine pipette should be used instead of the loop.

In using the cultures upon solid media, it is of course necessary to bear in mind the necessity for taking very little of the growth and stirring it in very thoroughly, otherwise little clumps of bacilli might mislead an inexperienced observer.

Both Dr. Ritchie and myself have observed a fact not hitherto mentioned, viz., that the diagnosis can very generally be made with the naked eye, a fact which might sometimes be serviceable, though of course the microscope is to be used when at hand. In cases in which the reaction occurs, the whole mount in cover-glass preparation may be seen with proper light to assume a characteristic mottled appearance, not present in mounts from cases in which the reaction is absent.

It is to be hoped that the test will stand thorough and extended investigation, for by it one of the most difficult of diagnostic problems is made easy, and, so far as diagnosis is concerned, Jaccoud's "greatest problem of the nineteenth century" has found its solution.

THE RADICAL CURE OF FEMORAL HERNIA, PREFERABLE OPERATION: THE SURGICAL ANATOMY OF THE TRANSVERSALIS FASCIA AT THE INTERNAL INGUINAL AND FEMORAL RINGS.

By J. COPLIN STINSON, M.D.,

SAN FRANCISCO.

IN an earlier paper on the operative treatment of inguinal hernia¹ I reported seventy-nine cases in which I had performed or assisted at a radical operation. In this I shall report five cases of femoral hernia in which radical operations were performed. Before proceeding with this method of the treatment of femoral hernia, I shall give a concise description of the transversalis fascia at the internal inguinal and femoral rings, basing my report on excerpts from several authorities² and on notes of some dissections I have made. The subjects I used were two children under five years of age, four children from five to fifteen, four adults from twenty to thirty, and two old people from sixty to seventy. The transversalis fascia is strongest and best developed in the inguinal region. At the internal ring it consists, in most cases, of firm and almost tendinous fibres. On the outer side of this ring it forms a well-marked band called the outer limb of the internal ring (Hesselbach, Henlé), or the outer portion of the transversalis fascia (Sir A. Cooper). This band passes along parallel with Poupart's ligament and spreads out toward the anterior superior spinous process. On the inner side of the ring is another band of fibres similar to the one described. It is the internal limb of the internal ring (Hesselbach, Henlé), or the inner portion of the transversalis fascia (Sir A. Cooper). It proceeds from near the angle between the rectus and the pubis, and turns upward as it approaches the internal ring, forming its inner boundary. Some of these strong fibres can be traced as far as the fold of Douglas. On the deep surface of

Gimbernat's ligament this fascia blends with the iliac fascia and together, as they turn around its free border, give the ligament a round edge. It is best marked at its attachments:

1. To Poupart's ligament.
2. To the ilio-pectineal line (Gimbernat's ligament) beyond the conjoined tendon.
3. Where it descends to the femoral vessels.
4. Where it separates the transversalis muscle and the conjoined tendon from the peritoneum.

After it passes under Poupart's ligament it unites with the iliac fascia to form the femoral sheath, the transversalis forming the anterior, the iliac the posterior layer. Under Poupart's ligament the sheath is large, loose, and funnel-shaped. Well-defined connective-tissue septa separate the artery from the vein and the latter from the femoral canal. The internal inguinal ring is a funnel-shaped expansion of the transversalis fascia which the cord carries on it. This expansion may be weakened, but is not an opening except when made so artificially. When the peritoneum and subserous fat are removed, this ring appears as a crescentic edge, over which at its most dependent portion, close to the pubic bones, turns the cord. This ring is situated one and a half inches below the centre of Poupart's ligament. Its artificial measurements are approximately one inch by half an inch. After the descent of the testicle the internal ring is carried upward and outward from the external ring, the result of the growth of the bony pelvis. The outer and inner sides of the internal ring are well defined, as already described, and the spermatic cord, entering it at the most dependent part, near the pubic bone, passes down to the base of the bladder. An operation for the radical cure of hernia should restore the structures durably to their normal positions and physiological relations.³ In four of the cases of femoral hernia I report, the method used was high ligation of the sac and closure of the saphenous opening only by uniting by a purse-string suture the iliac and pubic portions of the fascia lata. In the other case the sac was tied off with silk and the ends, left long, were used to close the saphenous opening by uniting the iliac and pubic portions of the fascia lata. The cases were operated upon since 1893. The mortality was *nil*. All the wounds healed by primary union and there has fortunately not been a relapse. Two of the patients were children under twelve years of age.

The other principal methods which have been used for radical cure of femoral hernia are Hackenbach's,² "a modified form of osteoplastic operation originated by Trendelenburg;" Bassini's,³ "which consists in twisting and ligating the sac, and closure of the wound as follows: a suture applied close to the pubic spine through Poupart's ligament and the pectineal fascia, several sutures being inserted in a similar manner approaching the femoral vein. The fourth suture includes the falciform process and the pectineal fascia. No suture is tied till all are introduced, and the skin is closed separately;" Fabricius,⁴ which consists "in suturing Poupart's ligament to the horizontal ramus of the pubis and the spine, care being taken to include the periosteum. At the same time the external inguinal ring is sutured to prevent inguinal hernia."

A study of the surgical anatomy of femoral hernia shows that all these operations are open to serious objections. The neck of the sac of any hernia should not be twisted nor tied off. The ligature is liable to slip off; a piece of bowel or omentum may be included;

⁴ Centrabl. f. Chir., Bd. 6, 1894.

the tying or twisting causes puckering of the peritoneum, which favors the formation of adhesions and interferes with the free movement of the intestines over the surface. The neck of the sac should not be anchored in the canal nor at any other place, as this favors a relapse by keeping the ring and canal open; the neck, being fixed, forms a cone of the peritoneum into which intestine or omentum slips, and the cone by the pressure of a protrusion from within and behind acts as a wedge which will be apt to reopen the ring and canal. The suturing of the saphenous opening alone is incomplete. Relapse is favored, as the femoral ring and canal continue patent. The suturing of Poupart's ligament to the pectineal fascia is also incomplete, as the femoral ring and upper portion of the canal are left open. It is plain that the entire opening should be repaired, by first closing the breach at the femoral ring and then reinforcing this by as many barriers as possible. It is as important to close the femoral ring and canal as the internal inguinal ring and canal. No one could expect to cure many inguinal hernias by closing the external ring only, or the external ring and part of the canal. The same applies to femoral hernia. The falciform process should not be sutured to the pectineal fascia, as the latter does not bear any physiological relation to the former. It is dangerous, at times impossible, and altogether unnecessary for the needles and sutures to include the pectineus and the periosteum. The needles are liable to be broken in trying to include the periosteum; the contractions of the muscle cause irritation in and around the stitches, producing pain, etc. Better results can be obtained by simpler means. Any osteoplastic operation is not even to be considered, as it is dangerous and unnecessary. The hammering and chiselling increase the gravity of the operation and may do irreparable damage. The following operation I consider fulfils all the indications and overcomes the objections to the methods described:

1. The external incision begins about one-half an inch below the spine of the pubis and is carried upward and outward for about three inches parallel with Poupart's ligament. This exposes the sac and the saphenous opening. Poupart's ligament and the spine are well exposed by dissecting up the superficial fascia. The iliac and pubic portions of the fascia lata bordering the saphenous opening are each in turn lifted and freed sufficiently by blunt dissection from the structures beneath to expose clearly the canal and femoral ring.

2. Any adhesions of the sac to the surrounding structures should be separated high up within the femoral ring. The sac is opened, and if any adhesions exist internally these should be separated. If the content is omentum, it should be removed, ligating the vessels only. To insure the ligatures not slipping, the "fixation" ligature should be used. The vessel to be tied is defined by spreading out the omentum, and a needle carrying the catgut is passed round the artery by piercing the tissues of the omentum surrounding the vessel. The ligature is tied and the vessel severed beyond it. By this means the ligature is fixed in the omentum and cannot slip. After clearing out the sac, its neck should be dragged down with forceps. The sac, neck, and peritoneum as high as possible are to be removed and the cut edges united by catgut sutures (supracorrection of the peritoneum at the internal ring). The sutured edges when released slip back.

3. The adipose and glandular tissues, etc., are removed from the saphenous opening and femoral canal.

4. The femoral ring is exposed by retracting the iliac and pubic portions of the fascia lata, Poupart's ligament, and the deep crural arch. Any masses of fat, glands, etc., which bulge into the ring from the

subperitoneal connective tissue should also be removed. The femoral sheath is now lifted with the forceps. The excess is trimmed away and, the operator keeping the immediate work well in view, the internal opening is closed by bringing together the anterior and posterior layers of the femoral sheath at the femoral ring. The first stitch is inserted close to the outer side of Gimbernat's ligament and also includes some of its fibres. Several stitches are inserted as described, approaching the femoral vein. The last one is placed near the septa separating the ring from the vein, but must not be inserted close enough to constrict or in any other manner interfere with the full vein. The number of sutures required depends upon the size of the ring. When Gimbernat's ligament is not well developed, sutures may be required as far inward as the pubic spine.

5. The iliac and pubic portions of the fascia lata are retracted, and, commencing close to the pubic spine, Poupart's ligament and the deep crural arch are sutured to the contiguous portions of the fascia lata covering the pectineus and the reflection of this fascia passing behind the femoral sheath, each stitch extending to but not including any muscular fibres of the pectineus. Several sutures are passed in a similar manner approaching the femoral vein. The last must not be inserted near enough to constrict or in any other manner interfere with the full vein.

6. Next the saphenous opening is closed. The first stitch is inserted above close to Poupart's ligament, the needle being passed first through the pubic portion of the fascia lata on the inner side of the saphenous opening, then through the iliac portion of this fascia on the outer side. Suture from above downward, leaving only sufficient room at the lower angle for the full saphenous vein. The number of sutures required here depends upon the size of the opening.

7. The skin is closed with catgut or fine silk without drainage.

The most suitable material for a buried suture is chromicized tendon, as it is non-irritating and is not absorbed for two or three months. Busse¹ in his experiments showed that perfect tendinous union does not occur under ten weeks, or just about the period required for the absorption of chromicized tendon.² For the accurate approximation of the separate layers the continuous stitch described by Dr. C. Ford³ should be used. This is the individual stitch inserted continuously. In my last four hernia cases I have used it with every advantage. A detailed description of this stitch can be found in the *Pacific Medical Journal*, July, 1896, vol. xxxix., No. 7. As the stitch is new and very ingenious I shall briefly describe it. Pass the threaded needle through the divided structures and, without cutting, tie a reef knot. For the next stitch pass the needle, thrusting the point well through. Pick up the thread leading from the former knot and turn it toward the eye or heel of the needle and around under the point. Draw the needle on through and adjust the tension. This forms the first half of a reef knot. Complete it by passing the needle under the thread between the knots in the opposite direction from which it was inserted into the tissues, drawing the needle out in the loop formed. I use the first half only of the stitch to suture the femoral ring and saphenous opening, but to close the canal I use it complete. This stitch may also be used for applying the fixation ligatures in tying vessels in the omentum. After tying the first fixation ligature in the usual way, do not cut the

¹ Busse: *Deutsche Zeitschr. für Chir.*, 1891-92, xxx.

² The chromicized kangaroo tendons I have been using for the past four years with such good results were sterilized by Messrs. Van Horn and Ellison, Park Avenue, New York.

³ C. Ford: "The Interrupted Stitch by a Continuous Method."

threads, but to save time tie each of the other vessels continuously, and when all are ligated make the ligatures interrupted by cutting away the excess of thread between the knots.

Dressing.—Sublimate gauze held firmly in place by strips of adhesive plaster; then a layer of cotton and firm spica bandages.

After-Treatment.—Dress the wound on the seventh day, or earlier if there are indications for interference. In removing the adhesive strips pull the ends toward the wound, to avoid tearing the freshly united edges asunder. Apply gauze, strips, cotton, and bandages as before. Keep the patient in bed two weeks, or longer if possible. If primary union is not obtained, do not allow the patient out of bed until cicatrization is complete. The firm bandages are not removed till one month after the operation; then the patient is allowed to go without any dressing, pad, or truss.

The removal of the sac and, as high as possible, the peritoneum continuous with its neck, the separation of adhesions internally and externally high up within the femoral ring, and the suturing of the cut edges with fine catgut cause total obliteration of the sac, change the outer surface from a convex to a slightly concave one, carrying the sutured edges high up within the abdomen away from the femoral ring, leaving a smooth surface to the peritoneum, and allowing free movement of the intestine over the surface. It is better to overcorrect, as the peritoneum is sure to relapse a little. Clearing out the rings and canal of fat, glands, etc., removes the material which would interfere with cure by keeping the rings and canal open. The closure of the femoral ring is a very important step of the operation, as it is at this ring that the breach first occurs. This layer of sutures forms a firm wall and the other layers closing the canal and saphenous opening form additional barriers against a relapse. It will be noted in closing the different layers that the femoral ring is closed by a transverse line of sutures, the canal by an oblique line, the saphenous opening by a nearly vertical line, and the skin by an oblique line which follows the natural crease of the groin. I unite each of the layers separately, as it is by this means alone that accurate approximation is obtained and strong and lasting union results. The chief reason for failures in operations for inguinal as well as this kind of hernia has been due to surgeons in not repairing and restoring the structures durably to their normal physiological relations and uses, but by illogical and unscientific introduction of extraneous substances, the disarrangement or displacement of structures, to improve on nature.

The operation I have described in detail has every advantage. It is simple, easy to follow, and may be quickly performed. It has all the advantages of the other methods, with none of their disadvantages, and, having additional advantages which I have summed up in my paper, should be followed by the best results.

326 KEARNY STREET.

Permanent Artificial Perforation of the Drum-head. Dr. Miot (*Rev. Hebdomadaire de Laryngol. et d'Otol.*, June 28, 1896) concludes, from his observation of certain cases of dry otitis media, that the best means of completing the diagnosis is to make an incision in the posterior half of the drumhead, along the bony case, which improves the hearing and should be large enough to see the incudo-stapedial articulation. To obtain permanent opening it is necessary to remove the drumhead and the long process of the malleus, and place a plug of cotton for a few days *in situ*. The hearing after this operation is very variable, being sometimes better and sometimes much worse.

THE USE OF CONGEALED OILS TO PREVENT THE REUNION OF NERVES AFTER THEIR SUBCUTANEOUS DIVISION; A CONTRIBUTION TO THE RADICAL TREATMENT OF CERTAIN FORMS OF NEURALGIA.

By J. LEONARD CORNING, A.M., M.D.,

NEW YORK.

WHEN, in dealing with inflammation of a sensory nerve, the resources of local and general therapy seem at length exhausted; when the changes have been rung on blister, cautery, and injection; when the coal-tar derivatives have left us in the lurch; and when, finally, etiology, so far as one is able to apprehend it, has been scrupulously regarded, yet to no purpose, one is certainly excusable for looking about in search of some radical expedient to gain exit from what, to say the least, is an intolerable dilemma.

To one thus situated—certainly to most neurologists—two operations are liable to suggest themselves, to wit, neurotomy and neurectomy.

The first of these consists, as every one knows, in simple division of the nerve; the second—by common consent a more promising procedure—in removal of a small segment from a suitable portion of its continuity.

Simple division of the nerve, neurotomy, cannot, as heretofore practised, boast of much success; for, to say the truth, the nerve is exceedingly prone to reunite, so that in no long time a return of pain is practically inevitable.

This re-establishment of conduction is, moreover, very rapidly achieved, so rapidly in fact as to tax one's physiological credulity to the utmost. Thus Glück, who has put the whole question to the touch of proof, found that in fowls restoration of conduction after simple section took place in two instances in twenty-four hours, when the ends were coaptated. Usually, however, after division of the sciatic and suturing of the cut surfaces, paralysis of the muscles supplied by the nerve persisted for fifty hours. Thereafter a gradual resumption of motion was observed in the affected muscles, so that recovery was practically complete by the fourth day.

In man, however, the process of restoration is evidently slower, for Paget found after division of the median nerve that sensation began to appear within two weeks, while complete recovery did not ensue till two weeks later. Nor is it to be forgotten that reunion may take place in the absence of suturing when the nerve is of small calibre and the cut ends are approximated by the pressure, or, as Rouvier puts it, "support" of the surrounding tissues.

The histological details of this self-restoration of the nerve are the source of considerable disagreement among pathologists. Some, like Waller and Vaulair, maintain that the reparative process proceeds from the central end of the divided nerve; while others, notably Eichhorst and Mayer, are convinced that the reorganization takes place from the nerve fibres below as well as above the incision. The former of these theories seems to me the more probable, though my own observations do not as yet permit me to speak with any degree of positiveness; nor is the question especially relevant to the purposes of the present paper. There is, however, a further element in the process that to me is significant; I mean the dictum of Rouvier regarding the "supporting" part played by the surrounding tissues in nerve repair.

But, to return to the original proposition, it is not to be forgotten that, while the inefficacy of simple section as a means of permanently arresting conduction is thus demonstrated, most neurologists are agreed that resection—the removal of a segment of the nerve—

offers, if not the promise of absolute success, at least decidedly greater likelihood of it. On the other hand resection, though not as a rule a formidable procedure, except when (as in the case of the fifth nerve) it is necessary to penetrate bony coverings to arrive at the branch to be operated upon, is still an elaborate undertaking as compared with simple section. Thus, to be specific, while several of the more superficially located nerves—notably the great and small occipital, the supra-orbital and the auricularis magnus—may be divided with a minimum of traumatism, to resect them involves more or less extensive incision—in short, operative inroads that are not lightly regarded by most patients. The affair looms still greater in the eyes of the timid when it is a question of operating upon two or three branches.

Realizing these things from daily contact with nervous patients, and especially with those who are subject not only to pain but to nervous irritability of a high degree as well, the thought came to me that it would be a marked advantage gained if by the introduction of some new factor, not too complicated, we could retard, ay, absolutely prevent, the reunion of the nerve after its simple subcutaneous division.

Without pausing to indicate the further evolution of the idea in my own mind—a matter rather of personal than general interest—I will state at once that the project resolved itself ultimately into a determination, 1, to devitalize the nerve as much as possible at the point of section, and 2, to interpose a substantial barrier between the cut ends, thereby checking the prolongation of the axis cylinders and preventing the rehabilitation of conduction.

To carry the above-mentioned principles into practical effect I decided to invoke the assistance of an oil, which after section of the nerve trunk, I could deposit in the wound, and then, by the application of cold, congeal, so that it (the oil) should form an impassable barrier between the cut ends. And in order that the solidified oil should not be liquefied (melted) and carried away by the blood stream, I decided that its melting-point could not be less than from three to five degrees above the normal blood temperature. A non-irritant oil was accordingly prepared by melting the oil of theobroma over the water bath and adding sufficient paraffin to bring the melting-point to about 105° F. The mode of application is as follows: An ordinary hypodermic syringe, armed with a somewhat coarser needle than that in common use, is filled with the melted oil, and immediately thereafter the needle is thrust into the tissues in such a manner that its point is brought as near as possible to the locality in the nerve where section is to be made. The syringe is then gradually emptied, care being taken, by moving the needle to and fro, to deposit the oil at right angles to the nerve stem. The oleaginous zone so formed should completely envelop the nerve and extend along the longitudinal axis of the same for at least an inch and transversely for an inch and a half. Immediately after the completion of the injection, which may be repeated if necessary, cold in the form of a rhigolene spray or ice is applied above the injected zone. As a consequence of this manoeuvre the oil is immediately congealed.

To carry out the second stage of the operation, the syringe is filled once more with the melted oil; but now a cannulated knife¹ (Fig. 1) two and one-half inches in length is substituted for the hypodermic needle. Its cutting surface, however, is but three-quarters of an inch in length by one-eighth in breadth; and the canal, thanks to skilful workmanship, de-

bouches at the point without impairing in the least the sharpness of the latter (A, Fig. 1). I am indebted to Mr. Ford, the instrument maker, for the careful manufacture of this pretty bit of mechanism.

Grasping the barrel of the syringe, which serves in lieu of a handle, the operator thrusts the point of the knife through the skin; and, carrying the blade beneath the integument and across the nerve, divides the latter by a simple downward cut. Then, with the aid of alternating lateral pressure to right and left, with the flat of the blade, the cut ends are pressed apart; and, thanks to the cohesiveness of the hardened oil, are prevented from again approximating. From this it is evident that a hiatus, a veritable chasm one-eighth of an inch or more in breadth, is found between the cut surfaces of the nerve: for, as just hinted, it is not to be forgotten that the wax-like consistency of the congealed oil causes it to remain in place, a thing impossible in the case of the normal tissues, whose natural resiliency would cause them to spring back immediately.

And now, as the knife is slowly withdrawn, the injection of the oil is begun; and, as it flows from the orifice at the point of the knife, the subcutaneous chasm is completely filled. Again, the knife having been extracted, cold is applied; and, sooner than it takes to tell it, the oil congeals, forming a solid wall between the cut extremities of the nerve, whereby the subsequent reunion of the latter is rendered impossible. Nor are there later any noteworthy signs of inflammation, the oil maintaining its rigid state, yet without apparent detriment to the surrounding structures.

Fig. 2 is a diagram showing the topographical relations as seen in horizontal section: *b*, *b'*, nerve; *c*, *c'*, hardened oil, in which the nerve is first embedded; *d*, hiatus between cut ends made by lateral pressure with the flat of cannulated knife and filled with plug of hardened oil.

As already mentioned at the beginning of this paper, occipital, or, more strictly speaking, cervico-occipital neuralgia lends itself with especial appropriateness to this form of treatment. Wending upward between the muscles of the neck, the nerves involved—the great and small occipital and the auricularis magnus—

FIG. 1.

FIG. 2.

spread out upon the posterior and lateral surfaces of the head, where, owing to their exposed situation, they are especially liable to injury from changes of temperature. This is well shown in Fig. 3, where *a* is the great occipital, *b* the small occipital, and *c* the auricularis magnus. Topographically noteworthy is the fact that the occipitalis minor runs upward along

¹ This is a modification of a device identical in principle but designed for a different purpose, described by the author more than two years ago. *Vide* the author's brochure on "Local Anæsthesia," D. Appleton & Co., New York, 1896.

the posterior border of the sterno-cleido-mastoid muscle, while the auricularis magnus pursues a diagonal course across the latter to supply the external ear and the integument immediately behind.

All these nerves may be the seat of neuritis, but in my experience tenderness is more often present in but one of them, although, as shown by the wide distribution of the pain, the others may be involved by sympathy. Nor is this astonishing when their relative community of origin is borne in mind. It follows from this that great care should be exercised to determine with precision which nerve is primarily affected; for neglect in this respect may lead to the cutting of the branch which is only secondarily affected; while that which is primarily involved, which is the seat of the neuritis, escapes, with the result that relief, even of a temporary kind, is not forthcoming. As a rule, tender points—sometimes one, two, or even three—are discoverable along the course of the affected nerve, more especially where it wends across the cranial bones; the cervical portion, on the contrary, being the more protected, exhibits relatively few signs of vehement inflammation.

The course of occipital neuralgia is sometimes comparatively brief; more often, however, it is severe and tedious to a degree. Especially about the fall of

FIG. 3.

night, when the sufferer, deluded by a period of immunity, drifts into brief oblivion, are the pains prone to make their appearance. Sometimes they are intermittent, fulgurating, severe; at other times less vehement, especially at their inception, when, with the uncanny stealth of an ignis fatuus, they flit across the field of consciousness, vague forerunners of the greater evil to come.

It is true that occipital neuralgia is commonly regarded, and rightly so regarded, as a less severe affection than faceache, yet occasionally it rises to a dolorous pre-eminence, comparable only with tic douloureux. Nor, to say truth, do the secondary phenomena of one of these severe cases lag much behind those of facial neuralgia; for, indeed, the irritability, melancholy, insomnia, loss of appetite, and weight are sometimes such as to excite the gravest apprehensions. Precisely here is to be found the warrant for energetic interference, the kind of interference previously recommended, where internal remedies and ordinary local measures have failed to afford permanent relief. So much for the exposition.

Turning now to inductions for final confirmation of the argument, I am glad to be able to add the synopses of two typical cases of occipital neuralgia treated in the manner herein advocated.

Miss C. D.—, spinster, of middle age, anemic and feeble, went for a drive during the cold weather immediately following the period of unusually hot weather that characterized the closing days of August. Her sister and a friend occupied the rear seat, and hence she was compelled to sit *en face*, her back toward the horses, the wind playing upon her neck and head—as she expressed it—in a continuous stream. On her return from the drive, which was long and fatiguing, she was aware of a sensation of chilliness and slight pain in the back of the head, at first dull and constant, later sharp, fulgurating, intermittent. That night she slept but little, the pains increasing in vehemence to such a degree that her physician was summoned in the morning. During the two weeks following she suffered greatly; indeed, in the absence of opiates, copiously administered both by day and by night, she could neither eat nor sleep, and being of a highly nervous temperament she was very difficult to manage. Electricity, counter-irritation, and internal medication were alike barren of permanent result. This, in a word, was her condition when I was summoned in consultation. On palpation the region over the great occipital was discovered to be very hyperæsthetic, and two points of exquisite tenderness were found in the course of the nerve. No such characteristic evidence of inflammation could, however, be found in the regions supplied by the small occipital and the auricularis magnus, though, to be sure, the distribution of the pain pointed clearly enough to the secondary “sympathetic” involvement of the nerves.

In view of the failure of conventional measures, and the patient's condition, that was now become truly deplorable from loss of appetite, sleeplessness, and depression, I decided to sever the great occipital. I was the more ready to do this, as she had parted with all faith in what was undertaken in her behalf, even to the extent of frequently declining the remedies that were prescribed for her.

Immediately after obtaining her acquiescence in this decision, I injected two drachms of the melted oil at the most centrally located point of tenderness. A spray of rhigolene was then thrown upon the integument above the injected zone, with the result that the oil congealed forthwith, forming a hard wound, of which the longitudinal axis, about an inch and a half in length, extended directly across the nerve, in such a manner as to incarcerate the latter in the waxy mass (Fig. 3, 1).

Again the syringe was filled with the melted oil, the cannulated knife substituted for the hollow needle, and the latter, after introduction beneath the skin, was made to traverse the waxy mass, and, in so doing, divide the nerve stem. The cut ends were then separated by lateral pressure with the flat of the blade, substantially as indicated in the general description. By this manoeuvre, as already noted, a subcutaneous tunnel-like excavation is produced in the oil-impregnated tissues, and, thanks to the cohesiveness of the hardened mass, the ends of the nerve at the point of division are held apart. The injection of the oil through the cannulated knife was now undertaken while the latter was slowly withdrawn, and immediately thereafter the rhigolene spray, projected once more upon the integument, caused the oil to congeal in the tunnel, whereby an impregnable barrier was formed between the cut ends of the nerve stem. And here let me observe parenthetically that, should the oil congeal prematurely in the canal of the knife blade or in the syringe, it can be reduced at once to a fluid state by dipping the implement in hot water.

To tell in few words the result in this case, I may state that, with the exception of slight, transient local soreness at the point of section, the relief experienced was instantaneous. Nor is there now—several weeks

after the operation—any likelihood, so far as one may predict, of a relapse; the ridge of fat still remains in place; sensibility is still obtuse below the point of incision; the patient still continues to improve in general health. Indeed, the progress made in the last-named regard has been truly amazing; for the insomnia, irritability, and melancholy have quite disappeared; and, thanks to simple tonic measures, her appetite and assimilative powers have so far reasserted themselves that she has not only recovered what she lost in weight but added several pounds thereto as well.

This intensification of vital activity after the individual has been relieved of the depression of the higher cerebral functions, which, to a greater or less degree, always accompanies severe physical or mental pain, is capable of being interpreted as an additional proof in favor of Schopenhauer's famous dictum which affirms the positive nature of pain and the purely negative quality of pleasure.

With an apology for this bit of metaphysical soliloquy between the lines, I return to the argument, and more especially that part of it which finds a further elucidation in my second case.

On a certain evening, about three months since, Mr. N—, aged sixty, fell asleep as he lay stretched upon the lounge in his bedroom. A friend of fresh air, he had opened all the windows; and so it befell that for several hours he was exposed to a strong draught. Awakening shortly after midnight, he was aware of a sensation of stiffness in the back of the neck, a feeling that became positive pain when rotation of the head was attempted. Deeming the matter of little consequence, he closed the windows, got to bed, and in no long time fell once more into a restless sleep. At dawn, however, he was suddenly awakened by an access of pain, severe, shooting, intermittent, involving the back and side of the head on the right, and extending thence to the muscles of the neck. As the day wore on the pain increased in vehemence; the muscles of the neck became more rigid, the periods of exemption grew hourly shorter. He was induced to invoke the services of a physician, but, despite the good offices of the latter, he obtained little relief. Blisters, anodynes, hot applications, local injections—all were tried, but to so little purpose that, except when, *faute de mieux*, he was given considerable doses of morphine, he suffered with scarcely an intermission.

Irritability and depression had mastered him now so wholly that he could neither eat nor sleep, and to these were added the usual sequences—derangement of nutrition, defective metabolism, and loss of weight. He began to run from one practitioner to another, and at length in the course of his peregrinations drifted to the consulting-room of a prominent practitioner of this city, who in turn referred him to me.

On examination the occipital and right parietal regions were discovered to be the seat of hyperæsthesia, the sensitiveness being especially exquisite throughout the region supplied by the small occipital. Two points of tenderness were found in the course of this nerve, and one in the auricularis magnus near the cranial attachment of the sterno-cleido-mastoid muscle. No such sensitiveness could, however, be made out above the great occipital. Moreover, the cervical portions of the two nerves first mentioned were devoid of painful points, the neuritis confining itself largely to the ramifications about the head. This predilection of the inflammation for the exposed portions of the nerves is quite characteristic of the type of neuralgia under consideration, and the fact itself has a favorable bearing upon the plan of treatment here advocated. Indeed, to say the truth, it is easier to divide the nerves subcutaneously as they spread out upon the cranial bones than lower down, where they spiral up between the cervical muscles.

Finding this patient set in his determination to submit no longer to medication of any kind, and encouraged not a little by the success obtained in the previous case, I proceeded to divide both the small occipital and auricularis magnus, choosing as before the most centrally located painful point. The point of section of the occipitalis minor is shown at 2, Fig. 3, that of the auricularis magnus at 3 of the same diagram. As to the manipulations, they were precisely the same as in the first case, viz.: (1) Injection of the melted oil about the nerve, at the point of section, and subsequent congelation of the same by the application of cold. 2. Passage of the cannulated knife into the mass of congealed fat, immediate division of the nerve, and separation of the cut ends by lateral pressure with the flat of the blade. 3. Expulsion of melted oil through the canal of the knife, during withdrawal of the latter, and prompt congelation of the oil by the application of cold, whereby the canal is filled and a substantial barrier formed between the cut ends.

I may add that the hemorrhage caused by burrowing thus into the tissues—and more especially by the lateral movements of the knife—ceases coincidentally with the solidification of the oil in the canal.

The result in this case was as happy as that obtained in the first, viz.: immediate cessation of pain about the head, and indeed of all pain, if we except slight soreness and stiffness in the neck—a condition that disappeared completely within the next two or three days. Nor is there now, several weeks after the operation, the slightest token of a relapse. With this emancipation from pain could be observed the passing of the irritability and melancholia, and the speedy restoration of the power of attention and the zest of living. He began to sleep as never before, remaining unconscious for fifteen hours at a time—a remarkable performance for a man of sixty. His appetite returned and he ate ravenously of all kinds of food. Soon his weight began to increase, the lines of his face to relax, and in no long time he was completely restored.

These cases are their own best commentary, and I shall therefore spare the patience of the reader by refraining from further disquisition.

In conclusion, however, let me recall the fact—for it may well happen that what I have here invoked for neurological purposes may receive a further application at other hands in other fields—that I have employed this same principle of treatment before, notably for the fixation of remedies (analgesics) in painful areas, and for the purpose of inhibiting the exaggerated action of the muscles in torticollis and other forms of local spasm.¹

53 WEST THIRTY-EIGHTH STREET.

After-Pains.—Dr. Winterburn (*Journal of Obstetrics*) says that in many cases a nice warm meal is better than any medicine; but, when pains are exhaustingly severe, he uses amyl nitrite. This potent drug is a very efficient controller of after-pains, and, used with caution, it need not result harmfully. A neat way of using it is to saturate a small piece of tissue paper with five or six drops, stuff this into a two-drachm vial, and request the patient to draw the cork and inhale the odor when she feels the pain coming on. It acts with magical celerity.

HEREDITARY SYPHILIS AND GENERAL PARESIS OF THE INSANE.

By EDWARD H. WILLIAMS, M.D.,

ASSISTANT PHYSICIAN, MATTEAWAN STATE HOSPITAL, FISHKILL LANDING, N. Y.

IN cases of general paralysis of the insane, the history of direct syphilitic infection, together with a life of general dissipation and excitement, is so often found that the disease has become very generally credited to, or at least associated with, primary syphilitic infection. The temperament of the majority of "paretics," the past history, and the general train of delusions are so characteristic that in a large percentage of cases the description of one will answer almost equally well for any other. For, as is well known, general paralysis presents more uniformity in symptoms than perhaps any other form of mental disease.

The cases in which there is positive proof of primary syphilitic infection (practically seventy-five per cent. of all cases) form such a majority that the small number of cases in which the history of such infection is lacking is generally ignored. The typical "man of the world"—ambitious, fond of society and high living, a light sleeper and a deep drinker—forms so characteristic a picture of the forerunner of the deplorable "paretic," with his delusions of grandeur, that we usually overlook a minor number of cases that present at first few typical symptoms and whose past history may be different in many respects from that of the majority of cases. If such cases are examined, it will be found that many of them, while having no history or proof of direct syphilitic infection, do bear unmistakable marks of hereditary syphilis—usually shown by the presence of Hutchinson's teeth. These cases are often obscure, even to the alienist, in the beginning, and the diagnosis is not facilitated by the lack of a characteristic syphilitic history.

As a marked contrast to the highly-organized, brilliant-minded, general paralytic, we often see in this man a dull and sluggish-minded being, who may have been more or less dissipated, but who has never attempted what might be called mental work of any kind, and who is in no sense of the "paretic temperament."

Yet this man is sometimes the victim of general paresis. I say "victim," because his more brilliant prototype is generally counted not so much a victim of the disease as an inviting host to it.

I have selected four cases from among quite a large number showing the syphilitic teeth and giving the

FIG. 1.

histories which do not coincide, in some respects at least, with those of a typical case.

In Fig. 1 are shown the teeth of J. T—, who was thirty-nine years of age when committed to an asylum. He was a harness maker by trade, was married, and had always lived a quiet, industrious life. He had been an habitual but rather a moderate beer drinker, and had been intoxicated several times, but

was not a drunkard in the ordinary sense of the term. After a family reunion and feast, at which he indulged freely both in eating and in drinking, he had an attack of "acute mania." This lasted for about three weeks, during which time he was emotional but happy, expressing no characteristic ideas of grandeur, only occasionally remarking that "he was a very fine man" and that "he felt splendid." There were no muscular

FIG. 2.

tremors of the tongue or lips, or ataxia of the throat muscles, and the diagnosis of general paresis was not made at the time. He remained in an apparently semi-demented condition, however, and was confined in an asylum. After nineteen months with practically no change, he had an epileptiform convulsion, which left him with marked paresis of the left side, irregular pupils, lip tremor, and well-developed ataxia of throat muscles. From this condition he did not fully recover, and gradually developed into the happy, talkative, ataxic-spoken "paretic," with unmistakable symptoms. These symptoms progressed rapidly, and he died eleven months after the first epileptiform seizure. At no time did he exhibit many delusions of grandeur—in fact, they were conspicuously absent. As was stated before, he had no history nor evidence of primary syphilitic infection; but, as is shown in the cut, his teeth had the telltale marks of hereditary syphilis.

Fig. 2 shows the teeth of J. B—, a grocery clerk, who was admitted to the asylum at the age of twenty-seven. He had always been quiet and industrious, was not given to venereal excesses, and had never had syphilis. He had been a steady drinker all his life, but was not given to excessive drinking. Insanity was first suspected when he began claiming other people's property as his own. The diagnosis of general paresis was not made until after he had been confined in the asylum for eighteen months. After that time he developed lip and tongue tremors, and gradually developed into a well-marked case of the disease. From the cut it will be seen that he had well-marked Hutchinson's teeth.

In Fig. 3 are shown the marked teeth of hereditary syphilis. This man, a stone-cutter by trade, was thirty years old on admission to the asylum, had no history of venereal excesses nor of primary syphilitic infection, but had been a hard drinker and given to frequent drunken debauches. Lip and tongue tremors were present almost from the beginning, and he developed delusions of grandeur early, and became a typical case after the first year of his confinement.

In Fig. 4 the right incisor shown is an artificial tooth; the left, however, shows the characteristic notch of hereditary syphilis. This man was a blacksmith by trade, was rather a "thick-headed" and in-

different workman, and a periodical drinker. There was nothing peculiar in the nature of his attack of paresis, but he had absolutely no history or evidences of ever having had primary syphilis, and the temperament of the man was quite opposite to that of the majority of general-paresis patients.

I have found that in about seventy per cent. of cases of general paresis, in which no history or evidences of

FIG. 3.

primary syphilitic infection could be found, there were evidences of hereditary syphilis in the teeth. In fully sixty per cent. of these cases there was no history of excessive dissipation, although almost to a man they had been addicted to the use of alcohol, and sometimes to an excessive degree. In ninety per cent. of these cases they were men of anything but the "parietic type"—men of rather sluggish mentality, with corresponding habits.

Since it is so definitely established that at least seventy-five per cent. of all cases of general paresis have had primary syphilitic infection, and as so large a percentage of those not showing primary syphilitic infection have marks of hereditary syphilis; and, furthermore, since almost all of both classes have been confirmed alcoholics, it is certainly interesting to notice the pathological conditions which closely resemble each other in primary syphilis, hereditary syphilis, chronic alcoholism, and general paresis. We know that both in primary and hereditary syphilis a thickening of the cerebral meninges, not unlike the condition found in general paresis, is a common thing; while a thickened condition of these membranes is also common to chronic alcoholism.

As yet we are unable to tell the exact relation which

FIG. 4.

the thickened membranes have to the mental condition in any of these diseases, but that they do have a definite relation cannot be doubted. It is possible that hereditary syphilis, which is sometimes manifested in the thickened membranes, not unlike those found in general paresis, may, through their agency, act as a

predisposing cause to this disease. If we assume this hypothesis to be true, it would be reasonable to suppose that a man with syphilitic meninges might develop general paresis without the great amount of dissipation and primary syphilitic infection of the ordinary general paretic patient. With such a man, it would be natural to infer that a less amount of alcohol might tend to produce changes in the cerebral meninges, since alcoholism tends to produce a somewhat similar change even in primarily healthy membranes.

Of course, any theories concerning the relative condition of the cerebral meninges in general paresis, hereditary syphilis, and chronic alcoholism are purely tentative; and whether or not the thickened membranes, caused either by primary or by inherited syphilis, could cause or assist in causing general paresis, aided, perhaps, by the effects of alcohol, is mere speculation. If, as many alienists think, alcohol produces insanity only in those who have some pre-existing neurosis, it may be that that neurosis is sometimes of syphilitic origin. Since syphilis is so closely associated with general paresis, one disease might thus be a manifestation of the other, or a factor in producing it.

Of course, until we establish the exact relation of syphilis to general paresis, we can do no more than draw relative inferences from existing conditions; but I believe that closer observation of the teeth in doubtful cases will assist in making a diagnosis in many cases of general paresis whose history and symptoms might be otherwise misleading.

ORRHOTHERAPY AT NURSERY AND CHILD'S HOSPITAL, 1895-96.¹

BY ALLEN M. THOMAS, M.D.,

ATTENDING PHYSICIAN, NURSERY AND CHILD'S HOSPITAL, NEW YORK.

DURING the past year the orrhoterapy of diphtheria has excited much additional interest among us on account of the brilliant results recorded, covering a large field both in private and hospital applications of it, and because of the more or less unique discussions which have gone on at the academy meetings. A little over a year ago a report was made to the society of the results of the immunizing effect of diphtheria antitoxin under the direct auspices of the late brilliant house physician, Dr. Mapes, of the Nursery and Child's Hospital. It may be of passing interest, at this time, to relate a little incident of that report. Shortly after publication it happened to the author of the paper to meet a physician of prominence in the case of a child of another physician of this city. The case being considered sufficiently indicative of diphtheria to warrant immediate treatment for that disease, without waiting for a culture test, the question arose at once as to the nature of the treatment to be installed.

In the course of ensuing discussion, upon referring to the report and asking what was thought of the result of immunization obtained at the hospital, the reply was: "It could only be considered a coincidence." This circumstance is narrated, not in a spirit of personal antagonism, but solely in the interest of the subject and to emphasize the ridiculous assumption of such opposition should it continue its adhesion to similar untenable statements in the face of the stultifying facts which the records of a successful orrhoterapy are constantly accumulating. In other words, the value of diphtheria antitoxin, in the record of results achieved and published, was never more conclusively in its favor than now, and no factor of that value more successful in its practical application than its use as an immunizing agent. What-

¹ Read before the New York Clinical Society, October 23, 1896.

ever future trials may determine, our judgment of it must continue to be weighed in this balance of results obtained, and will be rightly formed for that future, as it has been for the present, solely upon such evidence.

An honest purpose does not permit of continued miscalculations of "the returns," but rather guarantees us unprejudiced observations and ultimately true and easily reconcilable conclusions. Setting aside all personal issues and applying this principle to our practice, we may fairly assume that future work in the premises will bring to us still more wonderful and satisfactory results, sufficiently convincing in their simplicity to make all of one mind at the final settlement.

The object in addressing you to-night upon this topic is especially to present, in continuation of the report read last year, the results of our further work in this line at the Hospital from April, 1895, to July, 1896. Following upon the cessation of our epidemic of diphtheria, which was so successfully controlled by the immunization of the entire hospital in April, 1896, no case of diphtheria occurred in the institution for a period of six months thereafter, *i. e.*, until October 26, 1895. On account of the fatal illness of Dr. Mapes, the work has been chiefly carried on, since the time of the last report, by Dr. Neumann of the house staff, who, under my direction, has kindly collated the results of our subsequent work in the following report. Culture tests showed the case of October 26th, above spoken of, to be one of true diphtheria by the presence of the Klebs-Loeffler bacillus. The child was immediately isolated and antitoxin administered. All the other children in the ward, twenty-three in number, were given immunizing doses of serum, the amount varying from fifty to two hundred units, according to age. Although directly exposed for a number of hours, not one of these twenty-three children contracted diphtheria. A certain number (unfortunately not recorded) had nasal discharges prior to the development of the initial clinical case. Cultures taken from those having such discharge showed the presence of diphtheria bacillus in nine. These cases were all kept isolated until the bacilli were no longer demonstrable in subsequent cultures.

During and since the epidemic of diphtheria last year, a peculiar feature among the children, in regard to nasal discharges, has been that many of these patients, apparently well in other respects and with no visible or constitutional disturbance, would evidence upon culture test (for more or less prolonged periods) the Klebs-Loeffler bacillus in the discharge, and seemed, in some instances at least, to be the cause of outbreaks of decided cases of diphtheria in the same wards before showing any clinical signs of it themselves. The lesson it taught us was to beware of a running nose, each case of which is now considered worthy of special investigation. Cultures were then invariably taken from nasal discharges as well as from all suspicious sore throats, and if the Klebs-Loeffler bacilli were present children were isolated and subjected to treatment as a means of prophylaxis, and, as before, all the remaining children in the respective wards were given immunizing doses. Up to August, 1896, three hundred and twenty-six children have received antitoxin. Of this number fifty-nine were twice, and nine three times subjected to treatment, the youngest child to receive treatment being two weeks old.

The ages of the children were as follows: Under three months of age, 58; from three to six months of age, 45; from six to twelve months of age, 69; from one to two years of age, 75; from two to four years of age, 79; total, 326.

In all, there were eighty cases having the above

mentioned muco-purulent or bloody discharge from the nose, in which the diphtheria bacilli were found upon repeated examinations and confirmed by the bacteriologists of the health board. These children manifested no local or constitutional symptoms of diphtheria, yet, in many instances, the characteristic bacilli could be demonstrated in cultures three and four weeks after the most persistent and energetic local treatment. In one case, the bacilli were found in the nasal secretion and also in the discharge from a chronic otitis media and persisted for four weeks.

Of these eighty special cases immunized, none developed a clinical diphtheria or other untoward effect, though the majority at the outset were in poor physical condition, as the following shows: Chronic otitis media, 10; molluscum contagiosum, 3; marasmus, 5; syphilis, 1; suppurating tuberculous glands of neck, 1; chronic catarrhal gastro-enteritis, 1; pleurisy with effusion, 1; hypertrophied tonsils and adenoids, 3; catarrhal enteritis, 1; bronchitis, 2; rickets, 2; convalescent from broncho-pneumonia, 1; dentition and diarrhoea, 1; chronic eczema of scalp and face, 1; broncho-pneumonia, 2; enteritis, 1; pertussis, 6.

These continued good results from our use of antitoxin as an immunizing agent are surely most satisfactory, and in full accord with last year's work and that simultaneously done elsewhere. No serious ill effects from its use have been obtained in any of the three hundred and twenty-six cases. On the other hand, its positive value as a prophylactic agent is very pointedly evidenced from last year by the sudden cessation of our epidemic immediately after immunization was practised, and in this year by our escape from the usual and, for the past many years, more or less severe and fatal epidemic of diphtheria in various wards of the hospital.

Urticaria and erythema, circumscribed and diffuse, were observed in less than five per cent. of the cases. In one case (that of an adult) oedema, with redness and tenderness, followed a deep injection in the arm. In another case (that of a child) oedema extending from the hip to the toes was observed three days after a deep injection into the buttock. A moderate elevation of temperature followed the injection in some cases, and a slight diarrhoea was of frequent occurrence.

Of the persistent nasal-discharge cases, four showed cultures of Klebs-Loeffler bacilli for a period of at least two months after immunization and local treatment. Dr. Park, of the board of health, reported upon special examination that these bacilli showed no virulence when injected into guinea-pigs. Smears were also taken from the intestine of one child who died of entero-colitis and who had previously shown Klebs-Loeffler bacilli in the nasal discharge. Dr. Park reported upon the case that he found bacilli which looked like the diphtheria bacilli, but could not get them in pure culture and so had no means of demonstrating whether they were virulent or not.

This single investigation of Dr. Park, upon the four cases spoken of above, would, if supplemented later on by others in similar condition, with the same result, simply confirm the logical conclusions of our clinical observations and experience in the premises. As, however, our work in this direction is necessarily incomplete, no definite conclusion can at present be drawn from this class of cases. The very interesting question of the period of protection warranted in a given case of immunization is still unsettled, and our experience of the year adds little of value in this particular beyond the knowledge already obtained. As a rule, it was from four to six weeks or longer, though the following irregular cases are of interest in regard to this matter of time limit:

CASE I.—Child received two hundred units on January 12th, 1896; on January 24th, patient developed measles, which was followed in four days by diphtheria, the membrane involving the uvula, soft palate, and roof of mouth, spreading to the tongue and out on the corners of mouth. In this case the child developed the disease sixteen days after receiving an immunizing dose of two hundred units.

CASE II.—June 3, 1896, twenty-two children were admitted to the reception house, and, as is the custom, all received two hundred units of antitoxin as a means of prophylaxis. On June 27th, twenty-four days after immunization, one of the number, a rachitic child fourteen months of age, developed a severe diphtheria ophthalmia and died on July 2d.

CASE III.—Two children were found with Klebs-Loeffler bacilli in nasal discharge fifteen days after injection of two hundred units. (The condition of nasal discharge was not known in these cases at time of injection and its virulence at time of observation was not tested.)

CASE IV.—June 1, 1896, child received two hundred units, and on June 3d developed a severe diphtheria ophthalmia. (In this instance only two days elapsed between the time of injection and the development of the disease, and here too the condition of the conjunctival mucous membrane was not known at the time of injection. The observations in Cases III. and IV. are consequently of doubtful value.)

In several instances in which a mother with true diphtheria refused to be separated from her suckling infant or young child, she was permitted to keep her child with her in the diphtheria ward during her entire illness, the child being carefully watched and immunized. In no case of this sort did the child develop diphtheria.

Board-of-health virus was invariably used in the concentrated solutions and in the regularly established rules of dosage of that department. The following summary of all cases given prophylactic treatment by immunization, since its inception at the hospital, April, 1895, will be of interest:

Age.	Previously reported.	Present report.	Total.
3 weeks to 3 months	19	58	77
3 weeks to 6 months	36	45	81
6 months to 1 year	22	69	91
1 year to 4 years.	59	154	213
	136	326	462

In conclusion: the facts established for future guidance are, as forecast in the report of last year:

1. The safety of the agent (properly prepared and administered), even when given to patients of tender years and poor physical condition.
2. Its evident control for a variable period (about one month) over the inception of diphtheria by those who, having been exposed or subject to exposure, are protected by proper immunizing inoculations.
3. Its positive value as a therapeutic agent, in established cases of true diphtheria, particularly when given early in the course of the disease and administered in full doses, according to age and under careful aseptic precautions.¹

AUGUST 21, 1896.

¹ Although this third deduction is made independently of the foregoing report, it does not appear irrelevant to the tenor of the paper; that the statement may not seem presumptuous, it should be understood the deduction is made from personal observations and experience, but these are not at present in shape for statistical report. This, however, cannot detract from the significant fact that the conclusion wholly agrees with the accepted opinions of those whose broader observations and larger experience combine to give the added weight of recognized authority.

POISONING BY AMYL NITRITE.

By R. CADWALLADER, M.D.,

FALL RIVER MILLS, CAL.

Cases of poisoning from amyl nitrite are so rare that each is deserving of notice. Especially is the history of the following case peculiar, and I regret that I did not keep more careful notes of the same. My excuse is the personal interest I had in the result, and the strain and fatigue I was under, which have blended details into a confused remembrance. For many details of dates and sequence of events I am indebted to William H. Vale, D.D.S., of San Francisco, who was present and saw the case to the end.

While reporting a fatal case, I am also paying the last tribute to a friend and brother practitioner, who, at the age of twenty-four years, with a brilliant future before him, has contributed by his tragic death the material for the article.

On Wednesday, October 14th, Dr. F. A. Lutz, of Bieber, Cal., demonstrated the effects of amyl to several persons by inhaling the drug. Thursday he was unwell from indigestion, and made the remark that he believed a pain in his head was due to the amyl of the day before. Some state that his actions were peculiar that day, but this did not occur to them until later.

Thursday evening he stocked a new buggy case and put in a bottle all the amyl nitrite he had, one-half ounce of Merck's. A defective cork was used as a stopper. This case he placed in his room; then he made several calls, and retired at 10:30 P.M. He was not disturbed until 12:45 P.M. Friday, when he was found unconscious, with face dusky red, breathing slow and regular, pulse rapid and weak. He had evidently vomited during the night. The windows were closed, but were at once opened. Those present at first report the room "very close." Dr. L. F. Cate, of Adin, and myself were called. Dr. Cate reached him about 4:30 and I arrived about 7 P.M. Dr. Cate gave him iced milk and cold applications to the head.

A little after 6 P.M. he became semi-conscious, and was so when I arrived. I found him able to recognize every one. His face was suffused and dusky red; tongue swollen, dented by the teeth, and partially paralyzed. He could only with difficulty and after several attempts partially protrude it. Articulation was impossible. He was in no pain, but there was a spasmodic jerking of the muscles of the left leg. The pulse was full, bounding, regular. Temperature was 97.3° F.; respiration, 18, full; and urine normal upon examination.

We opened his case and found the cork still in the bottle, but the volatile amyl had soaked through and wet the case. It was too volatile to endure even until the labels could be looked over.

That night he rested well, and on Saturday, the 16th, dressed and came out to a sofa. His pulse was rapid and weak, and he complained of muscular relaxation and weariness; but he joked and tried to speak of his condition, but could not articulate. There was a tendency to sleep.

Saturday afternoon I returned home, but was sent for Sunday at dark. The messenger said his pulse was worse.

I arrived at his side about 11 P.M., and found him much the same—tongue enlarged and helpless, face dusky, temperature subnormal, respiration 12 to the minute and deep. Urine was drawn by the catheter. While he recognized persons, I found a condition of aphasia. He could pronounce names after me as well as his tongue would permit, but would misname even his best friends. Deglutition was never lost until his death; in fact, he was hungry continually and asked for food.

Up to this time no medicines were given: rest, food,

cold applications to his head and hot to his feet embraced the treatment. About 2 P.M. the heart was 70, but the pulse became soft, full, and the beats run together. I gave one drachm of fluid extract of ergot and ten minims of tincture of digitalis. By daylight Monday the pulse was 55, strong, and the radial arteries were well filled. The condition of somnolence, or partial coma, became persistent and lasted until his death; but he could always be aroused, and then seemed fully conscious of all going on around him.

Monday night the urine was discharged during his sleep. That night and Tuesday forenoon I gave one-sixtieth of a grain of strychnine sulphate and one-sixtieth of a grain of sparteine sulphate hypodermically, a few drops at a time, every few hours, as the heart seemed to require it.

Tuesday, about 3 P.M., the first failure to breathe occurred. Prior to this the respiration had been full, regular, and deep. I was called instantly and told that he stopped all at once, but upon being aroused he had begun again regularly. That morning I drew urine and cleaned the rectum by a solution of Epsom salts and glycerin. The urine was tested and found normal.

Tuesday night and Wednesday there was no change. Small shots of atropine were given every few hours. The heart was fair only, breathing normal. He slept most of the time, but was easily aroused.

Thursday morning, at ten o'clock, there was a momentary failure to breathe, but it passed off in a few minutes. The pupils were now somewhat dilated, and no more atropine was given. It had failed to affect the respiration noticeably, and was unsatisfactory. From this time on strychnine was used in minute doses every hour or two.

Friday, at 2:30 A.M., there was another failure to breathe, and when I reached the room Dr. Yale had begun artificial respiration, which was kept up fifteen minutes before he could be aroused.

Friday afternoon, about 2:30, while I was talking to him, he ceased breathing absolutely, and for two hours only did so when told to take a breath. He breathed for that time mechanically every so many seconds when told to do so. One-half grain of caffeine and the same of strychnine were given. The pulse was then for the first time irregular, running 60 to 70 per minute, and, as usual, weak.

Saturday morning, after sleeping well during the early part of the night, he suddenly failed again, and for four hours artificial respiration was kept up. The pulse was 60 to 70, weak and irregular, improving under strychnine, but the twitching muscles showed that our limit was about reached. At 6 A.M. digitalis was given, and by 10 A.M. the pulse was regular, fairly good, at 38 to 45 per minute. He was only semi-conscious all day. Brandy in egg-nog and by injections was given. All that forenoon he breathed only when punched and told to do so. Saturday night he rested well.

Sunday, at 4 A.M., there was a momentary failure to breathe. Pulse, 36 to 42; respiration, 14, full and regular. During the day he was semi-conscious when aroused.

Monday morning, at one o'clock, it was found impossible to arouse him. Pulse, 36 to 38; respiration, Cheyne-Stokes. This coma lasted until his death. From 7 until 11 A.M. he was kept alive by artificial respiration. The pulse was weak and irregular, intermittent, from 70 to 120. He rallied a little, but ceased to breathe again at 2 P.M. From 2 to 2:45 artificial respiration was used, the pulse ranging from 90 to 180. At 2:45 he began to breathe alone faintly: pulse, 180. At 3:10 only an occasional breath was drawn; pulse, 180, and very weak. The face became con-

gested and purple. At 3:20 the last breath was drawn, and at 3:28 the last flutter of the heart occurred.

During the first few days he would complain occasionally of violent neuralgic pains in the occiput and branches of the fifth nerve.

No post-mortem was allowed, but I embalmed the body and noticed the great difficulty of distinguishing the femoral artery from the vein; both were equally relaxed.

The reader must draw his own conclusions. I have been unable to learn of another even serious case: in fact, authorities seem to ignore the dangerous side of this drug. I would call attention to the fact that life was prolonged so long and that the heart seemed to show the effects long before the respiration. Were I to hazard a theory of its action, I would suggest that the drug exerts its effects directly on the centres controlling the muscular fibres of the blood-vessels, paralyzing them, and especially those of the brain; that this results in an extravasation of serum and increase of intracranial pressure, deranging the nuclei of origin of the spinal nerves. This would account for the symptoms of involvement of the fifth, tenth, and twelfth nerves.

There is no doubt that amyl nitrite alone was the cause. The presence of it in his room and his statements to me, together with my certain knowledge of his private affairs, forbids any mixed poisoning, either intentionally or by accident.

Progress of Medical Science.

Vaginal Hysterectomy.—In a paper discussing bilateral suppurative processes of the uterus and adnexa, Dr. W. D. Haggard, Jr. (*The Southern Practitioner*, November, 1896), says: "In suppurative disease of the uterus and appendages requiring removal, the vaginal method is preferred to the abdominal for the following reasons: 1. The preliminary step, vaginal section, allows thorough exploration and the application of any appropriate conservative treatment, with a minimum of risk. 2. The vagina is the natural approach and logical avenue for drainage of the pelvis and its contents. 3. It is immune from the unpleasant sequelae of laparotomy, possibility of ventral hernia, of stitch abscess, of infected ligature and sinuses, and the abdominal supporter. 4. There is less immediate shock: the convalescence is smoother and shorter. 5. There is no exposure or handling of intestine. 6. The mortality is lower."

Infantile Syphilis.—Dr. Coutts (*British Medical Journal*, 1896, No. 1,843) gives the results of his studies on this subject, summarized from the Hunterian lecture. He thinks a syphilitic mother much more potent in infecting than a syphilitic father. As far as prognosis in the treatment goes, it makes no difference whether the father or the mother is the infecting agent. In syphilis by conception, the mother's entire or partial immunity is caused by the production of antitoxins in her body, which increase with successive pregnancies. Marasmus and congenital atrophy of the secretive and absorptive surface of the intestinal tract are considered among the most important symptoms of inherited syphilis. First symptoms commonly appear in the second month, but may be delayed twelve months. Enlargement of the spleen and liver was found in most cases. Bone lesions are less often observed; pain was often absent in syphilitic epiphysitis; suppuration is rare and is usually seen in the long bones of children old enough to walk. Acquired syphilis is always accompanied by a chancre, followed by roseola and often by sore throat. Dr. Coutts calls attention to

two propositions embraced in Colles' law—the mother of an infant with inherited syphilis cannot acquire it from the infant, but such an infant would infect a healthy wetnurse. Inherited syphilis is very feebly contagious, while acquired syphilis is actively so. The limitations he would place on nursing would be that the mother or wetnurse should have no excoriations on the nipples, and that no ulcerations or fissures be present on the mouth of the infant.

Congenital and Pathognomonic Symptoms of Syphilis.—Dr. Silex (*Annals of Ophthalmology and Otolaryngology*) says the diagnosis is more difficult after the fourth year, especially when complicated by scrofula or rickets: after this time the eye specialist is in a better position to judge of the existence of inherited syphilis than the general practitioner. Fournier reported that the eyes were affected in one hundred and one out of two hundred and twelve congenital syphilitics. In eighty-two only were osteoplastic changes noted. In sixty-two to eighty-three per cent. of cases we find keratitis. The peculiar form of teeth described by Hutchinson and Knies were referred to. Hirschberg stated that choroiditis areolata, serpiginata, and disseminata were all believed by him to be the results of congenital syphilis. The writer would add Virchow's sign of congenital syphilis, the smooth base of the tongue.

Practical Treatment of Typhoid Fever.—Dr. C. E. Skinner writes as follows in the *New York Medical Journal*, October 24, 1896: "It is a prevalent notion that a too rapid return to solid from a liquid diet is capable of inducing a relapse of the disease. I do not believe this. This fever is infectious, and if, in any given case, it started to run another cycle, there must certainly have occurred another infection with fresh germs. It is much more logically explained by the probability that the faeces had not been thoroughly disinfected early enough to kill all the micro-organisms, and that some article—clothing, bedding, or the carpet, for instance—had suffered contamination. As their virulence is not destroyed by drying, it would be quite possible for some of them to effect a re-entrance into the patient's intestinal tract and set up mischief anew. Too heavy (*i.e.*, indigestible) a diet would be likely to produce acute dyspepsia, with its accompanying systemic disturbances, and this would be rendered more intense and easier of induction by the debility present; but I do not believe that it ever directly caused a relapse into true typhoid fever."

Erythromelalgia.—Not much has been added to our knowledge of the symptom complex designated by Weir Mitchell as erythromelalgia since his first description of the disorder in 1872. As the name indicates, the condition is characterized by pain and redness, not of an inflammatory nature, usually confined to an extremity, worse on dependency and in hot weather, with hyperalgesia and increased local temperature, and without definite trophic disturbance. Of the ultimate nature of the disorder we have no positive knowledge, although hypotheses as to its pathology are not wanting. One of Mitchell's cases was believed to be of spinal origin. In another the symptoms were attributed to a terminal neuritis; and this view seemed to receive support from the relief afforded by excision and stretching of the nerves presumably involved in the morbid process. A number of cases of erythromelalgia have been recently reported by German observers, two of whom, Lewin and Benda (*Deutsche medicinische Wochenschrift*, 1894, Nos. 3, 4, 5, 6), have collected a total of forty cases from the literature. A study of these leads to the conclusion that the affection is not a disease *sui generis*, but a manifestation at times of spinal or cerebral disease, at

others of some general neurosis, while in some instances it is to be viewed as the expression of a neuralgia, or of a neuritis, or even of a reflex influence. In reporting in detail a case recently, Dehio (*Berliner klinische Wochenschrift*, 1896, No. 37, p. 817), after an analysis of the symptoms, comes to the conclusion that the manifestations of erythromelalgia are due to abnormal irritability of the posterior and lateral horns of the gray matter of the spinal cord and, perhaps, also of the medulla oblongata. In this case examination of the nerves of the part of the body in which the symptoms of the disorder were manifested failed to disclose any morbid alteration. The local arterial sclerosis found was ascribed to the persistent diminution in vascular tone. The evidence thus far accumulated would seem to justify the conclusion that the group of symptoms included in the designation erythromelalgia may result from a multiplicity of causes acting upon different parts of the nervous system, and prognosis and treatment will vary accordingly.

Nervous Manifestations of Syphilis.—The diagnostic features of value are enumerated as follows in a paper by Dr. Hodges, read at the Richmond Academy of Medicine: 1. Headaches, which disappear if paralysis occurs. 2. Insomnia, nearly always associated with headache and disappearing with the appearance of convulsion or paralysis. It differs from the insomnia of neurasthenia and melancholia in that it occurs in the early night, the victim arising in the morning ready for his daily labor. 3. Vertigo, occurring usually with the headache. It may be transient, but becomes worse as the disease progresses. 4. Tremor, present in one-half of the cases. It occurs most often in the order named: In the hands, tongue, and over the whole body, and is accompanied by headache. If it occurs in a limb, it is the precursor of paralysis of the limb. 5. Hemiplegia. 6. Erratic distribution of paralysis, as aphasia with or without hemiplegia, ptosis, insanity, or epilepsy, with paralysis of one arm or leg. It is suggested that ptosis occurring suddenly points nearly always to syphilis. 7. The use of electricity to determine central or peripheral lesion. 8. The presence of great weakness and mental dulness. This is one of the most valuable of the nervous manifestations, being out of proportion to the seeming condition of the patient. 9. History of the case. In women, the history of many abortions in succession would point to syphilis.

Are Microbes Necessary to Human Life?—A correspondent writes to the *Philadelphia Polyclinic* in opposition to the theory that microbes are necessary to physiological digestion. The experiments of Nuttall and Thierfelder indicate that the animal body is independent of bacterial life, for they have shown that in the absence of all micro-organisms an animal may live and thrive. Their experiments were as follows: "A young guinea-pig was secured by Cæsarean section, under strict aseptic and antiseptic precautions, and immediately transferred to an apparatus consisting of a bell jar placed over a small vessel containing water covered with a layer of oil. Over this vessel was laid a piece of wire netting, upon which the animal could move about. In the sides of the bell jar were two apertures—in one a rubber glove, in the other a suction tube communicating with a bottle of sterilized cow's milk. The glove was connected with a rubber bag containing wads of cotton, which by manipulation of the glove could be placed on the wire screen, and after use could be dropped into the water beneath. The coating of oil prevented the evaporation of the water. From time to time the apparatus was ventilated with sterilized air. For a time the animal lay on its side, but soon rose on its legs, and, as it became

dry, grew active and lively. It received milk for the first time twelve hours after birth; thereafter, every hour, day and night. After eight days it was removed from the apparatus, killed, and opened under antiseptic precautions. A microscopic examination of the intestinal contents, in stained and unstained preparations, revealed a total absence of bacteria. Tubes inoculated with the contents and kept under both aerobic and anaerobic conditions remained perfectly sterile; not a single colony developed." From these results the experimenters conclude that bacteria need not necessarily be present in the intestinal canal of guinea-pigs, nor in other animals, nor in man—at least, not so long as the food is purely animal.

A New Method of Artificial Respiration.—Calliano (*British Medical Journal*) describes a new method of artificial respiration, which he has practised successfully in cases of asphyxia. Place the patient in Sylvester's position, draw the arms up so as fully to expand the thorax, and fix above and behind the head by tying the wrists together. Respiration is then produced by simply pressing with the hands on the thorax some eighteen or twenty times a minute. The advantages claimed for this modification of Sylvester's method are its greater simplicity, the smaller amount of labor required, and lessened fatigue of the operator; the absence of danger from contusion of the shoulder-joints, and the ease with which such a method could be taught to and practised by uneducated and untrained people.

Massage Movements and Bandaging in the Treatment of Displaced Semilunar Cartilages.—Dr. Douglas Graham, in a paper published in *The American Journal of the Medical Sciences*, November, 1896, concludes: 1. That neither in their natural nor in their unnatural positions can semilunar cartilages often be distinguished from the surrounding tissues. 2. That the position of the leg affords the best means of inferring whether one or the other semilunar cartilages may have been dislocated when it cannot be felt, the leg being usually flexed and the foot turned out when the internal meniscus is dislocated, the leg flexed and the foot turned in when it is the external. 3. To attempt to replace a dislocated semilunar cartilage, it is wise to flex the leg, then extend suddenly, rotating the leg inward if it be the internal cartilage, outward if it be the external, while exerting pressure over the offending region. 4. That there is a natural tendency in some cases of dislocated semilunar cartilages to slip back into place when the leg is not artificially restrained. 5. That if the knee be immovably fixed by plaster or splints before the cartilage has gotten back into its natural situation, the joint is locked and restrained from gentle instinctive movements that might favor its return. 6. That cases of displaced cartilage are attended by voluntary and involuntary restraint of motion, on account of pain and mechanical impediment; and in some cases by synovitis and the formation of adhesions. Forceful passive motion might then have the double purpose of breaking the adhesions and rectifying the displacement. 7. That even after a meniscus has been restored to its natural situation, it is not so securely and comfortably held by plaster and splints as by a pad of a few folds of bandage and a figure-eight bandage applied over this, which affords support and comfort and a safe limit of motion. 8. That it is possible, by carefully applied massage, resistive movements, home exercises, and electricity, so to strengthen the muscles on the front of the thigh, the fascia, ligaments, and attachments of the knee-joint that they will safely hold a previously dislocated semilunar cartilage without artificial support. 9. These remarks do not apply to cases requiring surgical

operation, though the above-mentioned combination of treatment might be safely tried in some cases before cutting into a knee-joint, but more especially after operation for restoring motion and strength to the knee.

Cholagogues.—Dr. E. Stadelmann (*Berliner klin. Woch.*) thus classifies the so-called cholagogues: 1. Substances having no true cholagogue action: bicarbonate of sodium, chloride of sodium, sulphate of sodium, etc. 2. Drastic substances, having no assured cholagogue action and often diminishing the biliary secretion: gamboge, jalap, aloes, scammony, senna, calomel. 3. Substances diminishing the biliary secretion more often than they increase it: alcohol, olive oil. 4. Substances certainly diminishing the biliary secretion: atropine, pilocarpine (?). 5. Substances having a doubtful cholagogue action: antipyrin, acetanilid, caffeine, diuretin, santonin, Durand's remedy. 6. Substances which are cholagogue: salicylate of sodium, bile.

Hydronephrosis.—1. Lumbar nephrotomy, followed by packing and aseptic drainage. If urinary fistula remains after three months: 2. Operation for the stenosis, namely, for (a) stricture of the ureter, or (b) valve formation and oblique insertion. If the fistula still remains with the ureter patent, which occurs only when there is obstruction above the ureter: 3. Operation for sacculated kidney as designed by me, namely, bisection of the kidney and division of the partition walls between sacs. When the entire territory of the sac is thus laid open and the ureter is patent, as demonstrated by free passage of bougies from the kidney to the bladder, and by free passage of injected fluid, then—4. Closure of the fistula by reunion of the bisected kidney. This last operation may confidently be expected to be followed by disappearance of the fistula. It should not, however, be done until the pyelitis, if present, has been cured by thorough irrigation from the kidney to the bladder. Kuster observed a case of nephrotomy in which the fistula closed spontaneously, with patent ureter, but the pyelitis persisted, giving an incomplete cure. I have seen, however, when we closed the fistula before the pus has disappeared entirely from the urine, the pus in the urine having remained unchanged in amount for a considerable time, that the closure of the fistula acts as a curative measure and causes the pyelitis to cease.—FENGER, *Annals of Surgery*, June, 1896.

Etiology of Lobular Pneumonia.—Dr. Kreibich, in a monograph published by Braumüller, Vienna, 1896, examined twenty-seven cases of pneumonia, twenty of which were of the inspiration variety. In twenty-three he found the diplococcus pneumoniae, eleven times in pure culture, five times with bacillus coli communis, four times with staphylococcus pyogenes aureus, once each with bacillus pneumoniae, streptococcus pyogenes, and another unrecognized micro-organism. Dr. Kreibich asserts that bronchopneumonia, and especially inspiration pneumonia, are generally caused by the diplococcus pneumoniae; but he notes that in man bacillus coli is also capable of causing lobar and lobular pneumonia. As an auto-infection from the cavity of the mouth, the occurrence of lobular pneumonia dependent upon the diplococcus pneumoniae is favored by such conditions as heart failure, hypostatic hyperæmia, etc. In most cases of coli pneumonia there is infection by the blood from the intestine or from inflammatory processes in the urogenital tract. Inspiration pneumonia may end in suppuration, in gangrene, or in induration. With regard to the first termination, the variety of exudation is not generally influenced by the question whether the diplococcus was alone present or in company with other organisms, though the exudation has a tendency

to be bloody if large infective masses are suddenly inspired. Gangrene is generally caused by anaerobes and saphrophytes, probably present in the inspired mass, which induce putrid changes in the contents of the bronchi, and by their katabolic products lead to necrosis of the inflamed portions of the lung. Induration apparently occurs when the metabolic products of the bacteria constitute a long-continued stimulus to productive inflammation.

The Cause of Warts.—Mechanical irritation of the papillæ is thought by Schaal (*Archiv für Derm. u. Syph.*, Bd. xxxv., H. 2) to be the cause of warty growths. In his own person, spiculæ of glass seemed to lead to increased formation of epidermic cells and the development of warts. The exposed surfaces being those on which warts habitually develop would lend weight to this theory. The delicate tissues of childhood also favor easy penetration of foreign bodies.

Hayseed Sprouted in the Ear.—Dr. Macnaughton Jones reports, in the *Journal of Laryngology, Rhinology, and Otolology*, a case in which the patient had been suffering from noises in the ear for some years, and had other evidences of middle-ear deafness. He sought advice for the deafness, being quite unconscious of the presence of any foreign body. On examining the meatus, what appeared to be a pink sprouting mass of fungus was seen with the transmitted light. The appearance was most puzzling, and it was not until the sprouting hayseed was withdrawn that its nature was discovered. It was quite firmly attached to the wall of the meatus, being removed clean with the lever forceps. The patient then remembered having, over two years previously, at harvest time, suddenly felt as if something had entered his ear, and the tinnitus began.

Myxodermia.—At a recent meeting of the Paris Academy of Medicine, Dr. H. de Brun presented a communication based upon the observation of a girl of seventeen years, who had entered his hospital service with the diagnosis of typhoid fever, and upon the further observation of a similar case by Dr. Haïdar, an externe of the service. The conclusions presented were to the effect that there exists a disease characterized by the following *ensemble* of phenomena: Rapid onset, with high fever, malaise, vomiting, and headache, followed at once by the development of the typhoid phenomena common to all infectious diseases, with predominance of agitation during the night, when the delirium takes on a particularly violent character. The temperature range is characterized by three periods: A primary period, during which the thermometer, after having registered 39° C. from the first, oscillates during eight or ten days between 39° and 40° C.; a second period (apyrexia), during which the temperature falls for about eight days to below normal; a third period, in which the temperature goes up again rapidly to the neighborhood of 39° C. There is a generalized contraction of the whole muscular system, especially pronounced in the masticatory muscles (trismus), the muscles of the face (special facies), and the muscles of the neck (stiffness of the neck and impossibility to turn the head). Here are also special alteration of the skin, which becomes like soft wax; subcutaneous hemorrhages coming on at the onset of the third period; multiple ecchymoses, which are voluminous, painful, and characterized by a large white zone, which surrounds them and distinguishes them from ecchymoses which may be produced in other infectious diseases and in scorbutus. This disease is equally remarkable for the absence of meteorism and of rosy lenticular spots or other eruption. Its duration is from three to four weeks. Its infectious principle is still to be determined; however, we may affirm that it has nothing in common with the bacillus of Eberth.

The prognosis is grave. The diagnosis of this affection is relatively easy, thanks to the existence of a certain number of symptoms truly pathognomonic, which permits us clearly to establish its autonomy and to call it, until a better name is agreed upon, *myxodermie contracturante hémorrhagique*.

Vaginal Cæsarean Section.—Dr. Dührssen describes the vaginal method as less dangerous than the classical Cæsarean section. His operation was done in spite of closure of the cervix, and without opening the peritoneum. He delivered a living child by the vagina. The vaginal portion was exposed by a large speculum, and sagittal openings having been made in the anterior and posterior vaginal vaults, the bladder and vesical fold of peritoneum and that of Douglas' pouch were detached from the cervix and lower segment of the uterus, which were then divided in the median plane. After the bleeding had been arrested by ligatures, he introduced his hand, and turned and extracted a child of nine and one-half pounds weight. The operation is indicated when, with an undilatable cervix, the mother's life is imperilled by circumstances which may be improved, or set aside, by emptying the uterus; for example, in severe eclampsia or uræmia; in cases of serious internal hemorrhage from a normally situated but prematurely displaced placenta; in grave pulmonary or cardiac disease; in the interests of the child, when the condition of the mother is expected to prove rapidly fatal; and, finally, in pathological conditions of the cervix or of the lower segment of the womb. In new growths of the cervix the operation may be supplemented by vaginal hysterectomy, which, directly after delivery, can be performed in a few minutes, by Doyen's method. Dührssen considers these procedures as logical developments of Czerny's vaginal myotomy and total extirpation, and as instances of the influence of the advances of gynecological surgery upon the field of obstetrics.—*Berliner klinische Wochenschrift*.

Tuberculous Hernia.—According to Dr. Renault, tubercle developing in a hernial sac or in its contents may assume two forms: Gross tubercle or miliary. These two forms may be either primary or may coexist with other lesions of the same kind in different organs, and the author points out as curious that femoral hernias are much more rarely tuberculous than inguinal, and that tuberculous umbilical or obturator hernias have never been observed. In general, it is those hernias of long standing that are more likely to become tuberculous. It is probable that the propagation of the tubercle takes place by the intestine, and the author believes that traumatism, being fairly frequent in hernia, may have a marked influence in the development of tubercle. He also suggests that variations in the local circulation may have an important bearing. Tubercle in a hernia may be found in either children or adults, and in the former it is important to bear it in mind, for a child already the subject of a congenital hernia may develop tubercle very insidiously, as a slight loss of weight and irritability may be the only general symptoms. Locally there may be an increase in the size of the hernia and marked pain on palpation, as constituting the only physical signs. That the diagnosis is important is shown by the fact that the tubercle may be confined to the sac and its contents, but can, and often does, spread to the general peritoneum. If diagnosed before extension takes place it is possible, the author believes, to obtain satisfactory results by treatment. This latter should be the ordinary treatment of hernia, the tubercle under these circumstances appearing to subside, as in the case of a general peritoneal invasion.—*Journal de Médecine de Paris*.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 5, 1896.

LEGAL RESPONSIBILITIES OF THE OPERATING SURGEON.

A RECENT suit for damages against a surgeon in London for exceeding the wishes of a patient regarding the extent of an operation has just been decided for the defendant. The case was one of double oöphorectomy, against the express wishes of the patient that but one ovary should be removed. During the progress of the operation it became evident to the surgeon that the removal of the remaining offending organ was necessary for a radical cure. The patient, in consequence of this act, was compelled to break a marriage engagement which had been pending. The testimony in the trial bore upon some very important questions of professional responsibility in this and similar cases. While the course to be pursued must be governed by individual circumstances, the general reasons for specific action are admittedly controlled by well-understood general principles. The result of the case in hand carries with it a lesson of danger in lawsuits which every surgeon should thoughtfully consider. It is legally held in this country and in other civilized communities that the consent of the patient, when such can be obtained, is always necessary in dividing the responsibility of any operative treatment. In the case of a child or of an insensible patient in imminent peril, the nearest relatives or friends are competent to decide for or against surgical interference. When such precautions are not or cannot be taken on the part of the operator, he assumes the sole responsibility of the result. No surgeon cares to do this when he can avoid it, and as a consequence he protects himself against the possibility of subsequent misunderstanding accordingly. A refusal to take proper advice under given circumstances is the affair of the patient and that of no one else. Hence, in the eyes of the law the patient has the right to decide his own chances; in other words, is privileged to take his life in his own hands, in spite of the judgment of the person who is summoned to his aid.

In the actual course of an operation the case is entirely different, and the discussion of the duties of the operator opens up a wide field for the exercise of his judgment in assuming unlooked-for risks, in meeting unsuspected conditions of emergency, or pressing matters of expediency. It is just here that a line can be drawn between what may be actually necessary to

avert immediate death or subsequent disability and the surgeon's ideal of a complete operation. Especially is this true when the loss of an important organ is to be considered, and when the patient has forbidden its removal under any circumstances. No good operator would care to undertake the treatment of any case with such an embarrassing handicap; but when he does, he must, save in very exceptional instances, religiously abide by the conditions.

In the present case, the testimony showed that the operator, when asked to promise that but one ovary should be removed, replied that he would use his best judgment in complying with the request. The tacit consent to such a proposition was legally implied by the patient voluntarily placing herself upon the operating-table, although she positively declared that she had given no direct assent to the proposal of the surgeon. Although it was not claimed that the removal of the second ovary was necessary to save the life of the patient at the time, but that it was for the sake of an ultimate cure, the jury, fortunately for the defendant, took the lenient side and most liberally endorsed what on general principles might be considered a laudable motive. Strictly speaking, however, there was a dangerous possibility for an entirely opposite view. That such chances should not be taken again is the real moral to this particular tale. One of the experts for the plaintiff expressed his belief that the second ovary was not sufficiently diseased to require removal, but he evidently merits the pity of every practical gynecologist.

While this case may be looked upon as a leading one in protecting the surgeon in doubtful emergencies, the pros and cons cannot be weighed too carefully to prevent a disastrous reversal of the present ruling. If it were necessary that one more word should be said on this point, it is better in cases of doubt, when such can be safely done, to perform an exploratory operation and obtain consent for more radical measures afterward, than to be called to account for what the patient may term to be disobedience to his or her commands; but safest and best of all is never to undertake any operation whatever without the freest possible liberty for the use of personal judgment on any and every contingency.

MEDICAL FEES AND MULTI-MILLIONAIRES.

It is said that since John W. Mackay refused to pay the bill of the physicians who extracted the assassin's bullet from his body, amounting to \$12,500, he has paid an attorney bill of \$26,160, for taking a will of which he was executor through the probate court—an automatic procedure requiring neither skill, great ability, learning, nor judgment.

The California press was unanimous in condemning the physicians for rendering so large a bill, and in congratulating the lawyer upon receiving a handsome fee. We have only ourselves to thank for the way the public look upon these matters. Lawyers often think better of us than we have thought of ourselves, to judge from the excitement which is occa-

sioned when a physician dares assert his rightful claims.

In a recent speech to the Charing Cross medical students, Justice Vaughan Williams dwelt upon the affinity of law and medicine. Both required the same qualities. Both lawyer and physician were the recipients of confidences from their clients, and clients rarely found their confidences misplaced. As a lawyer he came into contact with doctors in the law courts, where the most important issues were often determined solely on the evidence of medical experts, who were for the most part safe guides in the administration of justice. One point, however, in which the professions differed was that the medical profession was essentially progressive, while the legal profession was in a sense stationary. If the doctors of the last century should come to life again, they would know comparatively nothing of contemporary medical science; but if the judges of former times were installed in the law courts to-morrow, they would try the cases quite as well, if not better than the judges of to-day.

This eminent representative of the bar might have proceeded to designate one other point in which the professions differed. If the legal profession is stationary in one sense, it has advanced in knowledge of how to secure at least fair remuneration from men of great wealth. This the medical man has yet to learn—and in learning it, the public will be taught.

ITCHING AND THE ITCH.

IN a recent number of *La Médecine Moderne*, the frequency with which formulæ are published in American medical journals for the relief of pruritus vulvæ is made a subject of comment. The question is asked whether there are peculiarities of race, climate, or environment which tend to make the affection so prevalent among American women that editors have become possessed of the necessity of bringing the matter forward so frequently in their publications. We do not know how others may account for the fact that pruritus vulvæ receives so much attention at American hands, but our itch editor, to whom we referred the matter, informs us that personally he is a great admirer of French journalism, and constantly flatters French editors in the sincerest way by imitating them. Now, as every one knows who reads the Paris journals, it would be considered an unpardonable oversight for an editor to send out a weekly issue which did not contain the recipe for at least one *pommade contre la gale*.

Having little or no scabies in this country, and much more pruritus scribendi than any other variety, these formulæ are reproduced and made to do service under the faked caption of "pruritus vulvæ."

Now, will our esteemed friend of "modern medicine" enlighten us upon the prevalence in France of *la gale*, to which his own and his contemporaries' journals devote so much attention?

Syphilis has been recognized as a cause for divorce by a Paris court.

News of the Week.

"Ian Maclaren" to Physicians.—The Rev. John Watson, D.D., "Ian Maclaren," author of "A Doctor of the Old School," will preach to medical men and medical students in the Fifth Avenue Presbyterian Church, Fifth Avenue and Fifty-fifth Street, on Sunday, December 7th, at 8 P.M. Tickets can be obtained free by medical men, medical students, and other college graduates, on personal application at the Students' Club, 129 Lexington Avenue. An opportunity is thus offered to the medical profession of this city to see and hear one who, by his charming creation of "Dr. Maclure," has endeared himself to the hearts of every one of his thousands of enthusiastic readers.

Pigeon Calls.—Dr. Harrey, a Scotch physician, is said to make a practice of leaving with such patients as are likely to require his prompt attendance one or more carrier pigeons to be dispatched with messages. He also takes the winged messengers with him on his rounds and sends them back to his office with prescriptions to be filled. It is not stated whether or not they carry back the medicine to the sufferer.

A Photo-Fluoroscope has been invented by Dr. Bleyer, of this city, by means of which it is said pictures of interior parts can be taken which are a surprise to scientists.

The New York Civil Service Commission will hold the following examination at its office in the new criminal court building, at 10 A.M. on the date named. Citizens of the United States, who are residents of the State of New York, and hold the degree of M.D. are eligible for this examination. Applications may be obtained from S. William Briscoe, secretary, new criminal court building, New York City. December 15th.—House physician, Bellevue Hospital, department of public charities. Candidates must hold degree of M.D., and will be examined on nervous and mental diseases. Salary, \$1,200 per annum.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending November 28, 1896. November 21st.—Surgeon A. G. Cabell detached from the *Michigan*, ordered home, and granted three months' leave. Passed Assistant Surgeon F. J. B. Cordeiro detached from the *Constellation* and ordered to the *Michigan*. Assistant Surgeon L. Morris detached from the naval hospital, *Philadelphia*, December 5th, ordered to examination for promotion at New York, December 7th, and then placed on waiting orders. Assistant Surgeon R. G. Brodrick ordered to the *Constellation*. November 24th.—Medical Director T. C. Walton detached from the naval academy, January 18th, instead of December 15th, and ordered to the naval laboratory, New York, January 19th. Medical Director H. M. Wells detached from the naval laboratory, New York, January 19th instead of December 19th. November 25th.—Surgeon W. S. Dixon detached from special duty in Washington and ordered to the *Brooklyn*, December 1st.

Pædiatric Society of Philadelphia.—At a well-attended meeting of Philadelphia medical men on November 19th it was agreed to form a pædiatric society.

Vienna Medical Society.—Dr. Adam Liewicz, a prominent member of this society, has been expelled for securing a patent upon his "cancroin," a cancer remedy.

The Late Dr. Thomas H. Burchard.—The Northwestern Medical and Surgical Society adopted the following resolutions in regard to Dr. Thomas H. Burchard:

Whereas, It has pleased God to take away Dr. Thomas H. Burchard, distinguished by twenty years of active and faithful membership in the Northwestern Medical and Surgical Society of New York; and

Whereas, Our hearts are touched with a deep sorrow by the suddenness of his decease; therefore,

Resolved, That we desire to place on record an expression of our esteem of our late colleague, who had endeared himself to us by a long line of friendly and generous offices—that we desire to commemorate his devotion to the medical profession, exemplified in so high a degree by his many contributions to this and to other medical bodies, and by his acknowledged skill as a surgeon—and that we realize in the life of our friend the large equipment of mind and body essential to the success of a true physician.

Resolved, That a copy of these minutes be sent to the bereaved wife and sons and near relatives of our late colleague, to whom we extend our sincere sympathy in their great affliction.

Resolved, Further, that a copy of these resolutions be sent to the various medical journals of New York for publication.

For the society,

EDWARD S. PECK, *Committee*.

Mortality in the State.—There were 8,676 deaths in the State in October, according to the monthly bulletin of the State board of health. The decrease in the mortality from all causes, which was reported in the last bulletin to amount to 500 fewer deaths than in the corresponding month of last year, has continued during October, the reported mortality being 600 less than that of October, 1895. There is also a decrease of 800 in the number of deaths reported from the preceding month. The estimated death rate is 16 per 1,000 population annually, against 17.50 in September and 17.20 in October, 1895. The number of deaths from diarrhœal diseases is unusually small, and has diminished from 1,077 in September to 338, and this decrease is distributed over all parts of the State. The number of deaths from diphtheria, compared with the mortality of a year ago, is less for the month by 100, but there is an increase from 294 deaths in September to 361 in October. This increase occurs in all parts of the State except the central and southern. Its prevalence is reported from thirty-five towns in the northern and eastern parts of the State. In New York City there were fewer deaths than in September, but the disease has increased in Brooklyn

and Long Island. Diphtheria caused less than 2 per cent. of the mortality in rural towns and 4.5 per cent. of the urban mortality. Scarlet fever is reported as prevalent from twenty-five towns in the southwestern counties; thirty-five deaths occurred, which is a slight increase over last month. Typhoid fever has slightly decreased; it caused 5.50 per cent. of the rural and 2 per cent. of the urban mortality. From acute respiratory diseases the mortality is excessive, the 1,123 deaths reported being 300 more than either that of the preceding month or the corresponding month of last year. No special cause for this increase has been reported. From other local diseases the mortality is diminished.

Obituary Notes.—HIRAM HENRY DARR, Caldwell, Tex., died November 22, 1896. He was born April 4, 1853, on the old Darr homestead in the vicinity of Yellow Prairie, Tex., and obtained a general education in the local schools and by private study; attended lectures at Louisville Medical College, Louisville, Ky., from which he was graduated February 25, 1875, with first honors, receiving the gold medal for general proficiency in all branches, and also the first prize in surgery. He then took an *ad eundem* course at the Kentucky School of Medicine, and was graduated from that institution in June of the same year, 1875. Locating near Hearne, Tex., he practised medicine there until 1879, and spent the winter of 1879-80 in study at the College of Physicians and Surgeons in the city of New York, giving special attention to diseases of the eye, ear, and throat. Returning to Texas, Dr. Darr located at Caldwell, in his native county. He was a member of the following-named organizations, having joined them in the years given: Texas State Medical Association, 1877, vice-president in 1884; American Public Health Association, 1882; American Medical Association, 1883; Burleson County Medical Society, which he helped to organize in 1885 and of which he was the first president. International Medical Congress, 1887; National Association of Railway Surgeons, 1891; American Academy of Political and Social Science, 1892.—DR. PINCKNEY WEBSTER ELLSWORTH, who had been a physician and surgeon of Hartford for fifty-three years, died December 1st, from a paralytic shock. He was born in Hartford on December 5, 1814. He was a descendant of Governor Bradford of the *Mayflower* and also of John Webster, one of the first governors of the Connecticut colony. Dr. Ellsworth graduated at Yale in the class of 1836 and from the College of Physicians and Surgeons of New York in 1839. He was one of the organizers of the Hartford Medical Society, a member of the Connecticut Medical Society, and an honorary member of the New York State Medical Society. His distinction as a surgeon led Governor Buckingham to appoint him surgeon of the Connecticut brigade of volunteers, and he participated in the first battle of Bull Run. He was a member of the Centre Church for over fifty years, the same church in which his father, Governor Ellsworth, was deacon for over half a century. He leaves a widow and six children.—DR. JACOB T. FIELD, who died at his home in Bayonne,

N. J., was fifty-seven years old, and was born in North Branch, Somerset County, N. J. His academic education was received at Rutgers College, and his medical degree was conferred by the College of Physicians and Surgeons. He was a war veteran, and leaves a widow and one son.

Generous Endowment.—The children of the late George Leib Harrison have added \$150,000 to the endowment fund of the "George L. Harrison Memorial House" of the Episcopal Hospital of Philadelphia, thus completing the total of \$300,000.

Typhoid is reported very prevalent at Paterson, N. J.

The Late Dr. Francis H. Rankin.—At a special meeting of the Newport Medical Society, held at the residence of Horatio R. Storer, presided over by First Vice-President Dr. C. F. Barker, the following preamble and resolutions were adopted:

Whereas, In His inscrutable wisdom Almighty God has seen fit to remove from the scene of his earthly labors, our beloved president; therefore,

Resolved, That we bow in submission to His divine will.

Resolved, That in the death of Dr. Francis H. Rankin, the medical society of which he was the founder has met with an irretrievable loss.

Resolved, That the profession of medicine has parted with one of its brightest leaders, a man who was always working for the sanitary welfare of this city, for the good of the poor, and the benefit of the profession of which he was so bright an ornament.

Resolved, That no man could have led a purer or more useful and disinterested life, and that the urbanity of his manners, the gentleness of his disposition, the truthfulness of his character, and the manliness of his nature served to bind with bonds of sincerest love the enduring friendship which he always inspired in all who had the privilege of knowing him.

Resolved, That we offer our sincere sympathy to his afflicted wife and relatives.

Resolved, That the society attend his funeral in a body.

Resolved, That a copy of these resolutions be published in the daily papers of this city and in a prominent medical publication in New York, Boston, and Providence, and that a copy be presented to his family.

V. MOTT FRANCIS, M.D.,

Second Vice-President,

HENRY E. TURNER, M.D.,

STEPHEN C. POWELL, M.D.,

Committee.

Philadelphia County Medical Society.—At a stated meeting of the Philadelphia County Medical Society, on November 11th. Dr. J. T. Rugh read a paper entitled "Eight Primary Movements of the Normal Spine as a Basis for Gymnastics in the Treatment of Scoliosis and Allied Conditions." These movements consist in bending forward, bending backward, bending to the right, bending to the left, combination of these movements in circumduction to the right, combination

of these movements in circumduction to the left, rotation of the spine upon its vertical axis to the right, and rotation of the spine upon its axis to the left. By special invitation, Mr. Tallerman, of London, exhibited a localized hot-air bath apparatus, and demonstrated its extraordinary efficacy in a case of saturnine gout and in one of lumbago. This device promises to prove of large service in the treatment of such disorders, especially, as chronic and painful affections of the joints and muscles of varied kind, and has for several years been in successful employment at the hands of English surgeons and physicians. Dr. Max J. Stern made a "Report of Work with Roentgen Rays at the Polyclinic Hospital, with Exhibit of Skiagraphs."

Traffic in Corpses.—The department of charities has suspended Morgue-Keeper White for selling bodies to the Polyclinic. Under the section of the penal code which makes it a felony for any person to sell a human body for dissection purposes, Mr. White was arrested. The penalty for each offence is \$1,000 fine or five years' imprisonment, or both. It has long been suspected in certain institutions that the difficulties in obtaining autopsies when bodies were not claimed by friends was because they were too valuable to some one.

Leprosy in Russia.—In July, 1895, the Russian government issued a decree that every case of leprosy must be notified to the authorities. In July of the present year it was found that in the course of the previous twelve months 894 cases had been notified. Of this number, 63.3 per cent. suffered from the tubercular form of the disease. As regards the age of the patients, 3 per cent. were under five; 14.42 per cent. under twenty; 28.2 per cent. over fifty; and 4.1 per cent. over seventy. In eighteen cases the disease appeared to have been transmitted from man to wife, or *vice versa*. There are already five leper asylums and two leper colonies in Russia, and it is in contemplation to increase the number of these places of isolation.—*British Medical Journal*, November 7, 1896.

College of Physicians of Philadelphia.—At a stated meeting of the section on gynecology of the College of Physicians of Philadelphia on November 19th Dr. C. B. Penrose reported a case presenting an enormous fibroid tumor of the uterus, weighing upward of eighty pounds. The patient died from heart failure several hours after the operation, in consequence, it was thought, of the sudden removal of the intra-abdominal pressure that had previously existed. Dr. Penrose also reported a case of spontaneous rupture of an oöphoritic cyst, in which removal was practised successfully. By invitation of the executive committee Dr. W. A. Newman Dorland read a paper entitled "Gestational Disturbances and Dystocia Subsequent to Anterior Fixation of the Uterus." Dr. Richard C. Norris reported the course of two labors following suspensio uteri, and Dr. Barton Cooke Hirst also reported two deliveries succeeding the operation of suspensio uteri. Dr. Hirst also read a paper entitled "Technique in Cæsarean Section."

Brooklyn Hospital.—Three members of the medical staff of the County Hospital in Brooklyn recently submitted a report to the commissioners of charities in regard to the overcrowding of some of the buildings. In the hospital nearly seven hundred patients were crowded into a space originally intended for four hundred.

The Late Dr. F. W. Ring.—Resolutions adopted by the medical board of the Manhattan Eye and Ear Hospital on the occasion of the death of Dr. Frank Whitman Ring, on July 17, 1896:

Whereas, The hand of death has removed from our midst our executive surgeon, Dr. Frank W. Ring:

Resolved, That, in submitting to the will of Almighty God, we wish to express our personal sorrow at the loss of a most faithful and efficient colleague.

Resolved, That we extend to his widow and family our deepest sympathy in their bereavement.

Resolved, That the surgical staff of the hospital attend his funeral services in a body, and that a committee of four be appointed to accompany his remains to their final resting-place.

Resolved, That the flag of the hospital be displayed at half-mast until after his interment.

Resolved, That a copy of these resolutions be forwarded to his widow.

Resolutions adopted by the board of directors at its stated meeting, November 17, 1896:

Whereas, we are called upon to record the death of our associate, Dr. Frank Whitman Ring, which occurred on July 17, 1896; and

Whereas, Dr. Ring has, for the past twelve years, been actively connected with the Manhattan Eye and Ear Hospital, New York:

Resolved, That we heartily indorse the action taken by the medical board at the time of his death.

Resolved, That we hereby express our love and appreciation of Dr. Ring as a man, a surgeon, and a director of this hospital, and our own sorrow, as well as the loss to the institution, by his untimely death.

Resolved, That a copy of these resolutions, in conjunction with those passed by the medical board, be published in our annual report, the New York medical journals, and the *Maine Journal of Medicine and Science*, and that a copy of these resolutions be sent to his widow with the sympathy of this board.

DAVID WEBSTER, M.D.,

J. B. EMERSON, M.D.,

JOHN STEWART,

Committee.

Army Department, Bureau of Medicine and Surgery, Washington, D. C. The following changes in the stations and officers of the medical department are ordered under date of November 14th: Major John J. Hall, surgeon, will be relieved from duty at Madison Barracks, New York, by the commanding officer of that post, and will report to the commanding officer of Fort Wadsworth for duty at that post, to relieve Major Edward T. Comegys; Major Comegys, upon being relieved, will report to the commanding officer of Fort Sill, Oklahoma Territory, for duty at that post. Lieut.-Col. Albert Hartsuff, deputy surgeon-

general, and Capt. Norton Strong, assistant surgeon, have been ordered to Chicago to assist in examination of officers for promotion. Major J. V. Lauderdale, surgeon, was placed on the retired list.

Obituary.

EDWARD HAZEN PARKER, A.M., M.D.,

POUGHKEEPSIE, N. Y.

DR. EDWARD HAZEN PARKER, for many years one of the leading physicians of Poughkeepsie, N. Y., died in that city on November 10th, in the seventy-third year of his age. Widely known as a physician and surgeon, he was still more widely known as the author of that beautiful poem in which occur the following lines, which were inscribed over the remains of the late President Garfield:

"Life's race well run,
Life's work well done
Life's victory won;
Now cometh rest."

Dr. Parker was born in Boston in 1823, and was the son of Hon. Isaac and Sarah (Ainsworth) Parker, and nephew of Hon. Joel Parker, chief justice of New Hampshire and afterward Dane professor of law at Harvard University.

Dr. Parker graduated from Dartmouth College in 1846, and received his medical degree from Jefferson Medical College in 1848. After graduating in medicine he was at once appointed lecturer on anatomy and physiology at Bowdoin Medical College, and was connected editorially for several years with the *New Hampshire Medical Journal*. In 1853, on being called to the chair of physiology and pathology in the New York Medical College, Dr. Parker left Concord, N. H., and established himself in practice in New York City, two of his confrères in the college being the late Professors Peaslee and Fordyce Barker. During the three years that Dr. Parker held this professorship he established the *New York Medical Monthly*, which he continued to edit personally for many years with great ability and success.

In 1854 he received the degree of A.M. from Trinity College. In 1858, at the solicitation of many friends and patients, Dr. Parker was induced to remove to Poughkeepsie, where he practised with distinguished ability to the time of his death, a period of nearly forty years.

Dr. Parker was at one time president of the State Medical Society, to which he made several important contributions in the way of medical papers. He also was president of the Dutchess County Medical Society for the year 1861, was one of the prime movers in the establishment of the St. Barnabas Hospital, and for many years was attending surgeon and at the time of his death consulting surgeon to the Vassar Brothers' Hospital.

Dr. Parker was a physician of signal competency and skill, and as a surgeon he had few superiors. He was also a man of extremely fine fibre, of unusual cultivation, and high scholarly attainments. His classical education was liberal and sound, his sympathies were most acute, and he was also possessed of a fine poetic talent, which in his busy life was less frequently exercised than his friends could have desired. The single poem mentioned has already enjoyed a world-wide fame, and is one on which many an author would willingly rest his claims for immortality. Surely, as we review the long arduous career now closed, and recall the conspicuous purity and sweetness of character and the self-sacrifice which marked our friend and colleague's long years of devotion to his work, we can think of no other life to which his own tender lines will more fittingly apply.

Society Reports.

SECOND PAN-AMERICAN MEDICAL CONGRESS.

(Special Report to the MEDICAL RECORD.)

Wednesday, November 18th—Third Day.

SECTION ON GENERAL MEDICINE.

Autumnal Fevers of the Southern Atlantic States, and Their Treatment.—DR. BEDFORD BROWN, of Alexandria, Va., presented a paper with this title. The forms of autumnal fever are intermittent, or ague, remittent, and pernicious congestive. The remittent is subdivided into the acute, with sudden onset without premonition, chill, followed by acute active sthenic form of fever, temperature ranging from 103° to 105° F., followed by remission. In this form the curves of temperature are angular, extreme, sudden.

In the prolonged form there are certain premonitory signs lasting several days, as lassitude, neuralgic pains in the head, back, and limbs, loss of appetite, constipation. These are followed by a slight rise of temperature in the evening and remission toward morning. The curves of temperature in this form are slight, gentle, moderate. They never rise high, and during remission fall to the normal or near that point. During the first week of fever they rarely rise higher than 102° F.; in the second week to 103° F.; in the third week to 104° F.; and in the fourth week to 105° F.

This is the form usually mistaken for typhoid fever.

Etiology: The autumnal fevers of the Southern States are almost invariably of malarial origin. Occasionally there are cases of true typhoid. But the epidemic fevers in nineteen out of twenty cases are malarial in origin. The carriers of the malarial parasite, the author held, are both water and air, although the evidences are now greatly in favor of the belief that water is the principal means of the introduction of the parasite into the system. Dr. Brown then discussed the action of the plasmodium malariae on the blood in its relation to the phenomena of fever.

The season of prevalence of autumnal fevers of the South is from early in August to the middle of October. They cease to prevail after the appearance of frost, which is antagonistic to malaria. The symptoms of malarial fever were described, especial note being made of the rhythmic features of the disease. The differentiation between the symptoms of prolonged malarial fever and typhoid was also dwelt upon; and then Dr. Brown discussed the onset, symptoms, morbid phenomena, and course of pernicious congestive fever.

The prophylactic measures discussed were the purification of water, deep and surface water, artesian wells, sterilized water, filtered water, and the sterilization and filtration of water combined. The prophylactic powers of quinine and cinchona were also insisted upon. The author also discussed separately the treatment of intermittent fever, or ague; of remittent fever, acute and prolonged; and of pernicious congestive fever.

Quinine will ever be the chief and only reliable antidote to the malarial parasite. The important question in its administration is the manner of giving the remedy.

Malaria in Morelia.—DR. MARIANO CORDOBA, of Morelia, Mexico, presented a paper containing a study of the causes from which arises the endemic character of malaria in Morelia; the forms under which the disease generally presents itself; the treatment which the experience of many years has indicated as the best; and reflections on the hygienic works which it will be necessary to undertake with the view of suppressing this general scourge.

Facts of Practical Utility with Respect to Malaria.—DR. JOSÉ TERRES, of Mexico City, said that he was about to repeat what he had already said before other medical gatherings, and he did so because he deemed these facts of great practical importance, and they could not be stated too frequently or too emphatically. He had remarked that there was no appreciable difference, either in the number of the parasites or in the form under which they appear in the blood extracted from the finger tip, at whatever period of the attack the examination was made—that is to say, that the plasmodia are equally found during the access of malarial fever, shortly after its appearance, in full apyrexia, or shortly before the next attack comes on.

In malarial cachexia, and when the attacks do not present themselves at stated periods, the parasites are scarcer, and the half-moons and the grains free of pigment are then more frequent.

Ever since the year 1892 he had insisted that it is of the greatest importance in diagnosis to find in the blood, whether free or not, granulations of dark coffee-colored pigment, as such discovery almost guarantees the diagnosis, seeing that the pigment which results upon destruction of the red globules is of a very light coffee color, really yellow, and that the pigment of melanotic cancer is rarely found in the blood.

It being easier to see the pigment than to distinguish the plasmodia, the author considered it both useful and practical to recommend that the former be searched for rather than the latter, by physicians who are not very expert with the microscope or who have not one of high power at hand. The examination for plasmodia ought always to be made with one that increases at least seven hundred diameters.

The administration of quinine to the patient causes the disappearance of the hamatozoa from the blood only when it cures the disease, and in this case it causes them to disappear within two days after the administration is begun; on the intermediate day immovable forms are seen, which are almost always of an irregular shape.

The hamatozoa can live a long time in the blood, multiplying only slightly and without making their presence manifest. Their ordinary course is to make themselves manifest in such cases by destroying the red corpuscles; this is the mechanism of production of the true malaria anemia, which presents itself without any access of fever.

This anemia is the immediate cause of neuralgia, which therefore immediately depends on the action of the parasites. It is probable that they act directly or by means of their secretions on the nervous system, and thus favor the production of the neuralgic form of latent malaria.

When a person whose blood is known or supposed to contain hamatozoa is about to suffer from an attack, he can avoid it by taking, two days previously, the dose of quinine that in that locality prevents the access. This is an important fact for the application of hydrotherapy in the cure of malarial anemia.

Contrary to what is stated by Burdel, the speaker had never seen any glycosuria after the accesses, even after administering one hundred and fifty grams of syrup to the patients.

Quinine ought to be administered immediately after the diagnosis is made. It is an error to believe that it should be given any specific number of hours before the attack.

Orrhothorapy of Leprosy.—DR. JUAN DE D. CARRASQUILLA, of Bogota, United States of Colombia, presented a communication upon "A New Serotherapeutic Process for the Treatment of Leprosy," of which the following is an abstract:

1. The leprous patient is bled, and the serum separated from the blood.

2. The serum of the leper is injected into a horse.
3. The horse so prepared is bled, and the serum separated from the blood.
4. Patients are treated with hypodermic injections of the horse serum.
5. A horse is injected with thirty cubic centimetres of human serum three times, at intervals of ten days. He is bled ten days after the last injection, and is injected afresh after the bleeding. He is bled twenty or thirty days later, and so on successively.
6. The patient receives a hypodermic injection of one to five cubic centimetres every third day, or at longer intervals if any reaction should set in.
7. The injection produces a normal reaction, chill, fever, perspiration or accidental myalgias, arthralgias, neuralgias, cutaneous eruptions, asphyxia, vertigo, etc.
8. The lesions which are characteristic of the disease are at the same time modified: the tubercles are smoothed down and eliminated by absorption, suppuration, or scaling; the spots lose their color or disappear; the ulcers are healed; the sensibility becomes normal; the lost senses are recovered, and the general condition becomes satisfactory.
9. No medicine is administered to control the symptoms of reaction, unless it is lemonade to calm the thirst, and aromatic drinks.
10. The body is washed every day with a warm solution of permanganate of potassium, one to two parts per thousand. The ulcers are dressed with the same solution, aseptic cotton, and a bandage to cover the whole.
11. There are no special requirements as to diet.
12. The injection is not administered when the pulse is accelerated, the temperature is above the normal, or any other symptom of reaction is shown.
13. The horny ulcers on the feet are treated with salicylic acid in collodion. Those on the nasal and pharyngeal mucous membranes are treated with a solution of borate of sodium; the conjunctivitis, with sulphate of copper in a weak solution.

Acute Yellow Atrophy of the Liver.—DR. MANUEL CARMONA Y VALLE, of Mexico City, reported the following case: A man, thirty-eight years of age; a merchant, native of Mexico City, married; a moderate drinker; had never suffered from any previous serious illness. He was obliged to go to Vera Cruz on business, remaining there a week, and returning to the City of Mexico about the end of May. Three days after, and without any known cause, he suffered an intense chill at night, accompanied by cephalalgia, great lassitude, intense fever, and a feeling of nausea without vomiting. On June 24, 1883, he was admitted into the San Andres Hospital. He awoke the next day jaundiced, and suffering from an abundant epistaxis.

At the time of admittance to the hospital his temperature was 40.6° C.; the facies was animated; he showed a marked jaundice color, both of the skin and of the mucous membranes, together with a slightly delirious loquacity, but was able to give rational answers to any questions asked.

He complained of pains in the whole body, but said that he had no fixed pain except in the head; nevertheless, on examination, it was found that a pain appeared with the exercise of pressure on the right hypochondrium. The hepatic dulness was notably diminished and the spleen was very much swollen.

During the four days that the patient was in the hospital, his temperature varied between 39° and 41° C. (102.2° – 105.8° F.); he suffered from frequent epistaxis, hemorrhages from the gums and mucous membrane of the mouth, and, what was most remarkable, a spontaneous sanguineous flow through the urethra, but the urine did not contain any more blood than that which was carried by its natural flow. The symptoms

of ataxo-adyndamia shortly set in, and the patient died on the fourth day after admission to the hospital and the seventh of his sickness.

In the post-mortem the liver was found to be very much reduced in volume, and weighed six hundred and fifteen grams. It was of a yellow color like wash leather, of a soft consistency, and contained very little blood. The spleen was swollen and diffuent, and the blood in the vessels was dark and glutinous.

A microscopic examination of the liver showed that the cells had completely disappeared, and that the hepatic parenchyma had been transformed into a network of connective tissue, with its meshes entirely empty. The veins, especially the suprahepatic veins, had their walls thickened and their lumen was obstructed by thrombi.

The doctrine that now prevails with respect to the nature of icterus gravis can be summarized in the following formula, taken from the "Manual of Medicine" by Debove and Achard: "Icterus gravis is the visible sign of the rapid destruction of the hepatic cells, manifested by a typhoid condition with jaundice and hemorrhages."

Probably it is not necessary that the cellular destruction should be very rapid, seeing that there are certain forms of icterus gravis which last for a year and even more.

This being the case, it may be asked: Why is it that in ordinary cirrhosis and in simple atrophy of the liver there are no symptoms of icterus gravis? On the other hand, how can we explain the appearance of jaundice by the sole fact of the cellular destruction, when we know that the hepatic cell is that which produces the bile?

In the case presented there was evidently a suprahepatic endophlebitis, resulting in an obstruction of these vessels and a consequent destruction of the hepatic cells.

Comparing this result with that obtained by the study of the disease called by the speaker "intercellular hepatitis," and which consists in a swelling and hardening of the liver, accompanied by all the phenomena that are characteristic of severe jaundice, it is seen that in the latter disease the anatomical lesion is the periphlebitis that commences in the suprahepatic veins, obstructing their channels through the abundant conjunctive proliferation, and later on destroying the cells that form the hepatic lobes. From this, Dr. Carmona concluded that icterus gravis is produced by a disturbed circulation (produced by microbes or not) in the suprahepatic veins; that these disturbances first exaggerate the cellular functions, and later on destroy the cells themselves.

The variations in the progress of the disease and in the concomitant symptoms depend on the extent of the lesion and the form of the phlebitis.

Among other papers read by title or by the authors in this section were the following: "Connection Between the Temperature of the Patient and the Species of Bacteria which are Found in Appendicitis," by Dr. Robert T. Morris, of New York; "Antitoxin of Tubercle," by Dr. Paul Paquin, of St. Louis, Mo.; "Pernicious Malaria," by Dr. H. L. Bibb, of Colonia Station, Mexico; "Scirolula," by Dr. Fred. R. Weber, of Milwaukee, Wis.; "On Medicine," by Dr. Joaquin Martinez, of Pachuca, Mexico; "Tuberculosis in Mexico," by Dr. Francisco Blasquez, of Mexico City; "Notes for the Study of Typhus in Mexico," by Dr. Jesus Jiménez, of Mexico City; "Results of Several Original Experiments on Cancer in Animals," by Dr. Joshua M. Bulman, of Mexico City.

SECTION ON GENERAL AND ORTHOPÆDIC SURGERY.

Arterial Catheterism.—DR. ROQUE MANCOZET, of Morelia, Mexico, reported two cases of amputation, one of the thigh at the junction of the lower and middle thirds, the other at the point of election in the leg. The disease necessitating amputation in both cases was dry gangrene.

In the first case, a rheumatic endocarditis produced embolism of the femoral artery, thereby causing gangrene of the foot and leg up to the upper third. Having made certain of the diagnosis, the speaker amputated the thigh in the lower third, and to his great surprise, on removing the tourniquet, no arterial blood issued, but only venous. The femoral artery was completely open and empty, and he then decided to perform an arterial catheterism, with the object of re-

moving the obstruction in the artery and saving the patient from an operation for disarticulation of the thigh. This operation was carried out by means of a urethral bougie, made of whalebone and carefully disinfected. Dr. Mancozet lightly pressed against the obstacle, and with the help of the left hand, practised a soft massage in its neighborhood and over the artery. He commenced by moving the embolus and then loosened it, immediately after which a torrent of arterial blood burst forth.

The history of the other case was similar to the above, and in both cases the method resulted in a perfect and lasting success.

Radical Cure of Prostatism.—DR. RAMÓN MACIAS, of Mexico City, presented a communication on this subject. Prostatism, he said, is generally initiated in youth, is confirmed at the adult age, and is complicated by terrible accidents, which unfortunately are often mortal, during old age. Masturbation sometimes, and blennorrhagia almost always, are its first causes. The neglect of patients on the one hand, and the insufficient or erroneous treatment on the other, account for its passing on to a chronic condition.

The imprudent conduct of some old men, carelessness on the part of the physician, and the want of surgical therapeutics of a wise and timely character, explain its sad mortality.

That blennorrhagic infection engenders prostatitis is beyond a doubt. What is open to discussion, although for the speaker it is a fact, is that many cases of profound urethritis, and all those cases which up to now have been called cystitis of the neck, are nothing more than inflammation of the prostate.

Prostatism in youth and in mature age is not similar to that of old age, just as the anatomic-pathological condition of the urinary organs at these ages is not similar.

In the youth and in the adult man, congestion and enlargement predominate in the cells, though mostly of a transitory character, together with inflammation, exudation, and suppuration. In old age, passive congestion, new formation with cellular transformation, permanent enlargement of the tissues, neoplasms, and degeneration predominate.

In the youth and the adult, the hæmatic infection is of a vital origin through toxins. In old age, the blood is infected through the products of disassimilation, which are not eliminated, or which are reabsorbed together with certain chemical products, which mostly arise from putrid or ammoniacal fermentation.

The symptomatology of prostatism between the ages of eighteen and forty-five is not uniform. The books treating of genito-urinary diseases speak of spermatorrhœa, of chronic prostatitis, the existence of which some accept and others deny, of deep urethritis which is propagated or not to the seminal ducts, of cystitis of the neck, of vesical or renal calculus, etc.; but in none of them do we find any consistent doctrine which shows that all or the greater part of these diseases have originated in the prostate gland.

The principal intention of this paper was that of unifying the pathology of the uro-genital apparatus, demonstrating that prostatism exists as a constant cause for the sufferings of a great number of patients who up to this date have been treated only for secondary affections. We should be able to have uniform symptomatological tables that would lead us to reasonable medical or surgical therapy.

Internal medication exercises a very limited action on prostatism and its consequences. Surgical treatment constitutes the only means we have for the prompt and radical cure of confirmed prostatism.

The author includes among surgical measures antiseptic washings, medicinal instillation, catheterism, and, naturally, bleeding; also perineal cystotomy,

prostatotomy, curettage, and direct or indirect canalization.

Prostatic hypertrophy can not only be alleviated but also radically cured in many cases. The urethral form ought to be treated by the process which Dr. Macias calls "enucleation."

When the vesical form is greatly exaggerated, it requires a total extirpation of the growth and the restitution of the vesical funnel. The author's method by four sections with the galvano-caustic loop realizes this intention, he believes, with less danger and with a better guarantee of cure than any other procedure known up to this date. He proposes the use of an instrument which he calls an "enlarging speculum" of the bladder.

Diphtheria of the Penis.—DR. WILLIAM P. MUNN, of Denver, Col., reported three cases of this condition, which he regarded as one of rare occurrence, there being, so far as he could discover, no previous references to it in medical literature. It may occur whenever any operative treatment of the penis has been undertaken under circumstances that have permitted of diphtheritic infection. Before bacteriological methods of diagnosis were perfected it is probable that this condition was confounded with erysipelas, gangrene, or simple septic infection following operation.

The three reported cases occurred in the practice of three different surgeons, in the persons of children and subsequent to circumcision. In two, the diagnosis was made by bacteriological diagnosis, confirmed by a perfect succession of clinical signs. In the other, clinical appearances alone led to the diagnosis. In one instance, the child's mother was suffering from a mild sore throat at the time of operation and the infection probably came from her. In another the patient's mother and brother were found to have diphtheria after the operation; it could not be stated whether they infected the child or whether the child was first infected and conveyed the disease to them. In the other case, there was no recognizable history of infection, although the patient suffered from faucial diphtheria one year later.

All cases of infection of circumcision wounds, in children at least, should be subjected to bacteriological examination, both to promote exact diagnosis, to guide in the treatment of the case, and to permit of proper precautions for the prevention of contagion.

Antitoxin should be administered without delay, and local antiseptic measures should be resorted to. Catheterization should not be permitted, as there is danger of infecting the urethra and bladder.

Suprapubic Cystotomy.—DR. MIGUEL OTERO, of San Luis Potosi, Mexico, read a paper on cystotomy in which he expressed the conviction that perineal cystotomy was being gradually abandoned and that it was not long before it would cease to be a recognized surgical procedure, except under special and very rare conditions. The suprapubic operation was the one which would be chosen by preference, as it is free from the dangers of perineal section, such as hemorrhage, laceration of the prostate, persistent fistula, etc.

Other papers read in this section, either by the authors themselves or simply by title, were the following: "Kraske's Operation for Imperforate Rectum," by Dr. Rudolph Matas, of New Orleans; "Asbestos Fire-proof Surgical Dressing as Adapted to Army and Emergency Practice," by Dr. Evan O'Neill Kane, of Kane, Pa.; "Surgical Treatment of Bladder Diseases," by Dr. Ramon Guit  ras, of New York; "The Surgical Treatment of Epilepsy," by Dr. Edmund J. A. Rogers, of Denver, Col.; "The Treatment of Colles' Fracture," by Dr. Leonard Freeman, of Denver, Col.; "Treatment of Stricture of the Urethra by Continuous Elastic Dilatation," by Dr. Robert J. Wilding, of Malone, N. Y.; "Treatment of Chronic Gonorrh  a,"

by Dr. Ferd. C. Valentine, of New York; "The Value of the Roentgen Rays in Surgery," by Dr. Carl Beck, of New York; "The Effect of Operations *per se* in Tuberculosis and Malignant Growths," by Dr. A. C. Bernays, of St. Louis, Mo.; "Cerebral Tumors and Abscesses," by Dr. George N. Lowe, of Randall, Kan.; "The Surgical Treatment of Movable Kidney," by Dr. W. Easterly Ashton, of Philadelphia, Pa.; "Surgical Treatment of Gall Stones," by Dr. James T. W. Ross, of Toronto, Canada; "New Method for the Radical Cure of Crural and Inguinal Hernias," by Dr. Adrian de Garay, of Mexico City; "On Surgery," by Dr. Guillermo Parra, of Mexico City; "Personal Experience in the Treatment of Gunshot Wounds during the late Civil War in the United States as Contrasted with the Modern Aseptic Treatment," by Dr. Robert Reyburn, of Washington, D. C.; "The Deformity Following Fracture of the Femur," by Dr. Edward Martin, of Philadelphia, Pa.; "Hypnotic An  sthesia," by Dr. Thomas Bassett Keyes, of Chicago, Ill.; "Surgical Treatment of Insanity," by Dr. Ernest Laplace, of Philadelphia, Pa.; "A New Operation for the Radical Cure of Femoral Hernia," by Dr. George M. Edebohl, of New York; "The Electro-Cautery as a H  mostatic in Surgery," by Dr. Alexander J. C. Skene, of Brooklyn, N. Y.; "Suturing of Arteries Injured in Continuity, Experimental and Clinical Research," by Dr. John B. Murphy, of Chicago, Ill.; "On Surgery," by Dr. Joaquin Martinez, of Pachuca, of Mexico; "Renal Calculus" (the author presented a specimen weighing forty-five grams), by Dr. Ignacio Espinosa, of Morelos, Mexico; "Laparotomy and Fixation of Rectum by Sutures to Anterior Abdominal Wall in Several Cases of Prolapsus of the Rectum, with Report of a Successful Case," by Dr. Herman Mynter, of Buffalo, N. Y.; "Mastoid Diseases and Operations," by Dr. Seth Scott Bishop, of Chicago, Ill.; "Varix in the Lower Extremity," by Dr. Thomas H. Manley, of New York.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Intestinal Anastomosis.—DR. J. FRANK, of Chicago, read a paper on this subject, showing his decalcified bone button and numerous specimens in which divided ends of intestine had reunited while held by it in apposition. The dog which had been operated upon the previous day at the San Andres Hospital was shown and was then killed by chloroform. Upon opening the abdomen, the portion of the intestine on which the operation had been performed being cut out, it was found that a perfect union had resulted in the twenty-eight hours intervening between the operation and the animal's death. The bone plates were partially dissolved, and the continuity of the intestine was practically demonstrated.

Statistics from the Maternity Hospital of Puebla.—DR. JOS   MARIA DE ITA, of Puebla, Mexico, read a paper based upon the statistics of this hospital for the two years ending September 30, 1896. The mortality was one-half of one per cent., and no case of puerperal septic  mia occurred in this time. The antiseptic used was bichloride of mercury, and the following was the mode of its employment: Before labor, the genital organs having been washed externally and internally with soap and water, after the tepid-water bath and thorough evacuation of the rectum and bladder, an injection of solution of bichloride of mercury 1-2,000 was made, care being taken to disinfect thoroughly the fundus of the vagina by swabbing with the finger. The douche was repeated every six or eight hours during labor. After labor a vaginal injection of the same solution was made. In case of surgical interference or when rupture of the membranes had occurred before the arrival of the physician or mid-

wife, an intra-uterine injection was made with the same solution. The bichloride injections were continued also during the first three days after parturition.

The following papers were read by the authors or by title: "Management of Occipito-Posterior Positions," by Dr. Louis Faugères Bishop, of New York; "Treatment of Post-partum Hemorrhage," by Dr. J. C. Currie, Chicago, Ill.; "Intestinal Obstruction," by Dr. George W. Woods, U. S. Navy; "Vaginal Incision and Drainage in the Treatment of Peri-uterine Septic Diseases," by Dr. W. E. B. Davis, of Birmingham, Ala.; "Electrolysis in Endometritis," by Dr. Gustavo O'Farrill, of Puebla, Mexico; "A Contribution to Abdominal Surgery," by Dr. Alfonso Ortiz, of Alamos, Mexico; "Penetrating Wounds of the Abdomen," by Dr. Santos Medina, of Juchipila, Mexico; "On the Treatment of Puerperal Fever," by Dr. Rafael Norma, of Tulancingo, Mex.; "On the Technique and Results of Abdominal Hysterectomy," by Dr. Ernest Cushing, of Boston, Mass.; "Hysterectomy, its Applications and Technique," by Dr. Charles Bingham, of Philadelphia, Pa.; "Indications Respecting the Best Technique in the Operation of Shortening the Round Ligaments, with Favorable Results in Seventy-five Cases," by Dr. Laphorn Smith, of Montreal, Canada; "Treatment of Uterine Diseases and Appendages through the Vaginal Channel," by Dr. R. Stansbury Sutton, of Pittsburg, Pa.; "Rational Treatment of Pelvic Abscesses," by Dr. H. J. Boldt, of New York; "Hysterectomy," by Dr. Albert H. Tuttle, of Cambridge, Mass.; "Hysterectomy," by Dr. J. T. Johnson, of Washington, D. C.; "Septic Endometritis and Its Cure," by Dr. T. Griswold Comstock, of St. Louis, Mo.; "The Relation that Pelvic Deformity Bears to Unassisted Instrumental and Surgical Obstetrics," by Dr. Hugh Hamilton, of Harrisburg, Pa.; "Review of Disputed Points in the Treatment of Inflammatory Trouble of the Pelvic Organs," by Dr. Joseph Price, of Philadelphia, Pa.; "Remarks on Hydrocele of the Umbilicus with a Report of a Case," by Dr. Charles G. Cumston, of Boston, Mass.

PAN-AMERICAN CONGRESS NOTES.

The Inaugural Session was held in the Teatro Nacional, which had been specially and most effectively decorated for the occasion. The background of the decoration of the body of the theatre was scarlet. The fronts of the boxes were artistically draped with the flags of all the republics of America and with their coats of arms. The flags and escutcheons of Spain, France, and England were also displayed. The stage decorations were Aztec. An imitation of the calendar stone rose behind the dais of the President. The sides of the stage were enclosed with scenery representing Aztec architecture and trophies. In the centre of the tiers of boxes opposite the stage was a mammoth star of tricolor electric lights, in the centre of which was the mortar with coiling serpent. Flowers were everywhere in reckless profusion, such as can be seen only in this land of roses. Between each of the addresses a musical selection was rendered by an excellent orchestra. Following the report of Dr. Licéaga the Mexican national hymn was sung by the pupils of the Conservatory of Music, the audience in the mean while standing.

The President's Address.—The following is the full text of the address of welcome pronounced by General Diaz at the opening session, as stenographically reported by the *Mexican Herald*:

"Gentlemen: In the name of the government and the people of this republic, I extend to you the most cordial welcome. The Mexican nation, and the people of this capital in particular, rejoice at your presence, for it signifies not only the brotherhood of all

the nations on this continent, but the community of their efforts to promote a science which is of more interest to humanity than any other. The aim of that noble science is to preserve or restore the priceless blessing of health, and when it fails of attaining that aim to the fullest extent, it at least alleviates the ills that constitute the sad inheritance of humanity and is a timely auxiliary in warding off ailments.

"On this account, gentlemen, your coming to Mexico is for me and for all my countrymen a source of profound and sincere gratification, and, on this account, too, the Mexican government takes pleasure in aiding you in your labors to the best of its ability.

"We are cordially grateful for your choice of this city as the scene of the sessions which have to-day been inaugurated. It is to be hoped that those sessions will strengthen the cordial understanding and growing intercourse among the physicians of the New World, to the immense advantage of the useful science to which you have devoted your lives. I hope, too, that your short stay in this country, besides being useful in promoting the cause of science, will also be agreeable to you personally and that you will carry away with you as pleasant a memory of Mexico as I am sure your visit will leave among us."

The Number of registered members of the congress was four hundred and forty.

The Entertainments.—On Sunday evening preceding the opening of the congress, a reception was tendered the visitors in the School of Medicine by the physicians of the city. On Wednesday evening the members of the congress were entertained by the city council in the rooms of the Municipal Palace, the Cathedral Square and the principal approaches to it being illuminated. There were also fireworks in the plaza in honor of the guests. The rooms were beautifully decorated, and supper was served in the patio, or central court, of the building, which had been transformed into the semblance of a grotto brilliantly illuminated with incandescent lights. The crowning entertainment of all was a reception tendered to the visiting physicians and their ladies by the President of the Republic and Mrs. Diaz on Thursday afternoon in the Castle of Chapultepec. The palace is built upon a high mound which rises from the plain about two miles from the city. It was the ancient seat of the Aztec kings, later the residence of the Emperor Maximilian, and now the home of the President. The view from the broad balconies of the palace is accounted one of the most beautiful in the world. On Friday evening those members of the congress who still lingered in the city were pleasantly entertained at a reception given in the handsome rooms of the Jockey Club. The various hospitals, the schools, the new slaughter house, the penitentiary, the libraries, and all of the public buildings were open for inspection of the visitors. Excursions were also made in small parties to the drainage canal, the Shrine of Guadalupe, the gardens of Tacubaya, and other points of interest in the neighborhood. On the Sunday preceding the opening of the congress, the churches and the promenade in the Alameda were visited in the morning, and the Basque ball games, the bull fight, the horse and bicycle races, and the drive on the Paseo de la Reforma all received their quota of strangers in the afternoon.

The Spirit of Investment which is abroad in Mexico invaded the sacred precincts of the congress halls. Those attending the general session had thrust into their hands a circular of a Mexican physician who claimed to know a remedy for pulmonary tuberculosis, and desired to establish a sanatorium in a favorable locality of which he also knew. He modestly asked for a partner willing to put \$20,000 (good American gold, not Mexican silver) into the enterprise. Several

others of the visitors were approached to take up and exploit an herb growing in some secluded spot in Mexico, which was asserted to be an unfailing remedy for rheumatism of all sorts, acute and chronic. Others were solicited to throw medicine to the dogs and invest in coffee plantations in a country where the wages of the laborers could be paid in silver while the product of the soil would be sold for gold.

The Speakers at the First General Session were in most cases inaudible. They occupied a little box at one side of the stage, and addressed the President of the Republic, nearly turning their backs on the audience. A notable exception was Dr. Pepper, who stationed himself in the centre of the stage, seemingly to the consternation and horror of those who were escorting him to the little box, and turned toward the President only when he was directly addressing him, but toward the audience when his remarks were directed to them. His voice also was that of a practised speaker, and it was evident that his words were understood by many, even of his Spanish-speaking auditors.

The First Medical School in America was established in Mexico; the first printing-press on the western continent was set up in the same city.

The Altitude of Mexico (the city lies about seven thousand feet above the level of the sea) affected most of the visitors rather unpleasantly, causing them to suffer from shortness of breath on slight exertion. Several were even more seriously inconvenienced, and some had to descend at once to a lower level, on account of threatening heart symptoms, before the congress was over.

The Weather of the Congress Week, like weather everywhere and always, was exceptional. The temperature was abnormally low a part of the time; the mornings, which should have been brilliant, were usually dull, cloudy, and chilly; and the rain, which ought not to have come at all or at most in brief, smart showers, fell on several occasions in a persistent drizzle.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, November 19, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

The Object of the Anniversary Meeting.—THE PRESIDENT, before introducing the essayist, explained the purpose of the anniversary meetings to that portion of the audience, composed largely of the lay public, not familiar with the academy. It was customary, in commemoration of the birth of extraordinary events and of persons, to have an anniversary. The academy had regularly held an anniversary since its establishment. At that time it was customary to review important medical history. It seemed to him that an anniversary was a very wise provision, inasmuch as it connected with great distinctness the past with the present and the present with the future. The anticipations of the past became the realizations of the present, and we appreciated that the realization of the present gave hope for the future. At the last anniversary the library contained fifty-five thousand volumes, to which there had been added during the year twenty-five hundred more—a most healthy increase. That which might be of greater interest to the profession and the public was the fact that by the efforts which had been put forth during the year the library fund had been increased \$30,000, making a total amount of \$52,000. The aim of the academy was to secure a sufficient amount of money so that, with what it already possessed, it should have a round sum of \$100,000, the income of which should be devoted to no other purpose than that of adding to the library. The president an-

nounced that some time in January the academy would celebrate its semi-centennial, for which purpose the use of Carnegie Hall had been secured. President Cleveland would honor the occasion by his presence and by his speech.

The Evolution of the Surgery of the Twentieth Century.—DR. GEORGE R. FOWLER delivered the anniversary address. In choosing for his subject the evolution of the surgery of the twentieth century he sought to do more than simply chronicle the brilliant achievements accomplished during that period. It was his endeavor to point out the relations which the more important events bore to those processes of intellectual evolution which had made all things possible which had come to pass during the century. Discovery had followed discovery in unceasing and rapid succession. In looking back over the century, how rich the harvest had been, and yet how much had not yet blossomed! The development of the ligature for the control of hemorrhage, the discovery of anæsthesia and of antisepsis, stood in as important a relation to surgery as did Newton's discovery of the law of gravitation to astronomy. It was upon the development of these three essentials to the perfection of the surgery of the twentieth century, and the discovery of the Roentgen ray, that the orator dwelt in his essay. "The lessons of the past gather about us like the falling leaves of a summer's departing glory. But these lessons are not wasted. They but serve to emphasize man's opportunity now present and his hopes for the future. Not the least among these is that which teaches us that the unfolding of nature's secrets is but a part of the law of creation: that irresistible forces are at work evolving truth and casting out error: and that man's present position in this great work removes him from the place of the creation of the hour, and stamps him as the product of time and the heir of all eternity. The century upon the threshold of which we stand is lighted with jewels of hope in golden setting, and its atmosphere is filled with the sweet music of promise."

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, November 16, 1896.

JOSEPH E. JANVRIN, M.D., PRESIDENT, IN THE CHAIR.

Appendicitis Complicating Pregnancy.—DR. ROBERT ABRAHAM read the paper. If appendicitis in general merited so much attention as had been given it the past few years, how much more in pregnancy, when two lives instead of one were in jeopardy! Yet up to a short time ago appendicitis in pregnancy was unknown in medical literature, if a brief report of one case were excepted. It was not quite two years since Dr. Mundé's celebrated case was put on record, but now physicians everywhere realized the possibility of its occurrence, and were on the lookout to diagnose it. Up to the present, eleven cases had been placed on record, ten of them suppurative, one catarrhal. The author in this paper added four new ones, and their interest lay in the fact that the mothers as well as the children escaped an untimely death. The first case was one of catarrhal appendicitis, seen with another doctor in the city, October 1, 1895. The symptoms related to pain at McBurney's point, tumor, increased pulse, some elevation of temperature. These symptoms gradually disappeared, but on October 20th labor set in and a child was born at seven and a half months. It lived six days. The mother fully recovered, and had no pain after delivery. The second case was in a woman seven months pregnant. There were the constitutional symptoms referable to the pulse and

temperature, and locally pain, but no tumefaction. Diagnosis, catarrhal appendicitis. This patient was much constipated. The symptoms subsided after nine days, under cathartics, etc. She was delivered of a healthy child at term. He had treated her in two attacks of recurrent appendicitis since, but she refused operation. In the third case the patient was also habitually constipated: the temperature, pulse, localized pain, vomiting, and later some tumefaction established the diagnosis, and the patient was sent to the hospital, where the diagnosis was concurred in and an operation was about to be performed, but improvement began and she recovered without operation. He had not seen this patient since. The fourth case was one of traumatic appendicitis, which was also seen by Dr. Mundé, who concurred in the diagnosis but suggested waiting for a time. The patient markedly improved, but still had some pain in the region of the appendix. She was in the ninth month of pregnancy.

The pathology and etiology were for the most part the same as in women not pregnant, but the enlargement of the uterus would affect adhesions: and in all of his cases but one there was a history of obstinate constipation, which he thought might have been a cause, and pointed to the necessity for attention to the bowels during the pregnant state. As to diagnosis, the presence of the enlarged uterus would interfere somewhat with palpation and percussion, but with care local signs could be recognized if present. In all obscure cases, anæsthesia should be employed. The chief disease in differential diagnosis was tubal pregnancy, but here the duration of the tumor before rupture was only four months, and it need hardly be thought of after that period. As to hæmatocele, in only one of the cases on record had a tumor of doughy feel at the vault of the vagina proven to be a case of appendicitis. Inflammation of the pelvic organs, ovaritis and salpingitis, was almost always infectious in origin, so that the history would be found of value in diagnosis. Floating kidney and renal calculus might occasionally be mistaken for appendicitis, but patience and care would clear up the error. Typhoid fever offered some difficulties in diagnosis.

As to prognosis, in reported suppurative cases there had been seven deaths out of ten, or a mortality of seventy per cent. In all of the cases of catarrhal appendicitis the patients had recovered. Of subjects operated upon, only one child had lived; the others had perished before or after the operation. Of the total number of reported cases of pregnancy complicating appendicitis—fifteen—eight resulted in recovery, and eight in death.

All cases, unless running a very mild course, should be operated upon early. He gave the following rules, partly his own and partly from Willy Meyer: 1. Operate early, within twelve hours, in acute perforative appendicitis. 2. Take the pulse as a guide, 106 to 120 being an indication for operation. Dr. Abrahams added to this rule that the pulse should not only be rapid, but should be out of proportion to the temperature. 3. In cases of doubt operation is better than waiting. 4. Sudden lull of the symptoms, and within ten or twelve hours sudden recurrence. 5. In cases of old appendicitis lit up during pregnancy, operation ought to be done, even if the attack is a mild one, especially if it occurs early in pregnancy. Laparotomy is then easy and removes the possibility of future attacks when operation may not be easy.

Commends Early Operation.—DR. PAUL F. MUNDE referred to his case which had been mentioned in the paper, and said that when it was published it became the subject of general attention, as if it had never occurred to anybody that a woman who was pregnant could have appendicitis. But after his attention had been called to the subject by this case, he could see no

reason why a woman who was pregnant might not have appendicitis as well as anybody else. Since then he had seen several cases, and had published a very instructive one in the *MEDICAL RECORD*. He would not hesitate to operate, no matter what the period of pregnancy, and would expect to get as good results as in non-pregnant women. He was under obligations to the author for having put several cases into his hands, and was glad to share any honors with him.

DR. ROBERT T. MORRIS thought appendicitis had in all probability occurred frequently in pregnant women, but had been overlooked on account of there being other diseases which simulated it. We could fairly expect it to occur rather more frequently during pregnancy, for two reasons: 1. In pregnant women the appendix hung over the pelvic brim in about thirty-five per cent. of the cases, and in this position was liable to become bruised by the enlarging uterus. 2. In many cases adhesions existed, and as the uterus enlarged and rose out of the pelvis they were likely to be broken up and excite appendicitis. He thought he had had four or five cases of appendicitis in which pregnancy had played a rôle, but had not published them separately from his other cases. Regarding catarrhal appendicitis, he had not seen it in any case operated upon, yet he did not doubt that catarrh of the intestine might extend to the appendix. When symptoms arose peculiar to appendicitis, infection and exudation had taken place, which put the case out of the category of catarrhal appendicitis. Regarding diagnosis, he supposed there was some difficulty in distinguishing in some cases between typhoid and appendicitis. At least, he had seen a few cases with eminent physicians in this city, in which there was a difference of opinion, and, inasmuch as an operation was not performed, the diagnosis was not settled. Resisting tonic spasm of the abdominal wall served to distinguish acute appendicitis from typhoid and salpingitis. It was very seldom that surgeons made a mistake and operated for appendicitis when it did not exist. Dr. Morris said doubt was disappearing among the experienced with regard to ability to palpate the normal appendix.

Tubal Pregnancy Mistaken for Appendicitis.—DR. WILLIAM T. LUSK related a case which showed that even experienced surgeons as well as gynecologists sometimes made a mistake in diagnosing appendicitis. The patient was a girl of nineteen years, of excellent character, exceptional family, who had an attack of pain in the right side and other symptoms of appendicitis. The symptoms subsided, and she had another attack, in which he was called to examine the pelvic organs. The pain was in the right side. He found the tumor behind the uterus on the right. A surgeon of distinction saw the patient and diagnosed appendicitis, and recommended operation. All who examined her thought they felt the thickened appendix. On operation Dr. Lusk found in this young girl of exceptional character, who had given no history of passing by a menstrual period, tubal pregnancy. In this instance, the clearness with which his experienced friends had felt the supposed diseased appendix through the abdominal walls, was certainly very delightful!

DR. H. J. GARRIGUES had operated upon one case of appendicitis complicating pregnancy, and while he thought before the operation that the mass might be the diseased appendix, yet there was no reason to suppose that it might not be a neoplasm. The operation decided the diagnosis. The patient did well, but subsequently developed pleurisy, which led to exhaustion.

The Appendix Better Nourished in Females.—DR. WILLY MEYER had operated in about two hundred cases of appendicitis, and in only one did the disease complicate pregnancy. He had seen one of Dr.

Mundé's cases also. It seemed to be a clinical fact that appendicitis occurred more frequently in males than in females, and in trying to account for it he was disposed to think it might be due to better nutrition of the organ in females, and in them this was at its height during pregnancy. The case seen by him was a patient of Dr. S. Marx. She had had her first attack of appendicitis about the eighth month of pregnancy. It subsided under expectant treatment. A week later she had pain again, and gave birth to a child. A few hours after delivery she had a chill, high temperature, and symptoms of acute appendicitis. She was again treated on the expectant plan, recovered, and Dr. Meyer saw her afterward with Dr. Marx in a third attack, and they operated. An unusual condition was found. The appendix was situated in a sheath of new tissue, and when withdrawn was found to measure eight and one-half inches in length. Dr. Meyer had seen so many cases of recurrent appendicitis that he had come to the positive conclusion that all persons should be operated upon who had had one well-defined attack. The conscientious physician should turn them over to the surgeon at a time when ideal surgery could be done, guaranteeing the patient against future attacks of appendicitis and also against hernia in the operation wound.

Another Mistake in Diagnosis.—DR. HOWARD LILIENTHAL agreed with what seemed to be the consensus of opinion, to operate in time in all cases of severe appendicitis. He then mentioned a case of what seemed clearly to be appendicitis complicating pregnancy, although the possibility of typhoid fever was not excluded. He saw the case with Dr. Vineberg, who had already made up his mind to operate, but at the request of the family called Dr. Lilienthal in consultation. They operated and found an absolutely normal appendix, and nothing to account for the patient's symptoms. The patient growing steadily worse, Dr. Vineberg emptied the uterus. The collapse became more profound, and nobody supposed she would live, but there was a sudden turn for the better and she recovered. Regarding the diagnosis between appendicitis and typhoid fever, it should be remembered that the appendix might become perforated in the latter disease. He had seen two such cases.

Catarrhal Appendicitis.—DR. BERNARD S. TALMEY said, with regard to one not seeing the appendix in a state of catarrhal inflammation, the reason was clear: one did not operate in such cases. To deny the possibility of its occurrence was as reasonable as to deny the existence of catarrhal nephritis or catarrhal inflammation of the lungs, because not found in cases operated upon. Perhaps in not more than ten per cent. of all cases of appendicitis was it necessary for the physician to call in the surgeon; the other ninety per cent. got well. Now, since but few of the other forms of appendicitis recovered without operation, it was fair to infer that the ninety per cent. were catarrhal.

Constipation and Appendicitis.—DR. HENRY ILLOWAY referred to the fact that in most cases of operative appendicitis fecal concretion had been found, and to the further fact that in many instances, especially in pregnant women, there was a history of constipation. He thought the constipation might be an important factor in lighting up an attack of acute appendicitis by the pressure exerted through the hard masses upon the fecal concretion, which really was a foreign body within the appendix. In this way the fact was accounted for that appendicitis was set up from within the organ and not from without, the pressure simply being the means of opening the way to infection from within.

DR. ABRAHAM made some closing remarks.

Fatal Secondary Hemorrhage Following Nephrectomy.—DR. THOMAS MANLEY presented a kidney, the

seat of pyonephrosis from multiple abscess, which he had removed. He lost his patient the next day from secondary hemorrhage, although he had taken the extra precaution to put two ligatures around the vessels at the time of the operation.

Resection of Intestine in Hernia.—DR. MANLEY also presented twenty-six inches of small intestine, removed for gangrene in a case of strangulated hernia, the anastomosis practised being that of Connel, of Milwaukee. It was the operation which he commended above all others. His patient recovered.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Semi-Annual Meeting, Held at Hagerstown, Md., Tuesday and Wednesday, November 10 and 11, 1896.

WILLIAM OSLER, M.D., PRESIDENT, IN THE CHAIR.

First Day—Tuesday, November 10th.

AFTER an address of welcome by DR. J. W. HUMRICHOUSE, of Hagerstown, which was responded to by DR. WILLIAM OSLER, of Baltimore, the regular order of business began.

Continued Fevers.—This was the subject of a paper by DR. C. BIRNIE, of Taneytown. He related several cases of fever lasting from two to six weeks, or sometimes longer, lacking the characteristic symptoms or lesions of typhoid or malarial fever and not due to any definite lesion. He gave the points of distinction between the two cases related and typhoid fever. In many instances he treated the patients symptomatically. He found that antipyretics were useless and harmful. Phenacetin was very successful in his hands.

DR. JOHN C. HEMMETER asked what were the latest views concerning gastric fever; some insisted that such fevers did exist and others that they did not.

DR. BIRNIE said that no microscopic examination had been made in these cases, and he was of the opinion that gastric fever was more of a gastric catarrh.

DR. OSLER said that he had no personal knowledge of gastric fever.

DR. CHARLES M. ELLIS, of Elkton, said that he had had an experience similar to that related by Dr. Birnie.

DR. A. S. MASON, of Hagerstown, said that such cases as those related by Dr. Birnie were known to physicians and he was inclined to call them continued fevers; he did not know how else to classify these cases if not as simple continued fevers. In some cases quinine had no effect at all. He referred to an epidemic that spread over this country twelve years ago. He had had sixty or seventy such cases and typhoid cases from polluted water, but also many cases with no local disturbance. He did not know the classification of these fevers.

DR. GEORGE J. PRESTON said that the subject of the continued fevers was of great practical importance, and spoke of the physiology of heat and cold production in fevers. We did not give due weight to the physiological questions in the study of this fever. We often had distinct hysterical fever running over weeks; these were rare cases but they did occur. We rarely saw such cases in the hospital, because these mild cases did not usually enter the hospital. We did have certain cases, in typhoid fever, as a rule, such as walking typhoid fever, which was made known by the relapse. The enlargement of the spleen and liver was not diagnosed. The diazo reaction had not met with much success in his hands. There were many cases of fever in which quinine was of no use.

The Nature and Treatment of Gastric Acidity.

—This was the subject of a paper by DR. JOHN C. HEMMETER. He asked if there was a distinct lesion in these troubles or not. The question had often been asked, but, not having arrived at conclusions, he had examined the gastric contents with the double test meals of Salzer. These two consecutive meals represented an ordinary diet, and by them one could determine the number of important pathological states in gastric digestion almost without further analyses. These test meals consisted, first, of a cup of milk and a plate of rice with a piece of bread, followed four hours later by a roll and a glass of water. If the stomach contents were removed one hour after the second meal, there should be no remnants, if the stomach was healthy. Proteid remnants, such as meat and eggs, would point to anacidity, while a hyperacidity would be indicated by a large amount of carbohydrates in the remnants. After a few words on the digesting power of the stomach, he concluded by some important directions on the dietetic treatment in this trouble.

Cerebral Syphilis.—This was the subject of a paper by DR. GEORGE J. PRESTON. The symptoms of this trouble were very varied and the history of the primary lesion was often uncertain. Moreover, the interval between the primary lesion and the brain troubles might be so long as to make the connection between the two uncertain. Meningitis from syphilis was nearly always chronic, the symptoms coming on gradually, the first one being headache; then there might be paralysis of the third pair of nerves, or of the fourth or sixth, with hemianopsia. The most common form was great mental depression, or rather apathy. He related six typical cases, illustrating some of the most important symptoms of the cerebral syphilis. We should make our diagnosis and then treat vigorously. This method of treatment was much more used in this country than in Europe, hence the better results obtained here. He had given as much as three hundred to five hundred grains of iodide of potassium a day and felt justified in doing this. He thought that mercury very materially helped the iodide.

DR. E. N. BRUSH thought that the interval between primary lesion and the brain troubles was much longer than Dr. Preston intimated in his paper. In one case he had given nine hundred grains of iodide of potassium a day. He did not believe in the therapeutic test, and did not think that because a patient could take large doses of the iodide that he should be treated for mental troubles as for the specific complaint. Some syphilitics could not take large doses, while those who had never had the disease could often stand very large doses.

Malaria Complicating Gynecological Operations.

—This was the subject of a paper by DR. JOHN WHITRIDGE WILLIAMS. He spoke of the importance of examining the blood in all febrile conditions and the necessity for great accuracy, and said that post-partum fever was more frequently attributed to puerperal fever than to malarial fever and that in the text-books there were few references to malaria as post-partum. He had had two cases recently. In the first, the examination of the blood had given him great confidence and had allowed him to exclude sepsis. In the second case neglect of the blood examination had resulted in a faulty diagnosis, and as a consequence an operation was performed, although as it turned out this operation was entirely justifiable. These two cases convinced him of the importance of blood examinations in all febrile cases after labor, even though malaria be suspected. He was confident that malarial fever was often mistaken and treated for other post-partum troubles.

DR. J. M. HUNDLEY said that he had had several cases of late in which malaria complicated gynecological operations, and the blood examination had made the diagnosis certain. He thought that this year, especially, such malarial complications were more common.

The Cystoscope in the Diagnosis and Treatment of Diseases of the Female Bladder.

—This was the subject of a paper by DR. J. M. HUNDLEY. Heretofore the treatment of these diseases had been unsatisfactory; drugs internally and washing out the bladder were the two methods of treatment commonly used. Through the skill of Dr. H. A. Kelly, the modern cystoscope had been so perfected that the interior of the bladder could be examined and treated, and the openings of the ureters could be seen. The bladder was more frequently subject to organic disease than was believed before the use of the cystoscope. Not only uterine but also rectal diseases caused an irritable bladder. He thought that the routine examination of the bladder with the cystoscope should be made in every gynecological case, whether the complaint was referred to that organ or not. He related two cases attesting the value of the cystoscope in this line of work and urged the profession not to neglect this modern means of diagnosis.

DR. A. C. WENTZ, of Hanover, Pa., related a case in which he applied ichthyol ointment by balloon to the interior of the bladder, as recommended by Dr. Clarke. He also used applications of ten to fifteen per cent. of nitrate of silver.

To What Extent Does the Hypertrophied Pharyngeal Tonsil Atrophy at or about Puberty?

—This was the subject of a paper by DR. S. K. MERRICK. He had been struck by the frequency with which the family physicians had told parents that the enlarged pharyngeal tonsils of their children would disappear spontaneously at from twelve to fourteen years of age. Indeed he had found that several of the text-books gave this same opinion or else avoided the question altogether. He had been able to collect a few statistics from his own practice, and in none of the subjects whom he had seen who had refused operation in childhood had the tonsils disappeared at puberty. Some information was obtained in observing the ages at which patients applied to him for treatment: out of fifty subjects operated on in 1895 and 1896, sixteen were under fourteen years of age, while thirty-four were above that age. If the tonsils atrophied after puberty it was strange that so many cases came to operation after puberty. We might conclude that an insignificant number of hypertrophied glands would disappear at puberty if left to themselves. Not only this, but adenoids made a patient prone to repeated colds, as well as other throat affections that may become tuberculous in character.

DR. JOHN N. MACKENZIE said he had never allowed such a case to reach puberty without operation. It was amazing what troubles these pharyngeal growths might cause and what fearful inroads these troubles might make on the health. He had operated on infants in arms. The growth should be operated on as soon as discovered, and should never be allowed to proceed unchecked. He spoke of the great liability to disfigurements of the countenance from this trouble and the affections of hearing, etc.

The Early Symptoms of General Paresis.

—This was the subject of a paper by DR. GEORGE H. ROHÉ. We should look for the early symptoms, although the results of treatment are not encouraging. The diagnosis must be made from a collection of symptoms partly physical and partly psychical. The disease generally begins after the thirty-fifth year and rarely after the fiftieth. Those in the higher walks of life are attacked by preference and men more than women.

Clergymen are almost exempt and actors are most frequently affected. Syphilis may be one of the causes. The symptoms are various and the treatment is unsatisfactory, and rarely does more than prolong life a few years. The iodides may be given.

DR. EDWARD N. BUSH was much pleased with Dr. Rohé's paper. He thought that the early symptoms of paresis occurred in this order: 1st, vasomotor; 2d, motor; and 3d, psychic. Sometimes depressing ideas usher in the disease.

DR. WILLIAM OSLER presented a case of diffuse scleroderma. The patient was a white man, about thirty years old, who had suffered from a hardening, thickening, and gradual immobility of the skin. There had been inflammation, erosion, and finally disability. This trouble was most marked in the hands and arms and face, although the skin of the whole body was somewhat hide bound. It was hard to pinch the skin. The patient could not close his hands tight. There were two forms of this disease—the diffuse form and the local form. This was a case of diffuse scleroderma. The etiology of the disease was not known and the pathology was very obscure. Thyroid extract was sometimes efficacious in this disease and sometimes not. In this case the man had been helped very much by it, and there were chances that it would stop the progress of the disease, if not cure it. He could not elevate his shoulders. Scleroderma was a slow progressive disease and it was very rare; he himself had been in practice twenty years before he saw a case and had seen only six cases altogether.

The Pathology and Bacteriology of Typhoid Fever.—DR. SIMON FLEXNER made some remarks on this subject. We have every reason to believe that the disease comes from the germ, the bacillus, in the anatomical tract. There is no ground for believing that it gets into the body in any other way than through the intestines. This fact is based not only on the pathological anatomy but on experiments as well. We cannot produce the disease in animals. Not all parts of the intestines are alike prone to infection to the same extent. Infection takes place where the lymphatic follicles are in aggregation. Not all the lymphatic aggregations are affected to the same extent. There is a general distribution of these lymphatic follicles throughout the whole tract of the intestines, but not all are affected in typhoid fever. The agminated glands are more susceptible to the poison than the solitary ones, and those nearer the lower part of the small intestine are especially affected. Here the infectious material of typhoid fever is kept a long time, owing to the anatomical character of the parts. The ulceration produced by the bacilli may be very superficial, affecting only the mucous membrane, or the whole thickness of the intestinal coats may be affected, causing perforation. Many epidemics are from an infected water supply. The organism of this disease is not particular as to where it lives and can thrive in water a long time, also in milk. It is hard to discover and separate it from other organisms. The growth is often invisible and causes no change in the color or taste of the milk infected, nor does it cause coagulation. This fact helps in its recognition, because the organisms with which it is confused grow visibly, and recent methods allow the typhoid germ to be discovered in the intestines. By the use of the differentiation method of Elsner in culture media of varying acidities, the growth of the typhoid organism in plate culture may be easily separated. The methods of Pfeiffer and Widal, by which the disease is made out in its early stages, is very ingenious. A bouillon culture of typhoid germs is mixed with blood from a suspected case of typhoid. If the disease really exists, the effect of the serum from the typhoid case causes a loss of motility, a clinging together, and fi-

nally a disintegration of the organisms. Wyatt Johnston has been able to make a diagnosis of typhoid fever in many cases in a short time by means of a hanging drop of a pure culture of the typhoid organisms to which serum from a typhoid patient has been added. This is a great advance in our diagnostic methods and should be made use of by all physicians.

DR. WILLIAM OSLER spoke of the prevalence of typhoid fever, and said there were too many cases in the State of Maryland and in Baltimore. He said this prevalence was an index of the sanitary intelligence of the community and of the physicians, and that with the help of the public and of the politicians it could be stamped out within three years. He then called on Dr. Fulton, the new secretary of the State board of health, to make remarks on typhoid fever.

DR. JOHN S. FULTON said that within his one month of service as secretary of the State board of health he had made one observation, and that was that, while the country-bred bacillus enjoyed great prevalence in the city, the city-bred bacillus seemed to be especially prevalent in the country. As a preliminary step to obtain statistics he had written to fifty-six physicians throughout Baltimore and Maryland and had received twenty-three replies, and to explain his opening remark he had found that the city physicians maintained that the cases in their care had originated from infection in the country, while the country physicians blamed the city infection for their cases. He said there was also many cases of typhoid fever concealed under the name of typho-malarial fever, the majority of persons apparently thinking that this combined form of the disease was less serious than either one disease alone. To show how unreliable the statistics were, he would quote from one of the hospital reports (Bellevue Hospital), which showed sixteen cases of typhoid fever with a mortality of sixteen and seventy-six cases of typho-malarial fever with no deaths. Either the diagnosis was very bad, or the therapy was murderous. He had been studying the health reports of the State of Michigan since 1886 and had noticed that at first many cases of typhoid and typho-malarial fever were reported, but gradually, year by year, the typho-malarial cases had been disappearing, while the malarial and the typhoid cases were slightly increasing. He said that the State board of health of Maryland would shortly make a complete investigation to ascertain the sanitary conditions in reference to typhoid in Maryland, and letters would be written to every physician in the State. This would be the happiest and most profitable investment Maryland ever made. If we could place with the board of experts enough money to make a substantial beginning of the reform, its members would realize the possibilities that Dr. Osler had maintained.

Modern Method of Examining Urinary Sediment.

—DR. WILLIAM B. CANFIELD made some remarks on this topic. He said that, as a rule, the chemical examination of urine was easy, but the examination of the sediment not so easy unless it was especially abundant. When the sediment was scarce or apparently absent, important ingredients might be overlooked. The method of allowing the urine to stand in a conical glass had some disadvantages, especially in warm weather, when decomposition might occur; also casts might remain suspended, and often they adhered to the sides of the glass and escaped observation. Moreover, this method of examination involved a waste of time. For this reason he would advocate the more general use of the centrifugal machine. The centrifugal had been long known and used; for example, in sugar refining and also in many physiological experiments; but only of late had a smaller and portable machine been made which could be easily used. It was surprising to find so little mention in books of the

use of this machine, in even the most modern text-books on urinary analysis, and he also thought that, with the exception of the larger hospitals and a very few physicians, the centrifugal was still unknown. He then exhibited the machine which he had used and demonstrated the method employed.

DR. J. M. T. FINNEY then made some remarks on the use of the x-rays in surgery. Agents of the Edison Company first explained the use of the machine exhibited by them, and then Dr. Finney explained the advantages of it in diagnosing dislocations, fractures, or other deformities made visible by it, and suggested that by the use of photographs, which could be easily taken in the light without a lens, the surgeon could keep a complete record with illustrations of every case adaptable to the machine, and thus protect himself against malpractice suits. In conclusion Dr. Finney related some cases and explained the advantages of the machine from a surgical standpoint. After this general discussion followed and there was a demonstration with the machine of various cases which had been brought in by local physicians.

Second Day—Wednesday, November 11th.

Cancer of the Tongue.—DR. FRANK MARTIN read a paper on this subject, in which he described the character of the growth usually present, the epitheliomatous; the age when it was most prevalent, forty-five to sixty-eight; the length of time it took the growth to develop, six months to three years; and the various operations for its removal. He said that the symptoms at first were very undefined, with very little pain. It usually began on the side of the tongue and in its anterior half, and the duration of life without operation had been recorded as from one year to eighteen months. He spoke of the various operations, such as that done with tracheotomy, with excision of the jaw, and with operation through the mouth. He found that the operation by excision of the jawbone gave the most complete results and in his experience the wound healed kindly.

DR. JOHN M. T. FINNEY said that his experience with the wound left by the excision of the jaw was that it granulated very slowly and gave much trouble. He referred to several cases that he had had with such a result.

DR. J. W. HUMRICHOUSE, of Hagerstown, then read a paper on some of the results of bacteriological research, in which he reviewed what is known up to the present time of the various diseases and their specific organisms, and outlined the treatment. This paper was discussed by DR. DAVID F. UNGER, of Mercersburg, Pa.

DR. RANDOLPH WINSLOW then reported two cases of gastrostomy for cesophageal obstruction.

DR. JOSEPH GICHNER read a paper on "The Present Status of the Treatment of Tuberculosis," in which he reviewed various methods of treatment of that disease in vogue at the present day.

DR. H. O. REIK read a paper on "The Practical Use of Skiascopy."

Extra-Uterine Pregnancy.—Differential diagnosis: We must differentiate between: 1. Retroflexed pregnant uterus, possibly complicated by a cervical polyp, bleeding occasionally. 2. Pregnancy in bicornuate uterus. 3. Intra-uterine pregnancy complicated by an adnexa tumor. 4. Ruptured pus tube. 5. Ruptured varicose veins of tube, broad ligament, hamatocele from ruptured Graafian follicle, hamatosalpinx. 6. Rupture of an ulcer of the gastro-intestinal tract and appendicitis.—FRANKENTHAL, *Medical Standard*, November.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

ANNUAL MEETING AND DINNER OF THE ANGLO-AMERICAN CONTINENTAL MEDICAL SOCIETY—REMARKABLE CASE OF CATALEPTIC SLEEP LASTING OVER THIRTY-TWO YEARS—CONSULTATIONS BY CHARCOT AND BROUARDEL—AGITATION AGAINST EXPENSES ATTENDING THE STUDY AND PRACTICE OF MEDICINE IN FRANCE—LAYMEN DO NOT WISH THEIR SONS TO BECOME DOCTORS, ETC.

PARIS, November 15, 1896.

ONE of the most important professional events of the year took place on November 10th—we refer to the annual meeting of the Continental Anglo-American Medical Society, whose object is to serve as a bond of union between the British and American practitioners established on the continent of Europe, the Rivières, French as well as Italian, and in northern Africa. To become an active member of the society it is necessary to have a French qualification, which is calculated to keep the membership somewhat limited, although there are at present on the roll a hundred and more names, including, of course, the honorary presidents and members, among whom we note Sir Richard Quain, Sir Joseph Lister, Sir Spencer Wells, Dr. S. Weir Mitchell, Dr. J. B. Billings, Dr. W. M. Polk, and Dr. W. T. Lusk. On the executive committee are such men as Dr. the Hon. Alan Herbert, Dr. Clarke, Dr. Halsted Boyland, Dr. Austin, Dr. Bull, and Dr. Baldwin.

This society has been productive of great good in holding together the European physicians, chiefly the English and Americans, in upholding the dignity of the medical profession in general, and in elevating the tone thereof. Seventeen new members were elected, quite a phenomenal number. It is always customary to invite some distinguished guest to preside at the dinner, which comes off the same evening. This year the society delegated the Hon. Alan Herbert, Dr. Halsted Boyland, and Dr. Barnard to invite Mr. Austin Lee, C.B., H. B. M.'s attaché, to preside at the annual banquet, which invitation he accepted, and referred in a neat speech to the amity of the two nations, England and America, between whom so many ties existed, professional as well as other, proposing the health of the Queen and President Cleveland. The orator was of opinion that the society should exert its influence to obtain some mitigation of the present draconian laws, which really debar English and American practitioners from exercising their profession in France. He spoke in highly complimentary terms of Baron de Rothschild, who, with his great wealth and social position, had elevated himself still more by becoming a physician and practising his profession. Dr. Rothschild has also founded a polyclinic, in which he is doing valuable work for science and for the poor.

Dr. the Hon. Alan Herbert replied in a few well-chosen words, referring to the high standing, both professionally and socially, of physicians in England, the United States, and France, and thought that the medical profession was about to surpass all others in these respects.

The most curious and longest-lasting case of catalepsy known to science is still to be seen at the little village of Thérèlles, some hours distant from Paris.

On May 29, 1883, Marguerite Boyenval, then nineteen years of age, frightened by the appearance of a squad of gendarmes, who, she probably imagined, were coming to arrest her, suddenly uttered a cry and fell in a nervous attack. She was placed upon the bed

and went to sleep in a short time; from that day to this—that is, about thirteen years and five months—she has never awakened. The most distinguished physicians in France have seen her, and everything has been done, in vain. The young girl has become a woman sleeping. Charcot went four times to see her—the first time alone, the others in company with other consulting physicians; Professor Brouardel also, then Professor Bérillon. Dr. Charrier, the local practitioner, calls every day. The patient, reduced to a skeleton, lies with her head slightly bent upon the pillow, her arms concealed under the covers; pale and with hollow cheeks, she seems more dead than alive. The mouth and eyes are closed. If the eyelids are drawn up, only the white of the orbits is visible, the pupils being rolled upward under the orbital arches; and Marguerite Boyenval, with her white cap, has upon her face an ecstatic expression, such as we see in hysterical catalepsy less profound, reminding one of the pictures of nuns by the old Italian masters. At the beginning she made several starts, as if going to awaken, but the deep cataleptic sleep overtook her again in five or six minutes, to continue until the present writing. For a time she was nourished by sliding a teaspoon between her teeth, but for eight years past nutrient enemata, four times a day at regular hours, have been and are still resorted to. Of course, she has largely consumed herself, being now only skin and bones, with stiffened and fleshless fingers. The body to the touch shows some hyperthermia, for which the hot-water bags kept constantly at her feet are not sufficient to account.

The physicians who have seen her are of opinion that during the first months she could hear what was passing around her, but to-day the organs are too much weakened. It was during this period that the thorax still rose and fell a little with the respiratory movements. Now, the only sign of breathing is a slight mist upon the glass. The functions of menstruation and defecation are accomplished, though, of course, in an extremely limited and irregular manner.

There is nothing hereditary about this truly wonderful case. Her only attendant is her mother. Madam Boyenval is a large, buxom peasant woman, in rugged health and exuberant spirits, as her parents were before her, and does not know what illness is.

The subjects of the practice of medicine and of medical education, which have for several years past been agitating the profession and government, having been settled as far as foreigners are concerned, the French laity is now anxious lest its sons should study medicine and graduate in the ranks of a profession already overcrowded. Consequently, leaders and communications of different sorts are appearing in the daily press, notably in the *Figaro*, the most influential journal in France, showing why young Frenchmen ought not to embrace the profession of medicine. Here is about what it costs a father to-day who wishes to make his son a doctor: Ten years of university studies, at 1,800 francs a year; say, 18,000 francs. At least five years of medical study, at 2,500 francs; 12,500 francs. The year of military service costs 2,000 francs. Total, about 40,000 francs, or eight thousand and some dollars. This sum does not include the amount necessary for instruments, say 2,000 francs; nor for books, say a like sum, 2,000 francs. If the young doctor establishes himself in a large city, he will have his rent and furniture, to amount to six or seven thousand francs. In a word, the expenses of the average doctor in Paris are between four and seven thousand francs a year at the very beginning and before he has begun to subsist, with nothing allowed for horse and carriage.

This agitation against the study of medicine is very wise, and should be imitated in New York, where the

profession is as overcrowded as it is here. In Paris the field of practice is always a hotly contested one, even among the older members of the profession. So what a hopeless warfare must the young doctor wage in his comparative youth and inexperience, not only against his own confrères, but against his enemies, such as quacks, bone setters, veterinarians, often druggists, rich young doctors who found polyclinics where his patients can get advice and medicine gratis; older doctors, some of whom receive him in practice on unequal terms, and insist upon having their full consultation fees when called in by him and half of his hard-earned money besides; others, whose equal he certainly is, often their superior in many respects, give the patients he sees with them and others to understand that he is only a promising tyro, an assistant, and consequently to be appreciated and remunerated accordingly. (Indeed, he would not have been called in at all oftentimes, if the elder doctor had known to whom to turn.) These are only a few of the difficulties that beset him at every turn; the heavy *patente* or tax that he will have to pay annually for the privilege of practising his profession, in addition to the tax upon his furniture, etc., is not included in the estimate given above.

OUR LONDON LETTER.

(From our Special Correspondent.)

IRISH COLLEGE OF SURGEONS—POOR-LAW MEDICAL OFFICERS IN IRELAND—EDINBURGH STUDENTS—MEDICAL COUNCIL—PATHOLOGICAL SOCIETIES—EXHIBITION OF SPECIMENS AND REMARKS ON THEM—SOME RECENT DEATHS.

LONDON, November 13, 1896.

THE Royal College of Surgeons in Ireland is a teaching as well as an examining body. The president, Mr. Thomson, opened the session on the 2d inst. with an introductory address. Both Irish and Scotch schools open a month later than English. Mr. Thomson, according to a newspaper report, warned the students that the medical life is by no means one of delectable ease, that they will be not masters but servants of their patients, and that there are no comfortable pensions or sinecure appointments to retire on. He then pressed upon them the importance of general education, and especially urged them to master the English language; and as to the defence of bad spelling sometimes heard, that some good scholars have been examples of it, he declared that such defence flattered neither the scholar nor his teacher. Bad spelling, he held, was the result of bad teaching or else of a boy's carelessness. There was no excuse for a young man to be illiterate in his own tongue, and Mr. Thomson urged the students to familiarize their minds with the writings of the great English authors.

This day week an important deputation waited on the chief secretary for Ireland, Mr. Gerald Balfour, brother of the leader of the Commons, to lay before him the abuses of the Irish poor-law system and seek some consideration for the medical officers. The presidents of the two royal colleges, the Academy of Medicine and the Irish Medical Association, were present and advocated the cause of the distressed medical officers. But the dignified deputation does not seem to have impressed the minister, who was content to repeat the ridiculous fictions which have been doled out by the local board to successive secretaries. Evils were admitted, as they could not all be denied, but no remedy was offered, no hope of amelioration held out. It is a strange sight for a strong government in this year of grace to acknowledge injustice and admit nothing can be done but "grin and bear."

The Edinburgh students have elected Lord Balfour of Burleigh lord rector. I am sorry to say that some

of them emulated the follies of their noisier brethren at Glasgow.

Electioneering literature is being freely distributed by the rival candidates for the General Medical Council, and the question how to vote is exciting a good deal of attention.

At the last meeting of the Pathological Society, Mr. J. Hutchinson, Jr., showed a specimen of rodent ulcer of the forearm. Among the large number of cases of true rodent ulcer referred to and exhibited before the society in 1895, not one was on the limbs, and some doubted the possibility of its occurrence in such a position. This growth was situated on the outer aspect of the forearm of a woman aged forty-five years. It measured about an inch in long diameter and had existed for over a year. Vertical sections showed reticular downgrowths of cells from the rete mucosum, having the typical structure of rodent ulcer as met with on the face. Cell nests were practically absent and the corneous layer took no part in the downgrowth. Mr. Hutchinson, Jr., said he had seen a typical case in the groin also, and thought its occurrence in other parts of the body than the head and neck not so rare as supposed. Dr. A. A. Kanthack said that, in deciding the position from which rodent ulcer started, the growth should be examined before any ulceration had taken place. When examined early enough the rete mucosum is always found normal; the sweat glands are unaffected, but the sebaceous follicles disappear. Mr. A. A. Bowlby agreed with this view.

Mr. W. G. Spencer thought that a slow-growing epithelioma presented much the same characters as a rodent ulcer.

Mr. James Berry said he had examined many cases of rodent ulcer and in all of them the growth had begun below the rete mucosum. He had seen one case in which the growth occurred in the groin.

Mr. H. T. Butlin said that one distinctive feature of a rodent ulcer was the scarring over the surface which took place, the structure of the rodent ulcer being demonstrable below the skin; this never occurred in epithelioma. Mr. Shattock said that the finding of cell nests definitely proved that a growth was not a rodent ulcer.

Mr. J. Hutchinson, Jr., also showed a series of sections of adeno-chondroma of the left submaxillary gland in a young man who, nearly two years later, was free from any recurrence. The innocent nature of these tumors has been proved in a considerable number of cases.

Dr. Rolleston showed a specimen of extensive tuberculous disease of the thyroid gland. There were caseous areas through the gland which were of the normal size. In the left lobe the caseous material had softened down and formed an abscess, which had discharged into the upper part of the œsophagus on the left side. The lymphatic glands around the innominate artery were caseous and had softened down, and the resulting abscess had tracked up into the neck and opened into the œsophagus by several sinuses, the highest and largest being nearly opposite that of the tuberculous abscess in the left lobe of the thyroid body. Half an inch below these roughly symmetrical openings the œsophagus showed slight cicatricial contractions. The rarity of tubercles in the thyroid gland and the extreme rarity of large tuberculous abscesses were mentioned in the conversation that followed, and it was stated that no specimen existed in the museum of any London hospital.

Dr. H. H. Tooth described under the name of multiple bronchiolectasis the appearance of the lung of a boy, aged eighteen months, which was found to be riddled with small cavities from one-sixteenth of an inch to a quarter of an inch in diameter, smooth-

walled and containing only air. They were probably dilated bronchioles, a sequence of peribronchial inflammatory processes. Dr. Norman Moore said that similar cavities were seen in children who had died of whooping-cough.

Dr. A. A. Kanthack and Mr. E. H. Shaw read a paper on the use of formalin in the preservation of museum specimens. Excellent results had been obtained in preserving eyes. Some specimens were shown which had preserved their original color most excellently, among them a broncho-pneumonic lung and a granular kidney, both of which had all the appearances of fresh specimens.

Dr. Rolleston showed specimens of secondary poly-poid sarcomatous (melanotic) tumors in the mucosa of the small intestine.

Favell, of Sheffield, died on the 31st ult., aged sixty-four years. He had been invalided by heart disease for some time and a change for the worse was rapidly fatal. William Fisher Favell was consulting surgeon to the Sheffield Infirmary, having been surgeon to it for above thirty years. He was also president of the medical school and vice-president of the college which is to be connected with Victoria University. He was a justice of the peace and an important supporter of all local movements for the benefit of the poor. In 1876 he delivered the address in surgery at the meeting of the British Medical Association. On his retirement from the infirmary in 1893 there was a manifestation of the esteem in which he was held. It was proposed to place his portrait in the institution and £1,000 was raised in a very short time to secure the services of a first-rate artist. Mr. Shannon was selected and his portrait pronounced excellent, and a replica was presented to Mr. Favell's only daughter.

Mr. Thomas Chambers, of Sydney, N. S. W., who died at the end of August, was well known in London, where he achieved considerable success as a gynecologist. It was with regret his friends learned in 1882 that his health was so broken that he had determined to seek a better climate. Tom Chambers, as we familiarly called him, accordingly went to Australia, and there, too, he achieved success in the same specialty. An attack of bronchitis terminated his successful career. He leaves a widow and six sons.

Dr. Henry Trimen, who became director of the Royal Botanic Gardens in Ceylon sixteen years ago, died there on the 16th ult. His "Flora of Ceylon," of which three volumes have appeared, is a masterly production, but he has not lived to complete it. His joint work with the late Professor Bentley on "Medicinal Plants" may be better known to your readers.

The name of Morris, of Spalding, was a prominent one for many years. He was surgeon to the infirmary and held many local public offices. He practised at Spalding for fifty years, retiring in 1890. He died lately, aged eighty-one years. Dr. Morris was author of a work on "Neuralgia" and one on "Shock in Railway Accidents," besides contributions to the journals. He was M.D. of St. Andrew's and F.R.C.S. Eng.

Deputy Inspector-General Francis Robert Waring died on the 31st ult., at the advanced age of eighty-seven years.

THE CONTAGIOUSNESS OF PULMONARY PHTHISIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A little common sense cannot fail to meet with your approval, and I therefore venture to address a few words to you.

The notices in street cars prohibiting spitting are

treated with contempt, and are consequently valueless. In spite of this fact, our health authorities in this city of Buffalo are anxious to prohibit expectoration upon the streets, except in the gutter—or, rather, in what is called a gutter. The intention is, of course, good, since spitting is a most objectionable habit, for which there is no excuse. But the regulation could not be carried out in practice, and would not be of any importance if it could. The streets of Buffalo are chiefly asphalt; the portion of the asphalt next the sidewalk is quite as dry as the centre of the road, and men are employed to collect the dust and dirt in heaps. If there were a gutter containing water, the case would be different; but, as it is, the accumulations are dry and are being continually stirred up.

Suggestion No. 1: Let us cease to try to make laws or regulations which cannot be enforced, and which would be valueless if they could.

Spitting upon the streets or in public places is virtually unknown in Great Britain. So disgusting is the practice considered that cuspidors are not mentioned in decent society, and consumptives, I fear, very often swallow their sputum or expectorate into their handkerchiefs. Pulmonary phthisis is a disease as old as medical science itself, and the extreme contagionist who has persuaded himself that it can be conquered by such a simple process as taking care of the sputa of its victims is deceiving himself, because he is only taking one source of contagion into consideration. Nor is this all. It is the fashion in this country to laugh at the idea of a tuberculous diathesis, without which nobody ever succumbs to tuberculosis. But no writer whose work I have been able to consult denies its existence, and Koch specially recognizes it. The words of Dr. Flick, of Philadelphia, the most extreme contagionist in America—or anywhere else, I hope—are: "Persons who have healthy stomachs, and who do not overburden them, and who take sufficient exercise in a pure atmosphere to secure them a free circulation of well-oxygenized blood, will not contract tuberculosis, no difference what the exposure."

Suggestion No. 2: Let us cease talking about the "extreme contagiousness" of consumption, for it is not contagious in the sense in which a zymotic fever is. Paterfamilias has been so frightened that he is liable at any moment to protest against hospitals for consumptives being erected within city lines! One word more. There is great difference of opinion as to the contagiousness of this terrible disorder. I can give the names of a small army of German and English writers who are opposed to the contagion doctrine; and the report of the committee of the British Medical Association throws serious doubt upon the accuracy of the opinions of the extremists. About ten years since, Koch remarked that American interpretation of his views was "perfectly ridiculous." The opinions of Williams, James, Powell, Wilson-Fox (English), Dettweiler, Brehmer, Spinna, and Aufrecht (German)—all recent writers and men of great experience—seem to be that "the degree to which contagion ordinarily extends is singularly small."

We do not know how nature works. The genesis of a disease is not the same thing as the artificial transplantation of it, although every contagion enthusiast appears to believe that it is. This subject cannot be discussed in a letter.

Finally, Suggestion No. 3: Let us cease to talk or write about what we have accomplished, for we have accomplished very little. Phthisis has been on the decrease for about forty years in Boston, for about thirty years in Philadelphia, for about seventy years in New York, and for about seventy-six years in London. This decrease has been due to the process of natural selection, and to nothing else. I have not been able to discover any place in which there has been an ap-

preciably increased rate of decrease since the revival of the contagion doctrine in 1882. The real decrease of tuberculosis will come when persons of the phthisical type are sufficiently educated to realize that they ought not to marry. In the mean time, the few who are saved from the bacillus tuberculosis appear to succumb to other pulmonary complaints.

I cannot imagine any habit that is more offensive than the American practice of spitting—unless it is the American habit of swearing. But I submit, with great respect, that the educational process alone will prevent it, and that, as a source of tuberculous contagion, it is being exaggerated beyond all reason, while little is being attempted to reduce the consumption of the milk of tuberculous cattle.

LAWRENCE IRWELL, M.A., B.C.L. Oxon.

BUFFALO, N. Y., November 16, 1896.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 28, 1896:

	Cases.	Deaths.
Tuberculosis.....	142	88
Typhoid fever.....	31	10
Scarlet fever.....	121	12
Cerebro-spinal meningitis.....	3	4
Measles.....	92	0
Diphtheria.....	215	30
Small-pox.....	0	0

Onions are popularly supposed to have a decided effect in preventing scarlatina and diphtheria, besides being generally healthful, inducing sleep and keeping away worms. It would really seem that the fragrance of the fruit should have power in at least a few of these directions.

Cardiac Movements.—Professor Benedikt has recently found that thin layers of blood cast so deep a shadow with the x-rays that during systole the apex can be seen approaching the base. During systole the heart is not wholly emptied, as the shadow shows. During deep inspiration the heart is drawn away from the diaphragm.

Professional Contagion of Cancer.—Dr. Guernonprez, of Lisle, has communicated to the Paris Academy of Medicine two cases in which the contagion of cancer appeared to be quite probable. The first instance relates to a physician suffering from a cancerous ulceration, whose starting-point was in an acne pustule. This physician had no cancerous antecedents, but had the habit of scratching his face. As he had several women affected with uterine cancer under his care, and as he was somewhat negligent in the matter of asepsis, it is believed that an inoculation took place in this manner. The second case relates to Dr. Guernonprez himself. He was operating on an epithelioma of the face and his index finger was in the patient's mouth, when his nail was suddenly turned back violently by a movement on the part of the patient. Following this a papilloma occurred under the nail, and resisted for nineteen months all forms of cauterization.—*New York Therapeutic Review*.

Anæsthesia during Sleep.—It does seem to me that chloroform may be administered during normal sleep, to the degree of perfect anæsthesia, without arousing the sleeper, more frequently than we generally believe.—ISRAEL CLEAVER.

I operated upon a little girl, who had been run over

by a trolley car. We went to the house at 10 P.M., and found the child asleep. We gave chloroform and amputated two toes. The child awoke later and knew nothing about the operation.—LONGAKER.

One element of danger is that in many persons during sleep the vitality is at much lower ebb than during waking hours, and a fatal termination might result.—BURR.

Cocaine Dangers.—A recent death under cocaine anæsthesia in a physician's operating-room is a warning of the dangers of this most useful drug. Only qualified and responsible persons should prescribe or apply the remedy.

A Cycle Saddle has been introduced in England, which provides complete bifurcation with an adjustable interval to suit individual requirements, and takes all pressure from the perineum. A really good saddle is greatly to be desired, and physicians will welcome one which obviates the danger of undue pressure.

The Plague in India.—Views differ as to the origin and nature of the plague as it has developed at Bombay. On the one hand, it is ascribed to a specific germ, disseminated by clothing, merchandise, etc., and encouraged by filth; while on the other it is attributed to the use of poisonous grain. Overcrowding, foul air, sewage-soaked soil, and defective drainage would appear to influence its spread more than contagion from person to person, according to latest reports from the infected districts.

Cocaine Anæsthesia.—In an address commemorating the introduction of ether, delivered by Dr. Roswell Park at the University of Buffalo, the following tribute was made to the discoverer of cocaine, which is worthy of reproduction: "I will spend no further time upon the subject, save to do justice to modern anæsthesia by a very different method and by means of a very different drug, which is to-day in so common use that we almost forget to mention the man to whom we owe it. I allude to cocaine and its discoverer, Koller. Cocaine is now such a universally recognized local anæsthetic that there is the best of reason for referring to it here—the more so because it affords another opportunity to do honor to a discoverer, who has rendered a most important service to not only our profession, but to the world in general. The principal active constituent of coca leaves was discovered about 1860 by Niemann, and called by him cocaine. It is an alkaloid which combines with various acids in the formation of salts. It has the quality of benumbing raw and mucous surfaces, for which purpose it was applied first in 1862 by Schroff, and in 1868 by Moreno. In 1880 Van Aurap hinted that this property might some day be utilized. Karl Koller logically concluded from what was known about it that this anæsthetic property could be taken advantage of for work about the eye, and made a series of experiments upon the lower animals, by which he established its efficiency and made a brilliant discovery. He reported his experiments to the congress of German oculists, at Heidelberg, in 1884. News of this was transmitted with great rapidity, and within a few weeks the substance was used all over the world. Its use spread rapidly to other branches of surgery, and cocaine local anæsthesia became quickly an accomplished fact. More time was required to point out its disagreeable possibilities, its toxic properties, and the like; but it now has an assured and most important place among anæsthetic agents, and has been of the greatest use to probably ten per cent. of the civilized world. To Koller is entirely due the credit of establishing its remarkable properties. Had he patented his discovery he would have been vastly richer in pocket, though poorer in fame, than at present. He is now estab-

lished in New York, where he enjoys a modest competency, but is by no means in receipt of the income which is properly his due from the world at large. To a man who has been the means of relieving so much pain as Karl Koller, no amount of pecuniary return is too great."

Foreign Clinics.—But what I do wish to emphasize is the undoubted fact that we can find as good a clinic of any given kind in such cities as New York or Chicago as anywhere in the world. And so far as hospitals are concerned, I must say, to put it mildly, I am very proud of our own.—BOYES, *Vienna Letter*.

The Female Intestine is five feet and three inches shorter than that of the male.—BYRON ROBINSON.

Treatment of Flatulence.—Dr. Stephen McKenzie states that a certain amount of air is swallowed in the process of mastication and deglutition, but this has never produced any of the phenomena associated with flatulence. This condition is also attributed to fermentation occurring in the stomach, but he does not believe the gas of flatulence is the result of food fermentation, for fermentative processes are too slow for the rapid development of the flatulence observed in dyspepsia. Sir William Roberts has shown that a certain amount of flatulence may occur in acid dyspepsia through the action of an acid mucus upon the alkaline saliva swallowed with the food; but this is certainly a rare and minor cause in the production of gas. The regurgitation of carbonic-acid gas from the duodenum may sometimes occur and cause a flatulent distention of the stomach, but this is also a rare phenomenon and occurs only when the gastric juice is hyperacid. The writer, after discussing other theories, concludes that flatulent dyspepsia is due to a lack of gastric tonicities. In other words, the wall of the stomach being weak, flabby, and lacking in tone, suddenly dilates, and a volume of gas which was before somewhat compressed expands and fills out the enlarged viscus. The gas does not increase in quantity in the stomach, but only in volume. Associated with this gastric atony and perhaps dilatation, there is often a slight catarrhal condition of the stomach which lessens the power of normal gastric digestion and helps also to weaken the walls of the stomach. The most important thing in the treatment of flatulent dyspepsia is to use remedies which will increase the nervous vigor; hence tonics, and especially nerve tonics, are of the greatest importance. Nux vomica and strychnine should be placed at the head of the list. When there is gastritis associated with flatulent dyspepsia, with a coated tongue, the author gives bicarbonate of soda, strychnine, and spirit of chloroform, dissolved in a bitter infusion of calumba or gentian; two ounces three times a day, between meals. If pain is associated with the flatulence, bismuth is added to the mixture, or a pill containing carboic acid, valerianate of zinc, and alum is given. The compound asafœtida pill and the extract of belladonna are sometimes useful. In cases in which pain is located lower in the bowels, Indian hemp in doses of one-third of a grain often answers better than any other remedy. For the violent spasmodic attacks which these sufferers often have, associated with distention of the stomach and intestines, a mixture is given composed of equal parts of spirit of cajuput, aromatic spirit of ammonia, and spirit of chloroform: a teaspoonful in a wineglass of water every half or quarter of an hour. The writer does not believe in the use of charcoal in flatulence, nor does he place great stress on the value of bismuth. The purpose of his paper is, he says, to urge the importance of tonics and antispasmodics as the rational and effective treatment of flatulence by improving the muscular tone of the stomach.—*Practitioner*.

THE RADICAL TREATMENT OF PROSTATIC ENLARGEMENT BY PROSTATECTOMY.¹

BY SAMUEL ALEXANDER, A.M., M.D.,

PROFESSOR OF GENITO-URINARY SURGERY AND SYPHILIS IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, ATTENDING SURGEON TO BELLEVUE HOSPITAL.

PROSTATIC enlargement is purely a local affection. Its consequences are due primarily to the obstruction which it offers to the outflow of urine. Treatment becomes necessary when it begins to interfere with the function of the bladder. The prostate may attain a very considerable increase in size without causing any symptoms of note, and it is certain that in at least one-half of all those cases in which the prostate is enlarged no treatment is required. In these cases the obstruction is so slight, and the muscular power of the bladder is so good, that the patient remains unconscious of the enlargement. Whenever, however, the enlargement begins to interfere with the functions of the bladder, when there is sufficient obstruction to prevent this viscus from emptying itself and to weaken its expulsive power, treatment becomes a necessity. The more promptly such a condition is recognized and treatment begun, the better for the patient's future comfort and safety. Delay is dangerous. The bladder and kidneys are threatened, and unless the obstruction is relieved promptly these organs must inevitably suffer.

The choice of treatment lies between the habitual use of a catheter for the remainder of the patient's life, or the complete removal of the obstruction; and, when neither of these is possible, the establishment and maintenance of an artificial channel through which the urine may pass.

It should be stated at the outset that, in the ordinary cases of prostatic enlargement of however long standing, in which the obstruction is not great and the power of the bladder is fair, in which there is not an excessive amount of residual urine, in which catheterism is easy and painless, and in which cystitis, if it exists, is not severe and can be controlled by aseptic washings and regular catheterism, operative treatment is not indicated.

The value of regular, careful aseptic catheterism, as a palliative measure in the treatment of many cases of prostatic enlargement, cannot be too highly estimated. There are many individuals who have prostatic enlargement who live in a fair degree of comfort for many years—often for the rest of their lives—by the more or less frequent passing of a catheter and by following strictly a proper course of treatment. There are many others, however, who either cannot or will not use the catheter; and still others to whom, in spite of all precautions, catheterism gives little or no relief. In these patients the symptoms continue, more or less rapidly, to grow worse. The expulsive power of the bladder grows less and less, the quantity of residual urine gradually increases,

the irritability of the bladder and prostatic urethra also increases, the introduction of the catheter becomes more and more difficult, cystitis of a severe type intervenes, and the condition of the patient becomes most pitiable. But the value of catheterism in the treatment of prostatic enlargement depends largely upon the care with which its details are carried out. Catheterism and vesical washing, when properly done, are a valuable means of treatment; unskilful and uncleanly catheterism is the active cause of many of the unfortunate complications of enlarged prostate.

There are certain patients who have a peculiar immunity from infection, who may disregard all established rules of cleanliness, and who may continue for long periods to use a dirty catheter without infecting the bladder. These cases are exceptional. There are also patients whose bladders easily become infected at the beginning of catheter life, but who may, later on, acquire a certain degree of immunity, so that some of the aseptic precautions which were at first necessary to prevent cystitis may be given up. But in most prostatics the bladder is liable to become infected at any time, from causes seemingly slight, so that it is never safe to neglect the precautions necessary to prevent this accident.

It follows, therefore, that if catheterism is to be of service, the patient should be of sufficient intelligence to understand the necessity for the precautions taken to prevent infection, should have sufficient manual dexterity properly to use the catheter, and should be so situated that the necessary precautions in using the catheter can be thoroughly and invariably carried out.

But there are many cases in which, even under the most favorable circumstances, catheterism fails to give relief, owing to the character and conformation of the enlarged prostate and the obstruction which it offers to micturition. In these cases catheterism may seem to act admirably for a time, the symptoms are relieved, and all goes well; but sooner or later the disease becomes rebellious, and palliative treatment is undoubtedly a failure. This should be early recognized, and, before it is too late, radical treatment should be employed.

The conditions that demand operative treatment for prostatic enlargement may be summarized as follows:

1st. When there is complete, or almost complete, retention of urine, due to prostatic outgrowths about the internal urethral orifice or projecting into the prostatic urethra, making the patient entirely dependent at all times upon the use of his catheter. The consequences cannot be doubtful in such cases, and operation affords the only means of averting fatal disaster.

2d. When there is marked and continuous vesical irritability, due to intravesical outgrowths, which cannot be allayed by the most careful catheterism and washing of the bladder. These patients usually suffer from frequent attacks of hæmaturia, and cystitis, when it develops, is usually severe.

3d. When, in spite of careful catheterism, the amount of residual urine is steadily and surely increasing, showing a gradual failure of expulsive force in the bladder.

¹ Read in a discussion before the New York State Medical Association, on October 16, 1896.

4th. When catheterism is becoming more and more difficult, in spite of all precaution, and when it is frequently followed by hemorrhages.

5th. When catheterism, in spite of all precaution, is frequently followed by attacks of cystitis.

6th. In cases of long-continued vesical inflammation which do not yield to treatment.

7th. In cases in which the patients cannot or will not use a catheter and take the necessary aseptic precautions to make its use of value.

In a word, it may be stated that catheterism, with all that the term implies in the treatment of prostatic enlargement, should be employed in all cases until it fails to give relief; but that when it fails, and the integrity of the bladder and kidneys is threatened, we should resort to operative treatment before these organs have become hopelessly damaged.

The question is then presented: What operations may be performed for the permanent cure of prostatic enlargement?

In the first place, I believe that any operations designed for the permanent relief of prostatic enlargement should fulfil the following conditions:

1st. The obstruction should be thoroughly and immediately removed.

2d. As little damage should be done to the mucous membrane of the bladder and prostatic urethra as possible.

3d. Efficient drainage of the bladder should be established.

In order that the relief shall be permanent, it is necessary not only to remove the portions of the prostate which are causing obstruction at the time of operation, but also all those portions which, if they be left, may cause obstruction by their progressive enlargement. If this proposition is true, then any operation that does not take away all portions of the prostate that are enlarged cannot be regarded as a radical operation. This I believe to be a sound position, in spite of the opinion of those who claim that only portions of the prostate should be removed, and that the danger of the operation depends largely upon the amount of tissue removed. Many of the failures to give permanent relief by prostatectomy operations, and the relapses which have occurred after the removal of portions of the enlarged prostate are, without doubt, due to the removal of an insufficient amount of the enlarged gland.

The only prostatectomy operations which fulfil these conditions are those devised by McGill, Belfield, Nicoll, and Alexander. McGill's operation is that which is usually performed at the present day. In this operation, the bladder is opened above the pubes. The mucous membrane covering the projecting portions of the prostate is cut through by scissors, and the obstructing portions are removed, partly by enucleation with the finger, partly by cutting with forceps. E. Fuller, of this city, has modified the technique of this operation by making a comparatively small opening in the mucous membrane and enucleating through this the prostatic growths with the finger. McGill drains the bladder through the suprapubic opening. Fuller, following Keyes and Belfield, opens the membranous portion of the urethra and drains through the perineum.

In cases of prostatic enlargement in which the lateral lobes are principally enlarged, it is sometimes extremely difficult to remove these by the suprapubic incision, and it was mainly to meet these cases that Belfield first employed the combined perineal and suprapubic incision. By passing the finger into the prostatic urethra through the opening in the perineum, he was able to bring the lateral lobes within reach of the finger passed into the bladder through the suprapubic opening.

Although these operations, in the hands of skilful surgeons, have given gratifying results, and as experience is gained the death rate will undoubtedly be lowered still further than it has been, there are certain objections to the suprapubic method.

The chief of these are:

1st. That the mucous membrane of the bladder and that of the prostatic urethra are cut through and more or less torn and bruised.

2d. That the hemorrhage is frequently severe, and requires packing of the wound to control it.

3d. Another and still more vital objection to these methods is that, after prostatic obstruction is removed, a cavity is left which is freely accessible to the urine. In this the urine collects, and, as this is often foul in the cases operated upon, there is great danger of septic infection. Nor can this cavity from which the prostate has been removed be efficiently drained. Suprapubic drainage alone is entirely inefficient, and even when perineal drainage is employed the tube, in order properly to drain the bladder, must be placed above the level of this cavity.

To overcome these objections, Nicoll's operation and my own operation were devised. Since the publication of our respective methods, in 1894, several writers have confounded the two operations, which are essentially different in their technique. In order to correct this misapprehension, I shall give a description of my own method, and then call attention to the points of difference between it and that devised by Dr. Nicoll.

Alexander's Method.—The patient is prepared, when possible, by giving a cathartic the night before the operation, and by emptying the lower bowel by a large enema the following morning. The bladder is washed immediately before the operation with a solution of nitrate of silver (1 to 6,000). The patient being anæsthetized, the bladder is emptied by catheter, and is then distended with borax solution, from eight to ten ounces being sufficient in most cases to bring the organ well above the pubes. I have discarded the use of a rectal bag. The bladder is then exposed by vertical incision between the recti muscles, and two retraction sutures are introduced through its wall. Between these an opening is made into the bladder, large enough to allow the operator to insert two fingers. The bladder and the projecting portions of the prostate can now be examined thoroughly.

The suprapubic opening is then covered with gauze, and the patient placed in the lithotomy posture. A broad median-grooved staff is passed into the bladder through the urethra and held by an assistant. The membranous urethra is then opened by a median perineal section, the floor of the urethra being thoroughly cut from just behind the bulb back to the apex of the prostate. This must be done thoroughly. The staff is then withdrawn and the gauze removed from the suprapubic wound. The surgeon now washes and disinfects his hands. Two fingers of the left hand are then passed into the bladder through the suprapubic wound, and by these the prostate is pressed downward into the perineum. With the forefinger of the right hand the surgeon begins the enucleation, which is performed entirely through the perineal opening. The fibrous sheath of the prostate covering its posterior and inferior surface is broken into by the finger, and the capsule entered; the entire prostate is shelled out from within its sheath by digital dissection. The inferior and posterior surfaces of the prostate should be first separated from the capsule. The mucous membrane of the bladder and prostatic urethra covering the enlargement, with the underlying muscular tissue, is stripped up from the part to be removed, but is not opened. The lateral lobes are first removed, after which, if there is a middle enlargement or a projecting

tumor or tumors, these can be pressed downward into the perineal wound and enucleated in the same manner. During the enucleation the prostate can be drawn down into the perineum by forceps, and for this purpose I use an ordinary ring sponge holder with a strong lock in the handle.

After the removal of all the prostatic growths, the lower wound is flushed with a 1 to 5,000 bichloride solution, a perineal tube is inserted into the bladder, and a rubber drainage tube of moderate size is placed in the bladder above the pubes. The retraction sutures are removed, and the bladder is allowed to drop back behind the pubes. The upper part of the suprapubic wound is then closed by sutures, and a dressing of gauze pads applied, which is perforated to permit the drainage tube to pass.

The after-treatment consists in daily washings of the bladder, the fluid being injected into the suprapubic tube. All urine flows out of the perineal tube. The upper tube is removed on the fourth day, and the lower tube three days later, after which the bladder is washed by catheter through the perineum for a few days. A full-sized sound is passed at the end of the second week, and then every five days until the perineal opening closes. Both wounds have usually healed in the course of five weeks.

If this description be compared with that of Dr. Nicoll's method, published in *The Lancet*, April 14, 1894, it will be seen that the two methods are essentially different. In each, the combined suprapubic and perineal incision is made, and the prostate is enucleated through the perineal wound, the suprapubic incision being used for the purpose of pressing the prostate into the perineum with the fingers, and thus facilitating its removal. In neither operation is the mucous membrane of the bladder or that of the prostatic urethra injured. But Dr. Nicoll exposes the prostate by a rather elaborate dissection, stripping the rectum away from its under surface; while in my operation a simple perineal section is made. Dr. Nicoll does not open the urethra, but drains the bladder by means of a catheter passed through the urethra; while I open the membranous portion of the urethra for the purpose of securing vesical drainage through the perineal wound. For the purposes of enucleation, Dr. Nicoll recommends, in difficult cases, the use of a blunt periosteum elevator and specially designed scissors and cutting forceps.¹ In the operations which I have done, the enucleation has been performed entirely with the finger. Dr. Nicoll packs the perineal wound and cavity, left after the removal of the prostate, with iodoform gauze. I simply allow the cavity to drain into the perineal wound, and keep it sweet and clean by frequent flushings with a mild antiseptic solution.

Dr. Nicoll's operation is certainly to be commended, and has been, I believe, eminently satisfactory in his hands. I have not personally performed it upon a living subject, but upon the cadaver it requires a much longer time than does my own operation. It has also the disadvantage that the bladder must be drained by a catheter tied in the urethra, a proceeding which is badly borne in most cases, and which in many becomes intolerable.

Dr. Nicoll states that in the cases operated upon by his method, up to the publication of his paper in January, 1894, he had not encountered a median projection of the prostate, the obstruction in his cases being due entirely to the enlargement of the lateral lobes. He recommends that when a median enlargement is present, it should be left at the time of the operation and removed some days later through the suprapubic opening. I can see no reason for this course, for it

seems as easy to remove such a projection through the perineum at the time of the original operation as to remove the lateral lobes. To do as Dr. Nicoll suggests is, practically, to perform McGill's operation as a secondary measure.

The operation which I have described above I first performed in January, 1894. Since then I have operated by this method in eight cases, with two deaths. The result in the six successful cases was complete restoration of voluntary micturition. The ability to empty the bladder completely was regained by all but one patient, and in this case the amount of residual urine is now only six drachms. I have removed by this method both lateral lobes entire, the lateral lobes and a median projecting mass, a lateral and median enlargement, the lateral lobes and two large projecting intravesical growths. These masses have been taken out entire. In none of these cases was the mucous membrane of the bladder or prostatic urethra cut or torn. The patients were usually confined to bed for three weeks, and both suprapubic and perineal wounds were closed in all the cases at the end of five weeks after operation. In one case in which I removed four very large masses, the patient had partial incontinence for several weeks after the wound had closed, but he subsequently gained good control over the sphincters. In none of these cases was the hemorrhage troublesome. In one of these cases the bladder contained six calculi, each about the size of a chestnut. In another about fifty small prostatic calculi were removed, together with the prostate. In all the cases the expulsive power of the bladder was greatly lessened at the time of operation; in most of the cases there was complete vesical atony. In one of the cases the bladder wall was greatly thickened and the mucous surface was markedly trabeculated. In all the cases but one the entire prostate was shelled out from its capsule. In the first operation performed by this method, the prostate was enucleated piecemeal; in all of the others, it was taken out in large masses.

The advantages I have claimed for this method of operation are:

1. The entire prostate is thoroughly and immediately removed by enucleation.
2. The mucous membrane of the bladder and prostatic urethra is uninjured, and the danger from septic absorption is thereby lessened.
3. Hemorrhage is reduced to a minimum.
4. The most efficient and thorough drainage is secured.
5. The time required by practised hands to perform the operation is comparatively short.

The Fatal Cases.—CASE I.—L—, aged fifty-eight years. Patient had been a hard drinker. History of prostatic obstruction for several years, frequent attacks of retention. On admission to Bellevue Hospital, patient could pass a very little urine voluntarily. He had great frequency and some overflow. The urine was ammoniacal, loaded with pus and blood: specific gravity, 1.018; twenty-five per cent. by bulk of albumin; hyaline and a few granular casts. He had a mitral regurgitant murmur, and a general atheromatous condition of the blood-vessels. A catheter was passed, and the bladder emptied and washed. Catheterism was difficult and produced hemorrhage.

Operation, September 30, 1895: Two large lateral lobes and a median enlargement were removed without much difficulty. Patient appeared to do well until October 2d, when he developed a pneumonia, urine became scanty, the perineal wound sloughed, and a small fistula formed between the rectum and the perineal wound. He died two days later. There was entire suppression of urine during the last twelve hours. The patient was operated on only as a last resort, and his death was not a surprise. This case is an exam-

¹ Letter in *Journal of Cutaneous and Genito-Urinary Diseases*, August, 1895.

ple of those in which operative measures are employed too late. I should prefer, with my present experience, to use vesical drainage in a similar case, rather than prostatectomy.

CASE II.—M—, aged sixty-four years. Patient a hard drinker; had several attacks of renal colic pre-

FIG. 1.—Both Lateral Lobes Removed from Case III. (exact size).

vious to his fortieth year. One year after his last attack he passed three calculi by the urethra. History of frequent micturition for several years. Five or six months prior to admission he began to have the acute symptoms for which he now sought relief. He had burning pain, especially severe after micturition, great frequency and urgency, which were increased by jolting. The stream of urine was feeble, and was suddenly arrested. He had never passed blood. Urine: specific gravity, 1.010; small amount of albumin and large amount of pus. A microscopical examination showed many blood cells; no casts. Rectal and urethral examination showed a moderate enlargement of both lateral lobes and a projecting median portion. The amount of residual urine was about five ounces. Examination of the bladder by searcher showed a number of calculi.

Suprapubic cystotomy performed, April 20, 1895, under ether anæsthesia. Six calculi, each about the size of a chestnut, were removed. Digital examination of the bladder showed that the prostatic enlargement formed a thick ring or collar about the vesical orifice, making thereby a very deep *bas-fond* behind the prostate. A perineal incision was made, and the entire prostate removed through the lower opening. Patient rallied well from the operation, but upon the second day developed uræmic symptoms, with almost complete suppression, and died April 24th, four days after operation.

The autopsy showed a general arterio-sclerosis, valves of the heart thickened, calcareous deposits in coronary arteries, lungs oedematous. Emphysema well marked, moderate bronchitis. Liver friable; weight, five pounds. A single renal calculus in pelvis of left kidney. Kidney showed chronic parenchymatous nephritis. No evidence of suppuration about the operative wounds. Mucous membrane of the bladder and prostatic urethra intact.

The Successful Cases.—CASE I.—Prostatic calculi and enlarged prostate. C. B—, aged fifty-three years, admitted to Bellevue Hospital, January, 1894. Symptoms of prostatic obstruction for over one year. Great frequency day and night. Intense tenesmus at end of act of micturition; frequent hæmaturia. Passed about one-half ounce at each act of micturition. Had never used catheter regularly. Rectal and urethral examination showed prostate rather irregular in outline, right lobe larger than the left, and small

median projection. Pressure upon the prostate caused great pain and revealed the presence of calculi in its substance, which could be rubbed together. Searcher showed presence of calculi projecting into the prostatic urethra. Residual urine about six ounces. Expulsive force of bladder fairly good. Urine showed chronic cystitis; kidneys were sound.

Operation, January 22, 1894, under ether anæsthesia. About fifty calculi and the entire prostate were removed. This being my first operation by this method, the prostate was shelled out piecemeal. The perineal tube was removed on the fifth day, as the patient complained of pain, and was reintroduced every two hours for the next twenty-four hours; the suprapubic tube was removed on the sixth day. Both wounds healed kindly. Patient passed all his urine by urethra at the end of the fourth week. He was kept under observation until March 22, 1894, when he was discharged cured. He could then empty his bladder completely, and his urethra admitted easily a No. 32 F. sound. Patient reported himself well in April, 1896.

CASE II.—E. R. B—, aged fifty-six years. Symptoms of prostatic obstruction for past six years; micturition difficult. During the past two months he had from time to time suffered from overflow. He had an attack of complete retention two years ago, after exposure to cold. This was relieved by catheter, and since then he had passed urine with greater difficulty, about every hour. Six months ago he had a second attack of retention, relieved by catheter, followed by severe cystitis. He had used a catheter since then every four hours, with little relief. Patient, when first seen by me, had complete retention—his third attack. Prostate was uniformly enlarged in the lateral lobes, and was rather tender. Coudé catheter passed with some difficulty; sixteen ounces of urine withdrawn. For two weeks patient was regularly catheterized and bladder treated. The residual urine, after voluntary micturition was restored, was nearly eight ounces. He absolutely refused to follow out directions as to catheterism and washing, and demanded an operation. This was performed by me early in February, 1894. Tubes removed on the fourth and sixth days respectively. Wounds healed kindly, and were completely closed by the fifth week. Patient left for his home in another State, and has since then reported that his urine remains clear and that he emp-

FIG. 2.—Lateral and Median Enlargement Removed from Case IV. (exact size).

ties his bladder completely. In this case, both lateral lobes were removed entire.

CASE III.—J. F—, aged sixty-six years. Prostatic symptoms dated back twelve years, when he began to have frequency. He had used a catheter every four hours for the past six years, and had washed his bladder once daily with various aseptic solutions. Six

months ago he had complete retention, and since then had suffered with severe cystitis. The intervals of catheterism had been becoming shorter for the past two months. He was now obliged to pass his catheter every two hours, night and day. Bladder had little expulsive force. He had eight ounces of residual urine. Rectal examination showed a smooth, rather soft enlargement of both lateral lobes. Urine: specific gravity, 1.021; alkaline, ammoniacal; thick, purulent sediment, trace of albumin, no sugar, no casts. As the patient's condition was growing very much worse, an operation was proposed and accepted.

Operation performed in October, 1895. Two large lateral masses were removed without great difficulty. The bladder was somewhat thickened. Drainage tubes removed on the sixth and tenth days respectively. Patient made an uninterrupted recovery; passed all his urine on the thirtieth day.

CASE IV.—This and the next case have been previously reported. T. O'C—, aged sixty years. Ten years ago he had a sudden attack of retention, which was relieved by catheterism; he was admitted to one of the city hospitals, and was there taught to pass a catheter, which he continued to use for several years. Three months ago he had a second attack of retention; this was also relieved by catheter. He was admitted to my service at Bellevue on February 11, 1895, with retention for the third time and considerable vesical distention and overflow. He was catheterized, and thirty-two ounces of residual urine were drawn. Rectal examination showed an enlargement of the prostate, the right and median portions being affected. The catheterism was not difficult when a Mercier instrument was used. A soft catheter could not be introduced. The bladder had no expulsive force. He was catheterized four times daily and the bladder washed once a day until March 17th. At the end of this time the patient could pass about half an ounce of urine voluntarily, there being about ten ounces of residual urine. It was found impossible to teach him to use a catheter and wash his bladder, and, as he had no facilities for performing this for himself out of the hospital, an operation was offered and accepted.

Operation, March 18th. Ether anæsthesia. A large right lobe and smaller median portion were removed through the perineal opening after enucleation without much difficulty. Bleeding slight. Bladder trabeculated and thickened. Suprapubic tube removed on sixth day. Perineal tube removed on thirteenth day. No. 32 sound passed. Suprapubic opening nearly closed. No urine escaped.

April 24th, perineal wound closed. All urine passed by urethra. At the present time he makes water every four or five hours and empties his bladder, except six drachms of residual urine.

CASE V.—James D—, aged sixty-two years; weight, two hundred and thirty-five pounds. Admitted March 26, 1895. Patient came in with a history of difficulty in passing water and great frequency, of several years' duration with a condition of acute retention of urine of twelve hours' duration. Catheterism was attempted by the house surgeon, but he was unable to pass any instrument into the bladder. After some difficulty I succeeded in passing a No. 6 E. styleted catheter, bent to an exaggerated curve, the stylet being withdrawn gradually as the catheter was introduced, so as to cause its point to override the obstruction presented by the middle portion of the prostate. Thirty-two ounces of ammoniacal bloody urine were withdrawn. Rectal examination showed an enormous prostatic tumor encroaching upon the cavity of

the bowel, the upper margin of which was well above the reach of the finger. The patient's bladder was washed and a catheter was passed by the above-described method every six hours. The urine continued to be foetid and to contain blood.

On March 28th the house surgeon again failed to make the instrument enter the bladder, and I succeeded only after a long trial. I decided to open the urethra through the perineum, as a preliminary to prostatectomy for the purpose of draining the bladder and disinfecting its cavity; I therefore, under ether anæsthesia, performed a perineal section, and attempted to dilate with my finger the prostatic urethra. I could not, however, pass my finger into the bladder, owing to the length of the prostatic portion of the urethra and the very great resistance offered by the prostatic growths. Accordingly, I simply introduced through the perineum into the bladder a No. 26 F. tube, and, having washed the bladder, secured this in place by tapes. This drainage I continued for a week; the loss of blood ceased, the urine became clearer, and the patient's condition improved. At the end of the week the perineal tube was taken out, and I then found no great difficulty in introducing through the urethra a Mercier catheter. Knowing, however, from the size of the prostate, that this improved condition would be only temporary, I decided to remove the prostate, which I did on April 11, 1895. The operation, owing to the depth of the perineum, was

FIG. 3.—Lateral and Median Enlargement Removed from Fatal Case II. (exact size).

difficult to perform. I succeeded, however, in removing the entire enlargement—two large lateral lobes and two large median tumors—without injury to the bladder or prostatic urethra. The tubes were removed on the tenth and sixteenth days respectively. The wounds healed slowly, but both were entirely healed at the end of the fifth week. The patient at first had almost complete incontinence, but now has control over his sphincter, and empties his bladder completely.

CASE VI.—O. D. H—, aged sixty-five years. Symptoms of prostatic enlargement for fifteen years. Had had retention, with overflow, for past two years, and had had to depend entirely upon his catheter for relief. His urethra was extremely sensitive, and catheterism was always followed by hemorrhage. He was obliged to pass the catheter every two hours, night and day, and these intervals were rapidly becoming shorter. He had a symmetrical enlargement of both lateral lobes, which projected far up into the bladder. He was put to bed, and an attempt made for a week to institute more perfect aseptic catheterism, but, as his symptoms showed no signs of improvement, I proposed an operation, which was accepted, and this was performed in September, 1895.

Two large lateral lobes were removed without difficulty. The drainage tubes were removed on the fourth and sixth days respectively. The patient entirely emptied his bladder on the thirty-fifth day. He re-

turned to his home, and I have not heard from him since his departure.

Prostatectomy, when it is performed before the kidneys have become seriously diseased, does not, I believe, involve much more risk than a suprapubic cystotomy for the relief of other conditions. The perineal incision does not increase the risk. In cases of advanced prostatic disease, however, when the bladder is the seat of severe cystitis, when the kidneys are seriously crippled, especially when pyelo-nephritis is present, the dangers of prostatectomy are greatly increased, as the principal cause of death after prostatectomy is failure of the kidneys to perform their function. In these cases I believe that it is better surgery to open the membranous urethra as a preliminary measure, and to

drain the bladder by a large catheter or tube introduced through the perineum; and later, when the conditions are more favorable, to do a prostatectomy. This course was pursued with good results in one of the cases which I have reported. The value of vesical drainage in cases of advanced prostatic enlargement is very great, and in these cases, unless the object of the operation be to make a permanent fistula, I prefer perineal to suprapubic drainage. In many cases in which catheterism has become difficult, especially if due to outgrowths from the lateral lobes into the prostatic urethra, dilatation of the latter by introducing the

finger through a perineal opening and drainage of the bladder make the introduction of a catheter comparatively easy for a time. This effect, however, is only temporary, and sooner or later these cases relapse unless the prostate is removed. I do not believe that prostatectomy should be performed during a period of acute congestion. It is better to wait until the congestion has subsided, as a result of careful catheterism, or, if this fails, to drain the bladder through the perineum for a few days, before deciding whether a more radical operation will be required. It may be stated, further, that an operation upon a highly congested prostate is certain to be accompanied by much more severe hemorrhage.

The question of relapse after prostatectomy is one deserving some consideration. If the operation has been thoroughly and skilfully performed and the entire prostate has been removed, it can be positively stated that no obstruction can occur in the future. If the prostate is only partially removed, return of the obstruction by progressive enlargement of the portion remaining is possible, and such cases have been reported.

Another question which requires careful consideration is: To what extent will the bladder regain its

power after prostatectomy? This cannot be positively answered in all cases. Cases have been reported in which the operation was performed after the bladder muscles had undergone structural change as the result of severe and prolonged cystitis and obstruction, and in these voluntary micturition was not restored by prostatectomy. My own experience has been that, in all cases in which structural changes of a severe type have not occurred in the vesical walls, even if the bladder is completely atonied, the power of voluntary micturition can be expected in the great majority of cases if the entire obstruction be removed. Even should the bladder fail in some cases to recover its power, and the use of a catheter be necessary after prostatectomy, it will be found that the difficulties and

dangers of catheterism are far less than before the operation.

The mortality after prostatectomy is still high—about eighteen or twenty per cent. for all operators. It is gradually becoming less as the indications for the operation are better understood. The death rate of individual operators will undoubtedly continue to grow less as they become more expert in performing the operation, and the cases of relapse and failure will be much fewer as more experience is gained.

In concluding, I desire to state that prostatectomy promises to be a more satisfactory method of radical treatment than any other yet proposed, provided that the

operation is performed before the kidneys have become hopelessly diseased.

5 WEST FIFTY-EIGHTH STREET, NEW YORK CITY.

FIG. 4.—The Two Lateral Lobes and Median Enlargement, with an Intravesical Projection, Removed from Case V. (exact size).

Tetanus and Its Antitoxin.—Dr. Ferdinand Blumenthal (*Zeits. f. klin. Med.*, xxx., No. 5-6, pp. 538-549) reports two cases of tetanus in which he had an opportunity to make a few researches as to the action, localization, and chemical nature of the tetanus toxin formed within the human organism. He concludes that the tetanus toxin circulating in the human body is soluble in water containing common salt, and that it does not belong to the albumin substances. The tetanus toxin is rendered inactive by the injection of curative serum (Heilserum). The tetanus toxin is found in the spinal cord. In this location the antitoxin circulating in the organism does not render it inactive. The tetanus toxin produced in the human organism does not produce an increase of temperature in guinea-pigs, as it does in man, but, on the contrary, lowers it. There is no tetanus toxin in active concentration in the urine of tetanus patients. Urine of animals not affected with tetanus can produce tetanoid symptoms in mice and guinea-pigs.

EXPERIENCES WITH THE PHYSICAL AND SCHOTT TREATMENT OF CHRONIC HEART DISEASE.¹

By H. NEWTON HEINEMAN, M.D.,

NEW YORK.

SEVEN years ago I had the pleasure of presenting to this society a paper² upon this subject. With the natural prejudice of my professional training, it was not strange that, while thinking well of the Schott treatment, the distinguished name of Oertel and his work should have impressed me somewhat more than that of Schott and his investigations. Careful studies continued since then, both at Bad Nauheim, where I had the opportunity of seeing many hundreds of cases, and at Berlin and Paris, where I put to the scientific test the physiological problems connected with this subject, have convinced me that the balneological and the Schott treatments, applied in accordance with my experience and under conditions which I will indicate, offer us far greater promise of relief in heart disease than any other method. Then, too, the scientific basis of the Oertel treatment has been much impugned, and the practical application of the same narrowed down to small limits.

Balneological Treatment.—Twenty-five years ago Beneke, professor at Marburg, determined scientifically that the saline waters of Bad Nauheim had a potent influence in relieving diseased cardiac conditions, and that it could be accepted without question that in cases of rheumatism with valvular disease, inflammatory deposits on the valves were to a large extent absorbed and the heart condition materially improved.

Despite his statements, the baths of Bad Nauheim received little recognition in this direction, and for many years the majority of patients visiting Bad Nauheim were sufferers, as a rule, from chronic rheumatism, who only sought relief from their rheumatic diathesis.

It was at this time that Dr. August Schott brought forward his "treatment by resistance exercises." He carefully went over the entire ground of the physiology of the baths, and by dint of unswerving scientific devotion and original methods of thinking so modified the manner of application of the baths as to avoid injurious effects, and by combining with these the resistance exercises, gave birth to a system, the so-called "Schott system of treatment for chronic cardiac disease."

The early death of Dr. August Schott threw upon Dr. Theodore Schott the labor of its elaboration and of its introduction to the profession.

For several years it has been a labor of love with me to stand at the side of Dr. Theo. Schott and devote my best efforts to the laying of a scientific basis for the work, and to act as an assistant in the propaganda of the system.

If my personal views differ from those expressed by any other authority upon the subject, they are those for which I alone am ready to assume complete responsibility.

Bad Nauheim, a well-drained and healthy village (distant forty minutes by railroad from Frankfort on the Main and a pleasant night's journey from Hamburg, Bremen, or Paris), contains (in addition to its several springs of drinking-water) two springs known as No. 7 and No. 12, which are used for bath purposes. The analysis of these two springs is given below, including the analysis of the mother lye (Mutterlauge), to be referred to hereafter:

ANALYSIS OF BAD NAUHEIM SPRINGS.

(Gram contents in 1,000 grams of each.)

	No. 12.	No. 7.	Mutterlauge (mother lye).
Sodium chloride.....	30.00	20.00	20.00
Ammonium chloride.....	1.00	0.50	

Calcium chloride.....	2.50	1.75	380.00
Potassium, caesium, and rubidium chloride.....	1.00		60.00
Calcium bicarbonate.....	2.50	2.50	5.50
Iron, magnesium, and zinc bicarbonates	1.00	1.00	
Lithium chloride.....	0.05	0.05	15.00
Magnesium chloride.....	0.50	0.50	75.00
Strontium chloride and sulphide (with baryta).....	0.05	0.05	10.00
Calcium sulphide.....	0.04	0.04	0.40
Magnesium bromide, iodide, and bi- carbonate.....	0.01	0.01	1.50

A Nauheim thermal saline bath in 500 litres of spring No. 12 (at 86° F.) contains 18.17 kgm. salts and 254 gm. = 127 lit. carbonic acid. A Nauheim thermal saline bath in 500 litres of spring No. 7 (at 86° F.) contains 13.43 kgm. salts and 571 gm. = 324 lit. carbonic acid. The Nauheim sprudel (effervescent) bath contains from three to four times the amount of carbonic acid.

It will be seen that these waters are iron waters, contain large quantities of the chlorides of sodium, lithium, calcium, and magnesium, of bicarbonate of calcium, considerable of the chlorides of caesium, rubidium, and potassium, bromide of magnesium, besides other rarer elements in appreciable quantity. The third and most important characteristic is the large quantity of carbonic acid (free and in combination) present in these waters. The Nauheim waters constitute the strongest thermal carbonated saline (ferruginous) waters of Europe. No other ferruginous bath contains more iron and carbonic acid, no known thermal saline bath contains so much carbonic acid. The fact of their being naturally warm (85° F. and 95° F.) avoids the necessity of heating them, as is done with the non-thermal saline waters, and by which the latter lose some of their elements and become changed in composition. The waters are made use of in several ways. Either they are drawn from reservoirs (in which they are stored and have lost some of their carbonic acid and have become somewhat cooler), or they are permitted to flow directly from the source in the earth through iron tubes into the bathtub itself.

The latter are called sprudel or natural effervescent baths (Sprudelbad). They are further modified by allowing the water to flow into and out of the tub by openings near the upper level of the bath; thus the tub remains full, but it is constantly replaced by a fresh supply. These are named flowing effervescent baths (Sprudelstrombad), and resemble a surf bath in some of their effects.

According as the waters are drawn from the reservoirs or directly from the earth, the temperature and amount of carbonic acid are varied similarly by mixture of the two springs, and by other usual means every desirable grade of temperature and degree of effervescence and strength of saline contents can be obtained.

The so-called mother lye (Mutterlauge) contains a nearly similar proportion of sodium chloride, but three hundred times the amount of lithium, two hundred times the amount of calcium, one hundred times the amount of magnesium, sixty times the amount of caesium, rubidium, and potassium, and two hundred times the amount of bromide of magnesium of the natural springs. It is used in quantities gradually increased of from one to three litres added to the natural spring bath, and very materially strengthens the saline contents. The mother lye is not a lye, but is the liquid residue of the waters Nos. 7-12 which is left over after the crystallizable salts are removed; it is a brown and somewhat oily liquid.

Mode of Application.—The baths are given at a temperature varying from 83° to 93° F., ordinarily. We begin at the highest temperature and recede slowly and gradually, being guided by the condition and habits of the patient, to the cooler temperature. The patient's sensations are an important guide in this direction, until we have had a large experience.

¹ Address delivered before the Academy of Medicine, New York, November 5, 1896.

² See New York MEDICAL RECORD, 1890.

The length of time of the immersion should never exceed twenty minutes, beginning with six or eight minutes, and increasing gradually. At first it is wise to interrupt or give pause on the alternate days; later two baths may be given in succession with pause on the third day. For myself, I prefer not to give three successive baths, save in exceptional cases. It is of great importance that the patient should be assisted during the bath, and even professionally watched. After the bath the patient is to be wrapped and served with warm bath towels, and the circulation of the extremities well looked to. An hour's rest (without sleep) is urgently to be recommended after each bath.

The period of time required for the entire treatment is ordinarily from four to six weeks. In cases in which the treatment must for one cause or another be interrupted, the duration may be extended over six or eight weeks. After a course of completed treatment, or after treatment for the latter length of time (even if incomplete) the patient should rest for from two to four weeks at some mountain resort, or in some quiet place. Then, in the incomplete cases, the treatment may again be taken up and completed, to be again followed by a rest after completion.

Physiological Action.—Time does not permit me as a preliminary to my work to consider the curative effect and its physiology in cases of rheumatism and gout for the relief of which conditions these waters have long held an unquestioned position.

It is not unusual, however, that sufferers from these affections, who, however, seek relief from their cardiac trouble, are obliged after a few baths to contend with what seems an acute attack or exacerbation of gout or rheumatism. In gouty cases the deposits very soon become softened and while circulating in the blood in their exit from the body, give rise to various symptoms of the disease. All these attacks are very soon recovered from, at times by the aid of a little medication.

If a patient with relaxed muscular fibre and consequent flabby heart, or a patient with diseased heart with loss of compensation, takes a saline bath at Bad Nauheim, the effects upon the patient are as follows: At first, after a few moments of immersion, there is a feeling of oppression or weight over the sternum or epigastrium. This soon disappears and the patient breathes more freely. The pulse almost invariably becomes fuller and generally slower. The arterial pressure taken of the radial or temporal arteries usually indicates slight increase, to be followed later by diminution of the same.

The capillary pulse, a subject of very recent investigation, for knowledge of which I am indebted to Dr. Max Herz, of Vienna, varies in a similar manner. An examination of the heart made before and after the bath will reveal in at least one-fourth of the cases, and particularly if it be the first bath or the first effervescent bath after a series of ordinary saline baths, an appreciable and frequently well-marked diminution in size and change of shape. In all cases, with few exceptions, this change in the heart's size and shape could be determined and appreciated after a number of baths, when it could not be noted after the single saline bath. Lest this phenomenon be wrongly ascribed to diagnostic error, or natural change of shape and size, the result of intervening time, I add that every precaution against error and self-deception was used. In the first place, I made a series of investigations to determine the changes in size and shape of the heart as the result of diurnal work, mental and physical, and as the result of changed position. No such changes in size and shape occur naturally within the period of time usually required in this examination. It is true that sometimes twenty minutes intervene between the first and second examinations, but in cases in

which the demonstration is to be made to others, eight minutes only are allowed to elapse; that is, the examination is made the instant prior to the patient's entering the bath, and again the moment the bath is ended and the patient has been only gently dried, sufficient to secure him against cold during the examination. Then, too, this change of shape and size has been shown in the presence of the most distinguished and critical of European physicians—Botkin, Rauschenbach, Pawlinski, and Von Dehn, of Russia; Broadbent, Bowles, Alexander Morison, Bezly Thorne, Gifford Ransford, and Saundby, of England; Grainger Stewart and Robertson, of Scotland; Sir Francis Cruise and Sir Philip Smyly, of Dublin, and others.

In all of my own investigations, differences of half a centimetre or under were left out of consideration, because such slight differences, if they constituted the most important ones to be relied upon, were considered within the limits of personal error.

The physical examination included the relative and absolute limits of dulness of the heart, the lower border of the lungs, the determination of the level of the diaphragm, the upper and lower limits of the liver, of the spleen when possible, and the diameter of the chest, both antero-posteriorly and laterally, besides its circumference above and below the mammary line. Occasionally the abdominal circumference was likewise taken. In the measurements which were made both before and after the bath, the pulse pressure was taken by the V. Basch sphygmomanometer, the calibre of the arteries was determined by the arteriometer, the pulse trace was taken by the Dudgeon sphygmograph, the capillary pulse by the Herz instrument—the position of the patient and the artery examined always being the same, before and after the bath.

As to the local action upon the skin, the effects in the case of the effervescent bath are much more marked, the skin as a rule being reddened and the patient having a distinct sense of warmth beyond that of the temperature of the bath. The same applies with greater force to the flowing effervescent bath. Naturally, also, after the latter (the effervescent and the flowing effervescent), the effect upon the heart and circulation is more decided.

The statement made by a Russian chemist, that the bubbles of free carbonic acid could not produce the effect, because such bubbles are surrounded by a layer of atmospheric air, is easily demonstrated to be untrue. For, if the bubbles of carbonic acid are brushed away from any portion of the body during the time of the bath, the skin of that portion remains pale, in sharp contrast to that of the rest of the body.

The question, Are the effects of the baths the result of absorption in its ordinary sense by the human integument? must be answered in the negative. Through the outer layer of the skin, a slight degree of imbibition takes place. It is surmised that the saline fluid penetrates the outer layer, at least as far as the nerve endings. Viewed from whichever side, it is beyond question that the heart is enabled to work with less muscular force and stimulated to more regular action by the effect produced upon the enormous capillary network of the integument. The relief of the internal organs while the blood is circulating in the previously congested cutaneous capillary vessels, the more equable distribution of the circulatory fluid, or the sending of a larger volume of blood to the heart in cases in which the amount flowing to the heart was at times either deficient or irregular—these and similar effects are too important not to lead us to accept the claim that the change in the capillary circulation of the skin must be a potent factor, even if it be disputed what rank is to be assigned to it.

When we next consider the great network formed by the nerve endings in the integument, it should not be

surprising to us that the nervous influence reflected from these should produce an effect upon the circulation and heart. For the present, the theory of reflex action, to which no serious scientific objection can be raised, seems the more acceptable, although the rôle of the capillaries is a not unimportant one.

It would be a source of great comfort to us and make the explanation simpler, if we could accept the idea of absorption by the blood-vessels of the integument. For recently Ringer has proven that the calcium salts have a strong stimulating effect upon the heart, and the Nauheim springs, and the mother lye in particular, contain these salts in large proportion.

It is of great importance that I draw attention to the difference in the effect produced upon the animal economy by fresh-water and saline baths. Zuntz and Roehrig have determined that saline baths give rise to greater tissue metamorphosis than fresh-water baths. Other authorities (Dapper and others) have since claimed a still greater difference. The fact that we are dealing with saline baths of a definite percentage constitution and of a certain temperature must always be borne in mind by the practitioner. To expect similar results from any bath and at any haphazard temperature is to foster disappointment and invite injury to the patient.

Artificial Bath.—While the baths of Bad Nauheim give us effects that cannot be entirely obtained from the artificial bath, yet the latter, as Schott¹ pointed out years ago, are capable of producing precisely similar if not equally great results. The manner of their preparation is not difficult, save in the case of the effervescent bath, which requires some caution because of the use of hydrochloric acid. I am in hopes that within a short period of time processes for carbonating waters will enable us to produce effervescent baths, and even the flowing effervescent bath be made without difficulty.

Ordinarily we commence by preparing a bath of a one or two per cent. solution of chloride of sodium, to which we add a half per cent. of chloride of calcium. Later we increase the strength of the bath by the use of the Nauheim Mutterlauge, or else in the equivalent mixture of its components salts. In making the effervescent bath we commence with a solution of bicarbonate of sodium, to which we add after the tub is properly filled, a little less than an equal (to the bicarbonate of sodium) quantity of hydrochloric acid. After the stopper of the bottle (turned upside down) has been removed beneath the surface of the water, the acid is poured out slowly, the bottle being moved about at different layers of the bath water. After three minutes the effervescence begins, and, having taken the precaution to see that the acid is everywhere well mixed with the water, we fan away the carbonic acid that at first accumulates above the level of the bath, and all is in readiness.

Exercises.—The Swedish gymnastics have long been known to a limited number of the profession. Under the name of the Zander movements they have been extensively employed in the larger cities of the world for the relief of different conditions. In certain kinds of nervous cases, in conditions of malnutrition, and as an antifat remedy, I have made use of and well know the results of this system. Stokes long ago noted the effects of mountain climbing in cases of heart disease, but he never adopted it or promulgated it as a system. It was the genius of the late Dr. August Schott who recognized the effects of certain movements upon the circulation and heart, and by careful study formulated a system of movements which enabled him to produce direct effects upon the heart muscle. The movements which he made use of were carried out by the patient in the following man-

ner: The patient was ordered to make a certain movement in a given direction, while the doctor or attendant would make resistance with the hands, so that the patient in completing the given movement had to overcome the hindrance or resistance thus made. To this system, the Schott system, the name of movements with resistance (*Widerstands-Gymnastik*)¹ has been given. Among the rules as originally laid down by August Schott are the following: All movements must be made slowly, without exertion, evenly, and without jerking. Each successive movement should bring a different group of muscles into exercise. After each movement there should be a momentary pause.

In addition to the above the attendant should carefully watch the movements of the *alæ nasi* for signs of dyspnoea, even when the patient does not complain of it. The pulse must be watched for any sign of intermission.

I desire to emphasize this latter, for any movement followed by this result should be omitted. It is more apt to occur in connection with the greater excursions involving the entire extremity. Experience has likewise forced me to abandon carrying any movement of both upper extremities above the level of the shoulder, and especially above the head. Likewise empirically it will be found that some persons with cardiac disease are hypersensitive to movements made with the left upper extremity, be it riding, exercising, or even holding anything in the left hand.

In every case the physician should at first either give the first movements himself or have them given in his presence, so that he can watch the pulse and the general effect upon the patient. It is wise to begin with the shorter simpler movements, and then, as the patient's improved muscular sense makes it manifest that he can bear the greater excursions and resistance, we can increase them, though the increase should be less than the patient can support with greatest ease. A brief explanation to the patient of the principle underlying the movements aids in securing his more exact co-operation. And it must be equally impressed upon the minds of both doctor and patient that these movements are not a course of athletics. It is the fact that the patient in executing any given movement must overcome resistance which lies at the bottom of the effect. Hence every movement, however simple or slight, produces an effect. Even the movements of the fingers resisted as though playing piano upon the fingers of the attendant give results similar in kind and differing only in degree from the larger movements.

When baths are employed, exercises should be given once a day. When, however, exercises are used without baths, the exercises, though given once a day at first, may later be employed twice daily. Under all circumstances begin slowly, giving from five to ten minutes of exercise at the outset, and increase gradually until you have reached thirty minutes. When exercises are given twice daily the second exercises should not exceed fifteen or twenty minutes. The time indicated includes the pauses as well, so that in thirty minutes about eighteen minutes are taken up by the exercises themselves.

Physiology of Exercises.—Both August and Theodore Schott have contended that the effect of these exercises is to produce change in the size of the heart and, as a rule, displacement of the apex beat upward and toward the median line. The difficulties resulting from percussion, the inability always accurately to determine the apex beat, have during the past years of active discussion of the method often caused doubt in the minds of many examiners as to the correctness

¹A modification called *Selbsthemmungs-Gymnastik* will be referred to in future articles.

of this assertion. It is four years ago that I became satisfied of the truth of the claim, and numerous investigators have since added their testimony and the results of their personal inquiry to it. B. Thorne led the crusade in England, and, although his technical and physiological claims were somewhat exaggerated, yet his practical results compelled attention and investigation. In the month of July I was privileged to be present while naval surgeons Berendsen and Schumburg and Prof. N. Zuntz, the eminent physiologist, applied the Roentgen rays to the hearts of a number of persons. The results obtained by them made me extremely desirous of securing testimony bearing upon the subject of "resistance exercise and its beneficial effects upon the heart." Zuntz had proven "that overexertion, however moderate, tended to dilatation of the heart."

After investigating with the barium-platino-cyanide fluoroscope I found that while my results showed the heart smaller than before the resistance exercises, yet the shadow thrown by the bifurcating pulmonary bronchi, the movement of the diaphragm, and the unsteady light left something to be desired. I therefore resorted to photography by the Roentgen rays. Having arranged my light and table so that the light and the patient would always be at the same distance from each other and in the same line, I took the photograph of the heart (developing the plate and reproducing it on paper in the usual manner) before and after the resistance exercises, and thus proved that the heart undergoes change in shape and diminution in size, the greatest difference in cardiac diameter before and after exercises being equivalent in one case to more than two centimetres.

In speaking of this subject, whether as the result of baths or exercises, it must not be presumed that the diminution in size or change in shape of the heart is a continuous one. Nor is the change in shape uniform in all directions. In different cases various portions of the heart, one or both auricles, one or both ventricles, in varying combination and extent, change their form. As to size, what has just been said of the change in shape will indicate the expected diminution in size in different directions. To presume, however, that each day's gain is permanent, would be to expect the impossible. The recovery of the heart during a certain day is lost in a measure by the following day, and in this manner of successive daily diminution, with partial loss of the ground gained, we gradually succeed in attaining to that diminished size which in the given case represents the heart in the condition of most perfect muscular compensation.

Upon applying the sphygmomanometer, sphygmograph, etc., and taking measurements before and after exercises, just as in the case of baths, allowing of course a sufficient interval of time to permit the immediate effects of the exercise to pass off, the pulse trace, arterial pressure, and capillary pulse showed changes similar to those following the bath, before referred to.

(It will be found in certain instances in which marked dilatation complicates the case that during the period of dilatation the effect upon the arterial pulse as recognized by the sphygmomanometer and arteriometer is just the reverse.)

It has been a subject of physiological investigation for many years to measure the increase in tissue metamorphosis following every variety of motion with the aid of the Mosso arm holder, and by its adjustment for measuring the work done by the individual fingers of the hand, with or without added weights to be lifted, aided by the Zuntz-Gippert analyzing apparatus for the expired air, by which latter the increase of oxygen absorbed and of carbonic acid exhaled is accurately measured, the increase of tissue change is gauged. Recently investigation made by Leber and Stuewe upon

the subject of tissue metabolism produced by massage (carried up to twenty-eight minutes' duration) proved that the increase of tissue change after massage did not equal that of the simple movements of the unweighted fingers repeated for a few times only.

The importance of this investigation is readily seen in its bearings upon the effects produced by the movements referred to, and particularly upon the point that I cannot repeat too often, to wit: that we should not hurry to get to the greater movements, since the smaller ones give us results.

In seeking for a physiological explanation of the effects of exercise we are again met by difficulties. It cannot be denied that the local circulation in the different parts of the body brought into movement, is influenced materially, and that the relief of local congestion, whether cutaneous or visceral, and the resulting equalization of the volume of blood in its direct and indirect effects upon the heart and viscera are of importance. But the nervous system plays a most important rôle in controlling the function of the heart and blood-vessels. The condition described by Jacob, of Cudowa, under the name of angiospastic cardiac dilatation, is a forcible reminder of the vast extent of reflex influence between the nervous and circulatory systems. But it is a well-established fact that the reflexes play an important rôle between one portion of the body and another. Considering that the heart is supplied with depressor as well as accelerator nerve fibres, and that its functional activity is thus controlled and kept within its bearable muscular limits, and the relations of the vasomotor system to the blood-vessels at large, we must be prepared to accept that the physiological action of exercises is the result of reflex action to some extent, be this small or large.

Combined Treatment.—While at Bad Nauheim the majority of patients received no medicinal treatment aside from the baths and exercises, in general practice it is strongly to be recommended to omit no ordinary means of medication, or any therapeutic measure by which the patients may be benefited. To every physician who adopts this method of treatment opportunities will come by which he can put the baths or exercises to the test by themselves. It can never be expected, however, that artificial baths will equal those of Bad Nauheim. Such, however, are the good results obtained by physicians in city practice that the profession need not hesitate in undertaking them. Previous study and preparation are, however, essential to the successful carrying out of the treatment and in order to prevent experimentation upon the patient.

Dietetics.—The theories of Oertel have not maintained themselves as to his antifat treatment. It is well of course to limit the amount of liquids taken at meals, and even an excessive amount between meals. All spirituous liquids should be avoided, save when the habit of life permits of a small quantity of diluted light wine (light Moselle or claret). Aerated waters should be used with care and no cold fluids of any kinds taken. As to solid food, the avoidance of excess of starches, sugars, and fat is urgent, but to recommend the suppression of carbohydrates is to leave the system in a materially weakened condition and without its main source of muscular energy.

Indications and Contraindications.—Indications: Generally speaking all circulatory disturbances, all diseases of the heart with or without valvular disease, and particularly with loss of compensation, angina pectoris (bath should always be first employed), Graves' disease, hamophilia, and Barlow's disease. The so-called disease of puberty or adolescence with or without cardiac murmur, congenital cardiac disease. Ordinary complications, such as œdema, anasarca, hydrothorax, hydropericardium, and moderate chronic renal congestion, do not contraindicate the above treatment.

Contraindications: Heart disease with serious complications, such as pulmonary infarctions and with excessive debility, particularly if the circumstances of the patient do not guarantee that the treatment can be carefully carried out; arterio-sclerosis in its advanced stages; aneurism of the aorta of the second and third degree; acute and chronic Bright's disease (more particularly the atrophic form).

The best results are obtained in that large group of cases of weakened heart, of overstrained heart, or irritable heart dependent upon or consequent upon nervous or physical strain or infectious disease, irrespective of the presence of degenerative change in the arteries of the heart muscle, or in the muscle itself.

Second to this we have a group of cases with relative insufficiency, in which the murmur of insufficiency (most often aortic) disappears as the result of treatment. These cases are often complicated with other cardiac lesions. In the third series, we find the large group of cardiac valvular cases with loss of compensation. Of these there is an untold number, in which, after all medicinal help at the hands of the most skilled physicians in the world had failed, the above treatment has restored the patient to such a degree of health as to enable him to continue in his vocation for a long number of years.

The improvement and relief in conditions of angina pectoris, and in the other conditions referred to, place this treatment, especially when in the hands of a prudent doctor to whom all the resources of his art are familiar, among the very first of remedies.

In noting the effects upon the patient, it is important to bear in mind that the addition of this physical means to our armamentaria for the treatment of cardiac disease means much for our patients, their comfort, and their longevity. In the first place, a considerable number of patients are enabled to go through the winter without treatment of any kind, and they return the following summer only because they wish to prolong the good effects. Secondly, in many cases in which digitalis and other cardiac stimulants have lost their effect, after a few baths or exercises, the heart muscle seems to be brought within the limits of action of these drugs and they then have a better effect than ever. Similarly, by being able to avoid digitalis and the like drugs for a time, we have these remedies as reserves for times of greatest need.

Relapses occur during the treatment at Nauheim as well as they are likely to occur under other conditions. At such times baths or exercises, or both, are stopped for one or more days, as may be necessary, and, if need be, drugs are administered. Usually, however, the patient soon rallies and ultimately secures the desired result. To expect marked improvement in every case would be, however, too optimistic by far.

It is nine years since first I visited Bad Nauheim, repeating this visit every year since, and I have seen an almost innumerable number of patients who, prior to their attempting this treatment, had been given up as hopeless. During these years, thanks to the courtesy of Dr. Theodore Schott, I have closely investigated 120 cases, following the patients almost daily at the bath and exercises, and examining them in the manner above referred to. Of these 120 cases 24 had come for the first time, 45 for the second time, 18 for the third time, 9 for the fourth time, 7 for the fifth time, 5 for the sixth time, 6 for the seventh time, 5 for the eighth time, and 1 for the eleventh time. Thus 96 of the 120 had been there two and more times, 51 three and more times, 33 four and more times, 24 five and more, 17 six and more, 11 seven and more, 6 eight times and more, and 1 each year for eleven years.

Such an experience as this, and that of an increasing number of European physicians, particularly of Great Britain (the recent reports of Sir Grainger Stew-

art, Broadbent, Bowles, Lauder Brunton, Sir Francis Cruise, of Dublin, supported by *The Lancet* commission report, made by Dr. Alexander Morison, of London, and personally expressed views of such men as Baldwin, of Florence, and a host of others), settled the question, which has often arisen before, as to the permanency of the effects of the treatment, in the decided affirmative.

Prior to asking your attention to a few histories of cases, I must reaffirm that careful study and preparation is necessary before a physician can hope to use so potent a remedy successfully. Nor is a prudent equipoise to be omitted in order to avoid the overdoing. For even in the hands of the expert, I have seen overbathing with its consequent bad effects, and overexercising which no number of wonder-exciting diagrams of the heart's diminution (?) in size could free from unhappy or fruitless result. Finally, it must not be supposed that every variety of so-called medical gymnastics, now so popular in orthopaedy, is in any way suited for the treatment of cardiac cases.

Cases.—CASES I. and II.—As an illustration of cases of relative aortic insufficiency, which was complicated with aortic stenosis in one case and in both with myocarditis, I quote the cases of two locomotive stokers, who had been obliged to give up work on account of dyspnœa, vertigo, and the usual symptoms of loss of compensation. In both, aortic regurgitant murmurs were clearly recognizable at the outset. These murmurs grew feebler as the heart grew stronger and more rhythmical in action, and finally disappeared. Both men were restored to a fair degree of robust health.

I note here that the restoration of compensation in a laborer does not mean that he can return to his former laborious work, such as blacksmithing, stoking, etc. Such men must seek work less fatiguing, and, if this can be secured for them, the compensation may be maintained so long as their hygienic surroundings and food continue proper.

CASE III.—Judge F. S.—, native of Wiesbaden, sixty years old, who first came to Bad Nauheim in 1886. He had suffered with dyspnœa, vertigo, inability to work, œdema, ascites, and had tried the Oertel cure, with bad results. He was so despondent of recovery that he was about to resign his judgeship. In a few weeks his improvement encouraged him to hope; he continued in his recovery, and retained his position for eight years, resigning on account of age. His heart was so dilated in 1886 that no murmur could be heard; later, aortic murmurs were recognizable, and persist to this day. The patient made his eleventh visit to Bad Nauheim this summer, is now nearly seventy-one years old, and has passed all these years without medication in the winter (save for a trifling cold at times), and enjoys excellent health.

CASE IV.—General X—, fifty years old, native of Russia, who came to Bad Nauheim in the summer of 1895. He had lost his health in consequence of influenza. Finally, dyspnœa and general weakness, combined with attacks of angina, compelled him to give up military work. He was examined by the medical experts of Europe, who all recognized well-marked cardiac dilatation and, later, aortic regurgitation. In six weeks' time the patient walked four miles and over a steep hill without dyspnœa, cardiac palpitation, or any detectable murmur being distinguishable by the closest investigation. Patient did well till the spring of 1896, and in the summer of 1896 returned for second treatment, and made a nice recovery. The patient's habits of smoking and self-indulgence, which he will not give up, have something to do with the result not being even better.

CASE V.—Attorney X—, forty years old, a German, who, in consequence of repeated rheumatic at-

tacks, was left with aortic stenosis and regurgitation and mitral regurgitation, came to Nauheim in 1886. All his disabilities, including œdema, disappeared. Barring an attack of rheumatism in 1888, he has required no medical treatment since, except his annual monthly pilgrimage to Nauheim and taking bath and exercise treatment. During the past four years he has worked long and hard throughout the winter, without discomfort or complaint. His heart is perfectly compensated; the murmurs are still present.

CASE VI.—Merchant X—, a Russian, fifty years old, came to Nauheim anasarous, with hydrothorax and hydropericardium, dyspnœa, vertigo, angina, etc. The patient, on arrival, was seen by Sir Grainger Stewart, McGregor, Robertson, Holman, and others; and the diagnosis of myocarditis with extreme dilatation and, after urinary examination, chronic congestion of the kidneys was made. Such was the recovery of this patient (despite two relapses), that after six weeks he was examined by Dr. R. L. Bowles, of London, with me, who found his heart in excellent compensation. In the summer of 1896 the patient returned, having had a good winter, and an examination by Dr. Alexander Morison, of London, showed the size of the heart exactly the same as it had been found by Bowles and myself in September, 1895.

CASE VII.—Lady, forty years old, English, with old history of atheromatous arteries and myocarditis. Patient had been told by a most conservative and able physician that she would be confined to her room and chair for the rest of her days. The heart was dilated, arrhythmical, and intermittent. After a course of treatment, which was carried out a second time in the same season (summer, 1896), the patient walked ten miles daily without fatigue.

CASE VIII.—Angina pectoris. An Englishman, forty-eight years of age, who had suffered from numerous daily attacks, brought on by any exertion, and lasting years, was so completely relieved that he was able to return to his home in India and continue at work two years without renewing treatment. The diagnosis in this case was moderate arterio-sclerosis and myocarditis.

CASE IX.—Physician, forty-three years old, with aortic stenosis and moderate arterio-sclerosis, had suffered with frequent daily attacks of angina; was relieved after the second week of treatment, and reported himself well six months later.

CASE X.—Englishman, forty-three years old, had literally lived upon nitroglycerin for years; was never free from attacks of angina or precordial pain. Diagnosis, aortic stenosis and insufficiency, mild arterio-sclerosis. This patient had several attacks during the first week of treatment, when they ceased; and during the succeeding winter he reported himself still well.

All of these three cases of angina were treated with baths and exercises.

CASES XI. and XII. refer to two girls, one ten and the other eight years of age, both with congenital cardiac disease. Having watched both children for four or five years, it is wonderful to note the improvement in both cases. In comparing these children with others suffering from patent foramen ovale, it cannot be denied that the treatment has markedly ameliorated the condition and materially aided the development of both children.

Cases of exophthalmic goitre and numerous other cases coming under the category referred to as amenable to this form of treatment will be mentioned in subsequent publications upon the individual disorders.

A Good Local Anæsthetic for spraying abscesses before lancing is made with half a drachm of chloroform in an ounce of ether.—*The Medical Summary.*

ANÆMIA IN CARDIAC DISEASE.

By ANDREW H. SMITH, M.D.,

EMERITUS PROFESSOR OF MEDICINE, NEW YORK POST-GRADUATE MEDICAL SCHOOL; PHYSICIAN TO THE PRESBYTERIAN HOSPITAL.

WHEN we consider that the three most striking phenomena of organic cardiac disease, dyspnœa on exertion, œdema of the extremities, and the presence of a heart-murmur, are also prominent features of pronounced anæmia, it is evident that when the two conditions occur together there is room for nice discrimination in assigning to each its share in the result. Unless we are on our guard, the tendency is to overlook the functional trouble and to attribute an undue importance to the organic lesion. No one in first approaching a supposed heart case fails to consider whether the affection is not purely functional, but, when once the diagnosis of organic disease is fixed, we are prone thereafter to attribute whatever we observe to this cause, and not fully to take into account the influence of blood changes, which are certain sooner or later to contribute more or less to the clinical aspect of the case.

This is, however, a grave error, for it may lead, on the one hand, to neglect of measures by which the condition of the blood and therefore of the patient might be improved, and, on the other, to a false estimate of the degree in which compensation is insufficient, thus urging to ill-timed efforts to correct the supposed defect. If there is any one point especially important in the management of cardiac disease, it is to appreciate accurately the result of nature's effort to meet the increased tax upon the heart muscle by adequate hypertrophy. So long as this compensation is maintained it is unnecessary and unwise to resort to medication designed to get more work out of the disabled organ. We should reserve such measures for the time, only too sure to arrive, when there will be evidence that the ventricle is no longer equal to the task imposed upon it. Chief among these signs will be dyspnœa and œdema of the extremities. But if the dyspnœa and œdema are in part the result of an impoverished condition of the blood, and we do not appreciate this fact, we shall be pushing digitalis and its congeners when we ought to be giving our principal attention to the production of better blood.

The occasions on which this discrimination is called for are numerous, from the fact that organic cardiac disease almost inevitably sooner or later leads to digestive disturbances that in their turn become causes of anæmia. The circulation in the chylipoietic viscera being deranged by the impaired action of the heart, the functions of digestion and absorption are not properly performed, and we have insufficient nutrition and consecutive anæmia as the result. It follows that in a large proportion of cases, as soon as compensation becomes defective, anæmic are associated with the organic phenomena.

In view also of the origin of so large a proportion of cases of cardiac valvular disease, it is to be remembered that the poison of rheumatism tends in a remarkable degree to impoverish the blood, and that the use of salicylic acid or its compounds contributes also to this result. Therefore, unless special care has been taken to obviate this tendency, we are likely, in a case of heart disease with a rheumatic basis, to have a condition of anæmia from the very first, as a legacy from the rheumatic attack.

Anæmia may also be the direct result of organic disease. Incompetency of the aortic valve induces this condition by lessening the supply of blood to the arterial system. To a patient suffering from organic cardiac disease the addition of anæmia is a complication of serious import. As already stated, so far as the anæmia is consequent upon the previously existing

condition of the heart, it is not likely to be developed until compensation begins to fail. Coming at this juncture, it adds much to the gravity of the case. The tissues, already beginning to feel the lack of a sufficient quantity of blood, suffer now in addition from deterioration in the quality of the fluid supplied. This extends to the heart muscle itself, and, at a time when more is required of it, it is less able to meet the demand. The organ, that already was overworked, is now underfed. This in turn lessens still further the vigor of the circulation, and a vicious circle is established. Unless the resources of art are sufficient to restore compensation on the one hand, and to bring about a better condition of the blood on the other, the downward progress is necessarily rapid.

If this be the case when the anæmia is secondary, it is more emphatically true when cardiac disease attacks a subject who is already anæmic. Compensation in these cases is maintained with difficulty and the response to treatment is imperfect. The tendency is to rapid development of digestive troubles, general anasarca, pulmonary œdema, and all the evils attendant upon cardiac insufficiency. In fact we have the condition to begin with, which in secondary cases belongs to the later stages of the cardiac disease.

The most obvious symptom of anæmia is pallor, but this may be obscured or masked by the dusky hue which often accompanies organic cardiac disease. When there is no tendency to cyanosis, the pallor has the same value as a sign of impoverished blood that it would have in the absence of a cardiac lesion. Stephen Mackenzie suggests that an idea as to the degree of anæmia can be formed by observing the nail beds. "So long as any pink color can be seen, it may be assumed that there is a proportion of at least fifty per cent. of red corpuscles. When the pink color entirely disappears from the nail bed the corpuscles will be found below fifty per cent" (Sansom).

In estimating to what extent thinness of blood is a factor in these mixed cases, we have to consider that the hæmic murmurs may be obscured or entirely concealed by the organic. Thus, when a blood murmur would be heard at the apex in the absence of an anatomical change in the mitral valve, it would be wholly obscured if there was incompetency of the valve due to organic lesion.

As hæmic murmurs are always systolic, the question would not arise in the case of a diastolic bruit. The problem, then, is practically confined to cases in which a systolic murmur is found in a locality in which a previous organic lesion has not been demonstrated. In such a case we shall be required to determine whether we have to do with a functional or an organic condition.

So far as the mere auscultatory signs go, they may be very inconclusive. While the inorganic murmurs are as a rule softer, less harsh, less grating than those of organic origin, it is not safe always to depend upon this quality. A blood murmur may have enough of harshness to be identical in this respect with a rather soft organic sound, and a sound that is unquestionably organic may be so soft as to pass for a strong bruit of hæmic origin.

Fortunately we are aided materially by the location of the sound. Organic disease of the pulmonary orifice is extremely rare, while this is the most frequent seat of anæmic murmurs. Sansom found that fifty-seven per cent. of all his cases presented the maximum intensity in the pulmonary area. If, then, a soft systolic murmur appears in this locality, we can be almost certain that it is functional. This conviction will be strengthened if we find that on changing the position of the patient from the standing or sitting posture to the recumbent the intensity of the murmur is decidedly increased, since in organic murmurs in

this situation the horizontal position adds comparatively little to the strength of the bruit, while in anæmic murmurs the increase is very marked. In the aortic area the vast preponderance of the murmurs are organic. A functional bruit, according to Sansom, occurs here only once for four and one-half times that it is heard in the corresponding area at the left of the sternum.

Hæmic murmurs occur very rarely in the mitral region. They are soft in character, but, contrary to the general opinion, they conform to the organic murmurs in a large proportion of cases, in this, that they are propagated toward the left and are heard at the back. Indeed, it seems probable that these murmurs are caused by a veritable though transient incompetency of the valve, resulting from defective muscular action. Certain it is that murmurs occur that resemble in everything except harshness the sounds accompanying organic mitral insufficiency, and yet at the autopsy the valve is found to be normal. But in these cases we do not have the displaced apex beat, nor the forcible impulse that usually goes with organic insufficiency of the mitral valve.

Anæmic murmurs are extremely rare in the tricuspid area. Sometimes, however, they extend downward from the pulmonary area so as almost to include the region in question. But in these cases the intensity will be found to be greater as the stethoscope is moved upward, thus indicating their true origin. Accentuation of the pulmonary second sound, if not referable to obstruction in the lesser circulation, is an indication of anæmia. Apparently the thinner the blood, the more readily and forcibly it is thrown back against the valve cusps. This, however, is to be carefully distinguished from the accentuation of the aortic-valve sound, so often present in reno-cardiac conditions, and which may be heard with considerable distinctness over a wide area, including the location of the pulmonary valve.

Leaving the cardiac region, we find evidence of the existence of anæmia afforded by murmurs in the great vessels of the neck. These are of two kinds, the interrupted arterial bruit synchronous with the cardiac systole, and the continuous hum produced in the veins. In pronounced anæmia, if we place the stethoscope above the clavicle and just outside the sterno-mastoid muscle, we shall generally, though not always, perceive a murmur with each ventricular systole. This sound, though not rough or grating, is more decided than the blood murmur heard in the pulmonary-valve region. It has more of a whizzing character. It may be heard for some distance in the course of the subclavian arteries and along the carotids. This murmur may be present when there is no bruit in the pulmonary area, and on the other hand it may be absent when the pulmonary murmur is pronounced.

The other sound heard in the neck is the venous hum, the *bruit de diable*. This is a continuous sound produced in the great veins, as is proved by the fact that pressure on the vein above the stethoscope causes it to cease. It may or may not coexist with the arterial murmur. It is intensified by turning the head toward the opposite side, thus putting the vessel and the overlying tissues on the stretch. It is also made louder by anything that quickens the current of blood through the veins, such as exercise, mental excitement, etc. It is more distinct in the upright than in the recumbent posture, and during inspiration than during expiration.

This venous hum, however, is not in every case an evidence of anæmia. It is found in a considerable proportion of perfectly healthy persons, especially females. Still it is more common in subjects whose blood is thin, and in such cases it disappears as the quality of the blood improves. Its value, therefore,

as corroborative evidence of anæmia is considerable, and in a doubtful case its presence inclines to the conclusion that a cardiac murmur is functional rather than organic.

Pulsation in the veins of the neck, if tricuspid regurgitation can be excluded, may be taken to indicate poverty of the blood.

The dyspnœa of anæmia may be very marked, but it scarcely reaches the degree which is often observed in organic valvular disease. Orthopnœa is rare. The shortness of breath is scarcely felt when the patient is at rest, but it is easily excited by any exertion. In these combined cases, there is, of course, no way of distinguishing the dyspnœa of organic origin from that of functional derangement. We can only judge, perhaps, that the degree is greater than the valvular lesion present would seem to warrant, and thus infer that thinness of blood is adding to the effect of anatomical changes.

Edema of purely cardiac origin is apt first to show itself in the feet and legs; that of anæmia is more generally diffused. If, therefore, we have an œdema confined for a while to the lower extremities and subsequently without any notable change in the cardiac signs there is superadded a more general puffiness, we may believe that poverty of the blood is becoming a factor in the production of the effusion, especially if other indications point in the same direction.

If, as is so often the case, there is nephritis as a complication, this also will have to be taken into account in our estimate of the resulting aggregate of œdema.

There remains to be considered the most conclusive and most precise evidence of the hæmic condition, viz., that afforded by direct examination of the blood itself. This should never be omitted if we wish to manage the case with a full appreciation of all that can be ascertained in regard to it. By means familiar to all, it is easy to determine with approximate accuracy the number of blood cells to the cubic millimetre and also the relative percentage of hæmoglobin which the blood contains. This puts us at once into a position to judge of the need of treatment designed to improve the quality of the blood, and subsequently affords a measure of the success of our efforts in this direction. These examinations should be repeated at short intervals, so that if one remedy does not give satisfactory result, another may be employed.

The treatment of anæmia associated with cardiac disease is not essentially different from that of the condition when occurring alone. If it has preceded the cardiac affection, its cause must be searched for and if possible removed. Chalybeates, etc., will then be in order, and just in proportion as they are successful in improving the quality of the blood they will oppose the tendency to early failure of compensation. In any case, when this failure begins to be manifest, cardiac tonics and stimulants will be required, and, if successful, they in turn will act as blood-making agents, by promoting a better circulation in the tissues concerned in that process.

The necessity for relief of the blood condition is often so urgent that the most prompt and efficient means must be selected. Nothing else has in my experience met this indication so satisfactorily as enemata of defibrinated blood. This substance seems to be taken up by the rectum almost unchanged, the absorption often being so perfect that the defecation on the following morning will show scarcely a trace of blood. From its use I have seen remarkable, indeed marvellous benefit, and I should employ it in any case in which prompt results were especially demanded.

From one to two ounces of blood diluted with an equal bulk of warm water may be injected twice a day, or more frequently. The rectum should be

cleansed with a simple enema every alternate day while the treatment is continued.

Of course this method does not exclude the simultaneous use of remedies by the stomach, and the preference of each practitioner will suggest the drugs to be employed.

In conclusion, what I wish especially to insist upon is that, not only in advanced cases, but even in the earliest stages of heart disease, the evidences of anæmia should be sought for, and as soon as they are recognized, appropriate treatment should be instituted and persisted in, so long as the condition remains. I am satisfied that by pursuing this course, very many patients may be carried along for an almost indefinite time, who would otherwise offer but comparatively little resistance to the combined effects of anæmia and cardiac insufficiency.

Progress of Medical Science.

Cocaine Poisoning.—Dr. Weinrich discusses cocaine poisoning originating from the urinary passages. The symptoms are very variable, but they are mostly referable to the nervous system. Cocaine must, therefore, be used with caution in neurotic individuals. The symptoms may consist of stupor, vertigo, headache, and these may end in collapse with severe precordial anxiety. Clonic and tonic spasms are noted, which may produce sleeplessness and restlessness in some people and unconsciousness in others. Mental excitement and a mild degree of mental aberration may be observed. Paralysis, tremor, slight loss of co-ordination may also be among the motor symptoms. If respiratory difficulty, cyanosis, loss of consciousness supervene, the prognosis becomes very serious. The unfavorable action of cocaine on the heart rarely becomes threatening, the respiratory symptoms being the most significant. A feeling of suffocation with irregular stertorous breathing may arise, and eventually Cheyne-Stokes breathing. Death may result from respiratory paralysis. Idiosyncrasy to cocaine is sometimes very marked, so that the size of the dose may be almost without perceptible influence on the intoxication symptoms produced. The author records two cases of cocaine poisoning, the first he had seen among several thousand of bladder cases which had been cocainized. In comparing experiments on animals with observations on man, it is proved that cocaine can be absorbed from the bladder, but the absorption is so slight as to be practically without significance. With increased dexterity in the use of the cystoscope, perhaps weaker solutions of cocaine can be employed or no local anæsthetic used at all. Cardiac and vascular diseases, pernicious anæmia, are contraindications to its use. The horizontal position should be adopted when it is used. Chloroform may be given when spasms arise, but the chief remedy against cocaine poisoning is artificial respiration. The proposal of Gauchier to add nitroglycerin (coc. mur., Merck, 0.2; aq. dest., 10; sol. nitroglyc., 1 per cent., gtt. x.) is worth bearing in mind.—*Berliner klinische Wochenschrift*.

The Secretion of the Skunk.—An article on this subject has been published in the *Journal of Experimental Medicine*, by Dr. Thomas B. Aldrich. He finds that the offensive secretion is discharged from two oval pouches, about one inch long, situated on the sides of the rectum close to the anus, by two ducts which terminate at the top of little papillæ just inside the sphincter ani. The wall of the pouches consists of a fibrous investment, a muscular coat of striped fibres, a submucous coat, and a mucous membrane;

the masses of glands are situated in the submucous layer. The glands are tubular and lined by cubical epithelium. They present strong analogies to the sudoriparous glands. The disgusting odor of the secretion is so intense that one of Dr. Aldrich's predecessors having collected a little for examination, the whole college of the Johns Hopkins University rose in revolt, and he had to get rid of his material. Dr. Aldrich was more fortunate and was permitted to pursue his examination without interruption. The fluid secretion is clear, limpid, and golden yellow or amber colored, having a characteristic penetrating and most powerful odor; its specific gravity is 0.939; it remains fluid at -13°C .; and its reaction is neutral. The vapor is highly inflammable and burns with a luminous flame, giving off sulphur dioxide. It is readily soluble in alcohol, ether, and chloroform. A fifty-per-cent. solution of sodium or potassium hydroxide dissolves the fluid partially, the odor almost disappearing, but returning on the addition of sulphuric acid. Its reactions justify the assumption that one or more mercaptans or thio-alcohols are present. It contains about thirty per cent. of sulphur. Experiment showed that when so far diluted that the air inhaled contained only one-sixty-nine-billionth in each cubic centimetre, it was still perceptible to the smell. It is a powerful anæsthetic. When inhaled without the admixture of a large amount of air, the victim loses consciousness, the temperature falls, the pulse slackens, and if the inhalation were prolonged fatal results would probably ensue. Introduced into the conjunctival sac, it produces intense pain and sets up acute inflammation. The fumes of this liquid are overpoweringly pungent and extremely irritating to the glottis.

The Forms of Diabetes.—Dr. George Harley gives the following classification in *The Lancet*: 1. Hepatic diabetes—including the gouty variety. 2. Cerebral diabetes—including all cases of saccharine urine arising from nerve derangements. 3. Pancreatic diabetes—the most deadly form of the disease. 4. Hereditary diabetes—a form by no means uncommon, and one, too, in which both brothers and sisters may labor under the disease without either their maternal or paternal parent having been affected by diabetes, though more distant members of the family may have suffered from it. 5. Food diabetes—including all forms of saccharine urine arising from the ingestion of unwholesome substances. Dr. Harley recommends, in addition to diet and opium or codeine, croton chloral, strychnine, phosphoric acid for thirst, and an absolute prohibition of alcohol.

Movable Kidney.—According to Dr. Franks, the symptoms presented by movable kidney come so frequently under the notice of the physician that he must be able to recognize it. This is the author's definition of the condition: "Suppose we get a patient lying in the dorsal position. Standing on the right side, I pass the four fingers of my left hand underneath the hollow of the loin just beneath the twelfth rib. The thumb in front encircles the abdomen just below the costal arch, but without exercising any pressure. I then direct the patient to draw a full breath. Immediately before expiration begins I press my thumb upward below the costal arch, and let it sink as deeply as possible, following the liver as it recedes during expiration, while the fingers behind press the loin forward: if now with my right hand I can feel the kidney lying entirely below the grasp of my left hand, I call that a right kidney pathologically movable. If the right hand presses on the tumor so felt, while the left hand relaxes its grasp gradually, the tumor can be felt to slip between the fingers of the left hand and to disappear from our ken—upward into the position normally occupied by the kidney. This sensation is,

I believe, pathognomonic of a movable kidney. A kidney which can be felt to descend so that its lower half can be felt, but which moves back on expiration, is a kidney physiologically movable." The kidney is normally wedged in its place and kept there by the pressure of the viscera acting upon it from above and below, but when the balance between these forces is lost the position of the kidney may be altered. This is especially liable to occur after parturition. Descent of the right kidney is liable to cause gastric crises. The best treatment is nephrorrhaphy or stitching the kidney in the loin. Mr. Bland Sutton has seen jaundice result from dragging down of the viscera by a movable right kidney.—*The Birmingham Medical Review*.

Resection of Nearly Eleven Feet of Small Intestine in a Boy Eight Years Old.—Dr. Ruggi has reported the case of a boy who was struck on the abdomen by the car of a large swing, and thrown into the water about forty feet distant. For two weeks he had some tenderness in the abdomen, but no other symptoms. He then showed signs of obstruction. The abdomen was opened, and a loop of intestine was found constricted by a band of omentum. He improved for a time, but signs of obstruction returned in more pronounced form, and the wound was reopened. The intestine was found stenosed at the point where the constricting band had been divided. This was freed, and for a time the boy again had relief, but complained, as he had before the first operation, most bitterly of hunger, crying night and day in spite of the fact that large quantities of food were given, in addition to rectal feeding. Obstruction again returning, it was decided to again open the abdomen. A large mass of intestine was found adherent to the abdominal wall. On attempting to free this, it was discovered that a large extent of bowel had been stripped of its mesentery. Dr. Ruggi determined to resect these portions, and removed successively ten feet nine inches. The lowest incision was six inches from the ileo-cæcal valve. The ends were brought together by silk sutures. In a few days the boy was again crying for food. Gradually, however, the hunger lessened, and in five weeks he was discharged cured. At the time of report, fifteen months later, he was in perfect health.—*The Canadian Practitioner*.

Symptoms of Incipient Exophthalmic Goitre.—It is important to be able to distinguish this disease from the first, instead of waiting for the exophthalmos and goitre to appear. Principal among the early signs by which it may be recognized is a series of ocular troubles, a lack of synergic action in the lid and brow when the globe is turned abruptly upward, incomplete closure of the palpebral fissure, pulsation in the lids, muscular paralyses, and sometimes diplopia or photophobia. There are also disturbances in the nervous system, besides a general irritability; there are often cramps, neuralgias, hyperæsthesias, insomnia, choreic movements, and sensations of excessive heat. The tremor, which is rarely absent from the first, has a specific character in its rapid vibrations. If there are no accompanying symptoms of hysteria, this tremor is of great diagnostic value. The general symptoms that may occur are numerous and various, from dyspepsia, bulimia, gastric and diarrhæic crises, to genital troubles and œdema resembling myxœdema. Other disturbances indicate the participation of the medulla oblongata, suffering from lack of the normal secretions of the thyroid gland, polyuria, albuminuria, and dyspnea. Pregnancy is one of the most important predisposing causes of this disease, and it may also appear as a complication of neurasthenia, chorea, epilepsy, paralysis agitans, syringomyelia, general paralysis, and various psychoses, especially tabes and hysteria.—*Revue de Médecine et de Chirurgie*.

Appendicitis and Perityphlitis.—In a paper upon this subject, in the *Albany Medical Annals* for November, Dr. Seth M. Mereness draws the following conclusions: From the statistics of the last decade, and particularly of Fitz and Porter, it may be concluded that an operation is necessary in at least one-half of all cases, and that the mortality, even when an early operation is performed, will be from twelve to fifteen per cent. There is probably no other disease on the border line between medicine and surgery that requires such thorough individualization, and for this reason no definite rules can be adhered to; but, in general, it may be said that an operation should be advised: 1. In all cases in which a purulent collection is known to have been formed in the pericæcal tissues. 2. When a purulent collection cannot be demonstrated, but when signs of perforation of the appendix exist. 3. In all cases in which there is a reasonable doubt as to perforation of the appendix or pericæcal suppuration, but in which symptoms of general peritonitis are present. 4. When after a reasonable time the patient does not improve under medical treatment, or in consequence of relapses life is rendered unbearable and the patient's vocation cannot be followed. On the other hand, operation is rarely necessary and should not be undertaken: 1. In all cases of simple, acute, or chronic catarrhal appendicitis. 2. While the symptoms indicate a purulent inflammation of the appendicular mucous membrane, but when perforation has not occurred and the presence of a marked resistance over the cæcal region shows the peritonitis to be localized. 3. In all cases in which perforation has occurred and has caused a diffuse septic peritonitis. This latter generalization is contrary to the famous maxim of Lawson Tait, never to let a patient die from peritonitis without an operation. The fact is, however, that practically all cases of well-marked septic peritonitis are fatal under any plan of treatment, be it medical or surgical, as Sonnenberg admits when he says: "Absolut schlecht bleibt die Prognose bei ausgesprochener, allgemeiner, septischer Peritonitis. Auch die letzten sechs Fälle sind alle tödlich verlaufen."

Vaginal Hysterectomy.—Dr. M. J. Boeckel, in a discussion in the recent congress of French surgeons, advanced the following propositions: 1. Before the menopause vaginal hysterectomy should not be practised in genital prolapse, excepting (*a*) when plastic operations previously tried have failed; (*b*) when the duration of the prolapse and its volume lead to prediction of certain failure by the employment of autoplasmic methods alone; (*c*) when the reduction cannot be maintained by reason of uterine hypertrophy; (*d*) when the prolapse, as it were strangulated, cannot be reduced. 2. Vaginal hysterectomy should always be followed by immediate colpoperineorrhaphy. This should be performed with a free hand. Success is assured only on this condition. 3. These operations combined give excellent results, and better than those of simple autoplasty. 4. The mortality is low, even *nil*, for the author's personal cases, he having operated eight times with eight successes. 5. After the menopause, vaginal hysterectomy, other things being equal, presents no contraindications. Advanced age of the patient even will not deter us at the present day. In the cases related women were operated on who were sixty years of age and over, and in one instance the limit was advanced to the age of eighty.—*Gaz. Hebdom.*

Indications for Suspensio Uteri.—Dr. Augustin H. Golet (*North Carolina Medical Journal*, November 5, 1896) writes that the recent controversy over the different operations for rectification of retroflexions of the uterus has been productive of some good, as it has brought out the contraindications for some and the absolute futility of others. Vaginal fixation deserves

only condemnation. Alexander's operation for shortening the round ligaments is appropriate when the retroflexed organ is freely movable and the adnexa are not diseased. In this condition another more simple procedure will accomplish as much in a much shorter time and with less inconvenience to the patient. This procedure aims at a cure of the metritis and endometritis, the maintaining cause of the displacement in a majority of cases in which the organ is movable. This places shortening of the round ligaments in the category of unnecessary operations, though there may be certain cases in which it is appropriate and even necessary. Ventral suspension should be reserved for those cases in which the organ is bound down by adhesions, the adnexa are irreparably diseased and require removal, and the retroflexed organ, though movable, is prolapsed, and for prolapsus without retroflexion.

Typho-Malarial Fever.—Dr. Gordon (*Virginia Medical Semi-Monthly*) discusses what typho-malarial fever is and concludes that: 1. Without extended bacteriological investigation it cannot be absolutely denied that there is a typho-malarial fever, answering to the usual descriptions and resulting from the co-operation or antagonism of two distinct germs. 2. On the other hand, it is thoroughly illogical to conclude that there is such a disease until the necessary conditions for its existence have been demonstrated. 3. Atypical typhoid fever is a very common disease, whose symptomatology, in numerous instances, cannot be differentiated from that of typho-malarial. It follows, therefore, that the two diseases, indistinguishable from each other throughout, have different causes. This is opposed to reason and the lessons drawn from clinical observation. 4. If the cause of only one case of disease on either side of the argument can be established, and if this cause be a typhoid infection, are we not justified in attributing the vast majority of all cases to the typhoid poison? 5. The appropriate use of quinine cures malarial poisoning with promptness and certainty, as a rule, and leaves us to determine the nature of diseases which it does not control. 6. Neglected cases of true malarial infection may, in rare instances, fail to yield at once to quinine, and lead to the suspicion of a typhoid element; but such cases are not and cannot be called typho-malarial fever, and a failure to resort to microscopic examination of the blood does not sanction a misnomer.

Woman's Inferior Sensitiveness to Pain.—Dr. Ottolenghi (*Centralbl. f. Nerv. u. Psych.*, No. 7) reports the tests made with Edelmann's faradimeter of the sensitiveness to pain and the endurance of pain in six hundred and eighty-two women. He finds that women are less sensitive to pain than men, and that this sensitiveness is less in early life, increases to the twenty-fourth year, and decreases after that. The higher classes are most sensitive and the degenerate least. He found the latter class very obtuse to the sensation of pain. Endurance of pain varies between much broader limits in women than in men, reaching a maximum far beyond the masculine limit, possibly due to the "greater suggestibility" of the female sex. General sensibility reaches the highest point in the nineteenth year. He concludes that sensitiveness to pain stands in close relation to the "psyche," while "general sensibility" depends upon the peripheral nerves. He considers woman's comparative insensibility to pain as a sign of her inferiority to man, as the uncivilized and degenerates are least sensitive. He attempts to prove a connection between this characteristic and her longevity.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 12, 1896.

THE NEEDS OF THE MEDICAL SERVICE OF THE NAVY.

THE annual report of Surgeon-General Tryon of the navy is of more than usual interest to the members of the medical profession, not only as physicians, surgeons, and sanitarians, but also as citizens. Those of us who have noted the increasing influence of our country and the growth of our force afloat have doubtless often considered that the efficiency of the new navy depends upon more than ships, guns, and men with the technical knowledge necessary for handling engines of war, however essential all these things may be. No one can fail to recall how useless the American squadron would have been at Rio, a year or two ago, had yellow fever, then prevailing on shore and invading the ships of all other countries, been able to evade the measures of safety so skilfully adopted for our own vessels. The medical department of every military or naval organization has an importance the world over that is rapidly increasing with the advance in knowledge. That this department in our navy should be deficient in any essential is a reproach to our sagacity as a nation and an obstacle to the advance of the humanitarian element of our civilization.

The report of the surgeon-general shows a knowledge of the needs of his department that has been derived from careful study stimulated by a desire for efficiency in caring for the sick and wounded of the navy under any emergency in peace or war. He states with much earnestness that the navy is without a hospital corps, and that unless such an organization be authorized by Congress no definite results can be obtained in the attempt to solve the most important problems relating to methods of handling the wounded in battle on board modern ships of war or of properly meeting many emergencies arising in times of peace. It appears that the subordinates of medical officers in the navy, with the exception of apothecaries, are without previous training, even the nurses on our ships being simply detailed from time to time for that service, but enlisted for other purposes. Such a state of affairs should not be allowed to continue. The efficiency of our costly machines of war as well as considerations of humanity demand a change, and Congress should act promptly in a matter of such moment. That such corps exist in the medical departments of

the navies of all important powers is a standing reproach to our American civilization.

The outline of a bill for a well-equipped and thoroughly organized hospital corps appears in this report. We hope it will receive immediate attention, and that the navy will not long appear at a great disadvantage in this respect when compared not only with our army but with the militia of the different States. Surely at the present day no naval hospital should be without a corps of well-trained nurses, and no naval ship should be allowed to go into commission without a requisite number of trained nurses on board.

The subject of a hospital corps is considered by the surgeon-general in relation also to that of ambulance ships. He makes a strong plea for such ships, believing that after battle some asylum for the immediate reception of the wounded should be at hand, and that only ambulance or hospital ships of special construction can answer this purpose. The whole question of rendering proper assistance to the wounded or drowning in naval warfare, irrespective of nationalities, is of such interest and importance that it well deserves the most serious attention and careful consideration.

Another weakness in the medical department of the navy appears to be the number of vacancies in the medical corps. It seems that during each year there is a large number of applicants for information in regard to appointment as assistant surgeon, but that few avail themselves of the opportunities to appear for examination. At the date of this report there were ten vacancies in this small corps in the grade of assistant surgeon, and it is stated that the department is embarrassed by not having a sufficient number of medical officers to fill important stations ashore and afloat. We believe that the medical corps of the navy has not had its complement since the war, and that this state of affairs will continue until there is some favorable legislation for junior medical officers. The corresponding corps in the army has no difficulty in this respect, and it is remarkable that the same corps in the navy should have its efficiency seriously impaired because it is not allowed by Congress to offer at least equal advantages. This subject is one of national importance as it relates to the efficiency of our national defences, and no influence within or without the navy should be allowed to delay suitable congressional action.

Dr. Tryon's administration of his department as surgeon-general of the navy has shown a most praiseworthy progressiveness, that will leave its mark on the naval service for very many years. This is apparent in his report in various directions, among which may be cited the establishing of a course of instruction for junior medical officers, preliminary to their entering upon active service, the introduction of electric lights in naval hospitals, their equipment with aseptic operating-rooms and furniture and with bacteriological and chemical laboratories, and the adoption of disinfecting plants of modern make. Improved outfits of microscopes and accessories have been added to the supplies of hospitals, ships, and navy yards, thus completing a supply table which we believe has been

made in the last year or two superior to that of any naval medical department in the world, especially in surgical instruments and appliances. An improved swinging cot of unique design has been adopted for sick-bays, and a method of transporting wounded on ships of suitable construction has been introduced which is extremely simple and, it is stated, very effective. By this method an injured man is moved along the deck of any ship of favorable design, lashed in a hammock, including the mattress, and is lowered through hatches by the use of a stretcher bar of special construction.

The improved method of gathering statistics recently adopted, the results appearing in this report for the first time, is very noticeable. The new nomenclature of diseases is adapted to the requirements of the naval service, but in view of the difficulties experienced in all directions in securing a suitable classification it is worthy of general attention. Much valuable information is conveyed by tables well arranged and apparently selected with great care. It appears that the death rate was 6.82 per thousand of strength, and that during the year there were no cases of yellow fever and but one of small-pox and two of cholera.

Appended to the report are a number of interesting articles by members of the medical corps and a good index follows, completing a volume of about two hundred and fifty pages.

We congratulate Surgeon-General Tryon upon his administration of affairs and his comprehensive grasp of the needs of his department in relation to the general efficiency of the naval service.

CONTAGION IN SCHOOLS.

THE health department of this city, being very properly convinced that the greatest source of transmission of infectious and contagious disease among children is through contact with each other in school, proposes to take radical measures for the mitigation if not suppression of this obvious danger. Appropriations are asked for paying a corps of physicians, at a low rate of course, whose duty it shall be to inspect the schools regularly and inform themselves directly and indirectly on all points connected with possible disease dissemination. How competent men can be obtained at \$30 per month can best be determined by officials who are notoriously indifferent to the real value of such services. Such, it strikes us, is a way of proving how not to do a good thing. This, however, is merely a remark in passing and especially in connection with a reasonably fat salary offered to a chief inspector, whose duties could be performed by the sanitary inspector or his ambitious and not overworked assistant.

Still, the proposed school inspection is a most excellent thing and it is to be sincerely hoped that it can be properly carried out. Not only should the public schools be under such a jurisdiction of the health board, but every parochial and private institution as well. We would extend the functions of such inspection to include that of infectious disease of every sort, even

those not classified by the health authorities as such; for instance, the numerous skin affections so prevalent in the schools, and other maladies propagated indirectly through water-closet seats, drinking-cups, books, slates, and the like.

THE PHYSICIAN OF THE NEAR FUTURE.

UNWILLING to combine in any manner with his fellow-workers for his own protection, giving the best of his early energy to work in institutions which take the very bread from his mouth by treating and caring for those who are not poor, his work competed with on every hand by an ever-increasing host of special fads and frauds, what will be the doctor's source of income in the near future unless a change is worked?

A crusade, organized to reclaim the holy shrines in Palestine, incidentally booms the sale of Jerusalem drops and other remedies supposed to originate with the Franciscan friars. The Kneipp curists do not walk long in dewy grass before the discovery is made that Kneipp remedies for all known ills should be placed on sale in every city of the world.

Park commissioners are asked to extend the courtesies of the grass to the early morning sockless perambulator with the sole object of advertising the Kneipp company's wares.

Faith, hope, and charity healers, mind, brain, and thought curers, hypnotic, hydropathic, magnetic, electric, eclectic, spiritualistic, human, and divine workers of miraculous cures increase and flourish. The reputable physician walks to his dispensary class and treats many who should be going to his own or to his brother's office, and who will to-morrow run off to "a divine healer" and leave a bank bill on his table in return for the benefit they hope will come from the laying on of hands. There are many things the self-respecting physician cannot fight against, but how some men can put up with the indignities placed upon them by hospital authorities and continue to respect themselves is more than we can explain.

MUSIC AND NOISY NUISANCE.

EVERY one who lives in the close quarters of a noisy city is interested in settling the difference between music and noisy nuisance. He may feel it, but it is not polite to say it. If he does both, there is danger that he may be open to the charge of want of culture and taste. This is the strong side of the music nuisance, and generally some professional artist has to sit in judgment on disputed proprieties. A sewer inspector in this city has material differences on this point with a neighboring music teacher. In times gone by they were very neighborly, but subsequently their partitions were not sufficiently impervious or strong to keep them at the required distance from each other. There was no question about the noise in the business of pupil's straining for high notes, but it was not music to the over particular and unappreciative neighbor. Not caring to endure the infliction, he trusted to a well-known and oft-tried remedy of counter-irritation. At given signals of distress well-paid organ grinders

and hurdy-gurdy performers were posted on the sidewalk as an improvised chorus. The rebuke was pronounced, emphatic, and overwhelming. In the mean while the suffering inspector kept the best time he could with an accompanying hammer tattoo on the partition. Then it became a question as to which of the contestants should have the privilege of creating the most noise, and an attempt was made to right the matter in a criminal court. The point was such a delicate one that the responsibility of its settlement was referred to civil authorities.

In the testimony it was asserted by the inspector that "every time the pupils sang, the putty in his window sashes cracked." This is probably an exaggeration of metaphorical license in his effort to differentiate between a subjective sensation and an objective fact. The comparison with "the howls of suffering dogs" perhaps comes nearer the mark. The organ grinder understands this when a stray dog is within earshot. When the Italian band was told to "move on," the members smilingly ground their teeth and their organs simultaneously. Thus there was no common ground upon which a general shut up could be adjudicated. As the fight is still on, the situation is an amusingly serious one, for the exasperated neighbors are willing to admit that so far the sewer inspector has the most emphatic side of the argument. If we could collect all the amateur horn blowers, the practising squealers, the exasperating piano thumpers, and harbor them in an isolated district, they might fight out the noise nuisance very effectually without harming innocent and forced listeners.

News of the Week.

Vaccine Virus in Liquid Form.—Formerly the vaccine virus employed by the health department of New York was the serum which issued from the base of a vaccine pock, dried on quills or ivory points. To determine the most valuable part of a vaccine vesicle, the following experiment was made: A typical vesicle was chosen, and the crust, the underlying pulp and base, and the serum exuding after the former were removed, were collected separately. Each was mixed with glycerin in the proportion of sixty per cent. vaccine matter and forty per cent. glycerin, then thoroughly comminuted in a mortar, and the products were used in the multiple vaccination of children. The pulp showed by far the best, the crust the next, and the serum the poorest results, as determined by the percentage of successful vaccinations. Other similar experiments confirmed these results, and it was concluded that the largest proportion of the active virus is contained in the pulp. Therefore the virus now issued is in the form of a glycerinated vaccine pulp. Before using the virus derived from an animal, first, the animal from which it was obtained is sent to autopsy and the organs are examined for any evidences of disease; second, two samples of the virus are given, one to the bacteriologist and the other to the medical tester of virus, and no virus is issued unless the reports of the pathologist, bacteriologist, and clinical

tester are all satisfactory. The clinical test consists in the inoculation of the virus after scarification in three places on each of five children who have never been previously vaccinated. There is thus a case test of five and an insertion test of fifteen points. The results from the new method with this rigid system of tests are shown in the records of the last three months. Since July 1, 1896, there have been vaccinated in the routine way thirty calves from which virus has been collected and tested as above described. All this virus gave one hundred per cent. case and one hundred per cent. insertion success at the original test, and the same percentages of success at the last re-test made about October 1, 1896. There can therefore be no doubt that the durability of the virus is assured for at least three months from the date of collection. In all the primary vaccinations made during September and October by the department vaccinators in which the results are known, more than seven hundred in number, there was not a single failure. The virus is a syrupy, opaque, brown emulsion of uniform consistency. It is put up in capillary tubes containing each enough for a single vaccination, and in vials of two sizes, one containing one-fifth of a cubic centimetre for ten vaccinations, and the other containing one cubic centimetre for fifty vaccinations. In using the new virus the skin is scarified in the usual way, and a drop of the liquid virus (discharged from a capillary tube by blowing out the contents with a rubber tube furnished for the purpose) is then thoroughly rubbed into the scarified area with a slip of wood, which accompanies each tube. The new virus, like the other products of the health department laboratories, is furnished free to all public institutions in the city on application. It is also supplied to physicians at a moderate price.

The Late Dr. Samuel Sexton.—At the meeting of the Practitioners' Society of New York, held December 5, 1896, the following preamble and resolutions were adopted:

"Whereas, It becomes our painful duty to announce the death of Dr. Samuel Sexton, one of the founders of this society, therefore be it

"Resolved, That the Practitioners' Society desires to place on record its due appreciation of his long and valuable services in his chosen line of work, his praiseworthy contributions to the literature of his specialty, his persistent and untiring advocacy of new methods of treatment, and of his laudable endeavors to broaden the domain of aural surgery by the patient test of varied operative procedures and the careful study of pathological conditions.

"Resolved, That the society has suffered a serious loss in being deprived of his wise counsels, his matured judgment, and of his high example of professional rectitude.

"Resolved, That his successful career will stimulate his professional associates to endeavor to follow his example in courtesy, loyalty, and unselfish work.

"GEORGE F. SHRADY,

"CHARLES L. DANA,

"FRANCIS P. KINNICUTT."

Hotel Accommodations in Los Angeles.—A correspondent writes that the disadvantage under which Los Angeles, Cal., has labored, of having no hotel in which a semi-invalid could be housed with comfort, is soon to be removed. There is now in course of erection a large hotel having many sunny rooms and provided with all the conveniences which the modern tourist or health seeker demands.

"Acromegaly."—The author of this paper, published in the issue of November 28th, is Dr. H. H. Vinke, not Dinke as printed.

Philadelphia Hospital.—The Association of Ex-resident and Resident Physicians of the Philadelphia Hospital held its annual dinner at the Hotel Bellevue, on the evening of December 1st. Some sixty members were present, and toasts were responded to by Drs. Horatio C. Wood, Francis M. Perkins, James C. Bloomfield, David Riesman, and Daniel McCarthy.

"Medico-Surgical Bulletin."—Dr. Egbert H. Grandin has retired from the associate editorship of the *American Medico-Surgical Bulletin*.

Dr. Lightner Witmer, professor of experimental psychology in the University of Pennsylvania, has been appointed psychologist to the Pennsylvania Institute for Feeble-Minded Children at Elwyn.

Vital Statistics of Philadelphia.—For the week ending November 28th, there occurred in the city of Philadelphia, 389 deaths, 15 more than during the preceding week, and 28 less than during the corresponding week of the previous year. Of this number, 118 were in children under the age of five years. The individual causes of the largest number of deaths were: Pulmonary tuberculosis, 52; pneumonia, 46; diphtheria, 24; heart disease, 21. There were reported to the board of health during the week, 133 cases of diphtheria, 77 cases of typhoid fever, and 31 cases of scarlet fever.

Obituary Notes.—DR. JOHN ELLIS died at his home in this city on December 3d from pneumonia. He was born in Ashfield, Mass., in 1815, and was graduated in medicine from the Pittsfield Medical College in 1842. He practised for a while in Michigan, later became a convert to homœopathy, and finally abandoned medicine to engage in the refining of petroleum.—DR. WILLIAM H. WOODRUFF died on December 1st, at the age of sixty-five years. He was a graduate of the Albany Medical College in 1854, and had practised since that time in Pine Bush, Orange County, N. Y., where he died. He left a widow and four children.—DR. HENRY G. DAVIS died recently at his home in Everett, Mass. He was born in Maine in 1807, and was graduated from the Yale Medical School in 1839. After practising in Massachusetts for a number of years he came to New York, where he was the pioneer in orthopædic surgery. He devised a number of ingenious forms of apparatus for the correction of deformity, among others the hip splint. He also wrote several monographs on orthopædics.—DR. GUIDO FURMAN died on December 2d at his home in this city. He was born in Nassau, Germany,

in 1831, and was graduated from the medical department of the New York University in 1856. All his professional life was passed in this city. He was a member of the Medical Association of the County of New York, of the Academy of Medicine, and of the New York Pathological Society.—DR. EMIL WOLFF, professor of chemistry, died at Stuttgart, Germany, on December 7th. He studied medicine and natural science, but early turned his attention to agricultural chemistry, of which he became perhaps the greatest exponent of his time.—DR. PINCKNEY WEBSTER ELLSWORTH, of Hartford, Conn., died in that city on November 29th, of cerebral hemorrhage. He was born in Hartford in 1814, and was educated at Yale College. He was graduated in medicine from the College of Physicians and Surgeons in this city in 1839. At the beginning of the civil war he was appointed surgeon of the Connecticut brigade of volunteers, and he participated in the first battle of Bull Run. He was one of the organizers of the Hartford Medical Society, a member of the Connecticut Medical Society, and an honorary member of the New York State Medical Society. Dr. Ellsworth's mother was the eldest daughter of Noah Webster, the lexicographer, and he was a grandson of Chief-Justice Oliver Ellsworth of the United States Supreme Court.—DR. C. S. FLOYD, of Austin, Pa., was killed on November 26th by falling down the stairs of a hotel at Coudersport.

Insane Prisoners.—It was developed in a recent court proceeding in Philadelphia that many inmates of the Eastern penitentiary in that city are insane, and are without the attention which should be given to insane people, despite the fact that Pennsylvania has a law providing for the removal of insane convicts from the prisons to the asylums. It is asserted that the enforced idleness of the prisoners has much to do with this increase of mental disorder among them.

Cremation in Canada.—It is proposed to establish a crematory in connection with the Mount Royal Cemetery in Montreal, but the measure has not yet been decided upon by the directors, and vigorous opposition to it is expected from the conservative members of the board.

Koch on the Rinderpest.—Dr. Koch and Dr. Kohlstock are on their way to South Africa to investigate, at the request of the Cape government, the outbreak of rinderpest. They will establish their laboratory at Cape Town.

The Trinidad Leper Asylum.—The report of the Trinidad Leper Asylum issued by the medical officer, Mr. R. H. E. Knaggs, for the year 1895, shows that there were two hundred and nine persons in the asylum at the end of the year and that there had been forty-seven deaths during the year, and fifteen patients discharged; two of these latter were sent to prison, one to the lunatic asylum, and one left for India.

The Anglo-American Continental Medical Society held its annual meeting in Paris on November 11th. Seventeen new members were elected.

A Congress of French Alienists and Neurologists will be held at Toulouse in 1897, under the presidency of Dr. Ritti, editor of the *Annales Médico-Psychologiques*.

Pathological Society of Philadelphia.—At a stated meeting of the Pathological Society of Philadelphia on November 12th Dr. Joseph McFarland exhibited a portion of small intestine displaying an ulcer of uncertain origin resulting in perforation and peritonitis. Dr. Joseph Sailer exhibited a heart whose aortic valve was formed of two cups only, and two other hearts whose pulmonary valves were each constituted of four leaflets; he also showed a renal tumor, probably sarcomatous, and an abnormally lobulated spleen from a colored person. Dr. D. Riesman exhibited two specimens of carcinoma of the œsophagus, a tuberculous tumor of the larynx, and lungs presenting miliary tuberculosis in conjunction with a caseous mesenteric gland. Dr. H. W. Cattell and J. D. Steele exhibited a specimen of aneurism of the sinus of Valsalva. Dr. W. S. Newcomet presented tuberculous ulcers of the intestine, with a vermiform appendix only three-eighths of an inch long. Dr. S. M. Hamill exhibited a dilated stomach due to pyloric obstruction, resulting, it was supposed, from an ulcer in the duodenum. The following card specimens were exhibited: Dr. A. W. Booth, a renal cyst; Dr. A. Stengel, probable sarcoma of the retroperitoneal glands with metastasis, especially in the spleen; Dr. D. Riesman, anomalous distribution of the coronary arteries and apparently supernumerary spleen.

A Worthy Celebration.—*The British Medical Journal* announces that the lord mayor elect, Alderman Faudel Phillips, proposes to signalize his mayoralty and commemorate the sixtieth anniversary of the Queen's reign by raising a national subscription to free the public hospitals from debt. It is estimated that the amount required will be from £800,000 to £1,000,000.

Leprosy Congress.—An invitation has been extended by Drs. Ehlers, of Copenhagen; Hausen, of Bergen; Koch and Lassar, of Berlin, to convene in the last-named city during the month of October, 1897.

Atlanta's Health Inspector has declared war against the city well. There has been of late much fever in the city, and its prevalence is accounted for by the drinking of unwholesome well water. The hydrant supply is said to be abundant and pure.

The Woman's Health Protective Association has started in upon a praiseworthy attempt to improve the hygiene of the bakery. Many of the underground shops in this city are foul. Of the fifty-two hundred and seven bakers investigated thirteen hundred and seventy-five were on the sick list. Most of them suffered with inflammation or congestion of the lungs, and there were quite a number of tuberculosis cases and also some cases of diseases arising from personal uncleanness or immorality.—*The Sanitarian*.

Tight Lacing was given as the cause of death in an inquest held within the past fortnight in London.

Abundant testimony pointed to the custom as having been the undoubted cause of death.

New York Otological Society for 1896-97.—The following officers were elected at the annual meeting held November 24, 1896: *President*, Dr. Gorham Bacon; *Vice-President*, C. J. Kipp; *Secretary and Treasurer*, H. A. Alderton.

Bacteriologists to the Pennsylvania State Board of Health.—Dr. W. M. L. Coplin, of Philadelphia, has been appointed bacteriologist to the Pennsylvania State board of health, and Dr. Richard Slee, of Swiftwater, Dr. Nelson F. Davis, of Bucknell University, and Dr. Robert L. Pitfield, of Germantown, assistant bacteriologists.

Philadelphia Neurological Society.—At a meeting of the Philadelphia Neurological Society on November 23d, Dr. C. W. Burr reported a case of mind blindness and touch amnesia.

Philadelphia County Medical Society.—At a meeting of the Philadelphia County Medical Society on November 25th a paper entitled "Eight Primary Movements in the Treatment of Curvature of the Spine," read at the preceding meeting by Dr. J. T. Rugh, was discussed by Drs. De Forest Willard, H. Augustus Wilson, James K. Young, J. Packard Mann, Bertha Lewis, Walin, and Benjamin Lee. By invitation of the directors Dr. A. O. J. Kelly read a paper entitled "The Neuron, with Exhibition of Specimens and Diagrammatic Representation of its Morphological Characteristics," which was discussed by Drs. Charles K. Mills, F. X. Dercum, and J. K. Mitchell.

Royal University of Ireland.—Dr. More Madden has had conferred upon him the degree of M.A.O. (master of obstetric art) *honoris causa*. Dr. Madden has long been known as a writer and teacher and this new honor only adds to the many which have preceded.

Pharmacists are not held in high esteem by Dr. Schweninger, Bismarck's physician. He says the physician who places himself at their service and aids them to lay up a fortune at the expense of humanity dishonors his calling.

The American Laryngological, Rhinological, and Otological Society.—The western section of the American Laryngological, Rhinological, and Otological Society will hold its meeting in Kansas City, February 2 and 3, 1897.

An Inefficient Army.—Venereal diseases keep over three thousand soldiers from performing duty in the English army in India, according to the recent report of the sanitary commissioner to that government. In 1894 sixty-two thousand admissions for venereal disease occurred, or 5,342 total admissions for each one thousand of strength of the whole English army. Thus a small army in itself is constantly incapacitated by diseases which for the most part are preventable.

Philadelphia Semi-Centennial Meeting of the American Medical Association, to be held June 1, 2, 3, and 4, 1897. In view of the fact that the next meeting will be the semi-centennial gathering, and

that it will occur in a great medical centre and near the other great cities of the Eastern coast, the committee of arrangements for this meeting has already made provision for the accommodation and entertainment of the delegates, by the engagement of the Academy of Music, Horticultural Hall, the South Broad Street Theatre, and the large meeting-rooms in the Hotel Walton and Hotel Stenton. As these large buildings are all within a short distance of the great railroad depots in the centre of the city and are all situated within one block on both sides of Broad Street, every department of the meeting will be conveniently arranged. At the last meeting of the association it was voted to devote the first evening of the meeting, Tuesday, June 1st, to dinners of the various sections. The officers of the sections desiring to give such a dinner will please communicate with Dr. G. E. de Schweinitz, chairman of the subcommittee on accommodation, 1,401 Locust Street, as early as possible, in order that dining-rooms may be engaged or other entertainment provided. As it is expected that fully three thousand physicians will be present, the committee suggests that application for accommodations be made as early as possible. It is hoped that every member of the association will make a special effort to attend. Further circulars of information will be issued by the committee from time to time. Individuals and firms desiring space for exhibition in the exhibition hall, which will be in the same block as the various meeting halls, will please apply promptly to the chairman of the subcommittee on exhibits, Dr. Edward Jackson, 1,633 Locust Street, Philadelphia.

H. A. HARE, M.D.,

CHAIRMAN OF THE COMMITTEE OF ARRANGEMENTS.

Typhoid Antitoxin.—It is announced that an efficacious and reliable antitoxin for typhoid fever has been elaborated in Germany by Pfeiffer. An account of the mode of preparation and the report of a series of experiments will soon be published.

Health Inspectors for Schools.—The board of health of this city proposes, if it can secure the necessary appropriation, to appoint medical examiners for all the schools—public, private, and parochial—in New York, with a view to prevent the spread of contagious diseases, especially diphtheria and scarlet fever, among children. It is the opinion of the medical officers of the board that the greatest source of transmission of infectious and contagious diseases among children in this city is through their contact with one another in schools. It is also believed that a material reduction in the number of cases of sickness and death from contagious diseases can be secured by a daily inspection of the pupils of each school by a medical inspector, and by ascertaining whether children absent from school are sick with contagious or infectious disease. It is proposed to appoint one hundred and fifty medical inspectors, to serve for ten months each year, at a salary of \$30 per month, and one chief inspector at a salary of \$2,500 per annum.

The Relationship of the Testicles and Prostate Gland.—The following is an instructive case in this

regard, which was published by Dr. John R. Gibson, in *The Lancet*: A man, aged between fifty and sixty years, afflicted with enlarged prostate gland and requiring the use of the catheter before any urine could be drawn off, recently became afflicted with acute orchitis of one testicle, the orchitis being probably caused by the irritation of the catheter, as great difficulty was experienced in passing it. Almost immediately after the onset of the orchitis, he could pass urine more or less freely, an act he had not performed for over a year, and all the bladder symptoms underwent great improvement.

Dr. Jameson, who was sentenced to Holloway Jail for unethical conduct in South Africa, has been released on account of serious illness, and is now in a private hospital in one of the suburbs of London.

St. Luke's Hospital.—The annual report of this hospital has just been issued. It states that the greater part of the ground formerly occupied by the hospital, on Fifth Avenue, has been sold, and that the corporation is now free from debt. The number of patients treated during the year was 1,439, of whom 663 were in the medical and 776 in the surgical wards. The expenses for the year were \$109,744.47. An appeal is made for funds to endow a pathological laboratory and to erect a pavilion for consumptives.

The Louisiana State Board of Health announces that it will supply antitoxin gratis to the poor who are suffering from diphtheria.

Wholesale Poisoning.—At a silver wedding anniversary banquet in Hollidaysburg, Pa., recently, sixty of the guests were made seriously ill by some poisonous material in the food.

Surgeons Wanted.—A dispatch from Madrid states that General Weyler has telegraphed that one hundred army surgeons are urgently needed in Cuba. The work of getting surgeons for the Cuban service is more difficult than that of raising raw recruits. The government has been forced to extend the maximum of age for admission into the army sanitary corps, the applicants above the age established by law to be assigned for service in Cuba.

Bogus Wines in Germany.—Commenting upon the enormous exports from Germany to the United States of artificially prepared wines and inferior spirits and beers, the *Berlin Neueste Nachrichten* says that, since the passage of the wine act by the Reichstag, in April, 1892, in regard to the adulteration of wines and alcoholic beverages, immense quantities of liquors have been brought into the market under the name of wines, at such low prices as to prove it impossible that they could have been prepared in accordance with the law.

Cholera in Southern Russia.—The Russian authorities have apparently come to the conclusion that cholera is now endemic in South Russia, for permanent cholera barracks are being erected at Odessa, Sebastopol, Novo Rossiisk, Batum, Kertch, Poti, Berdiansk, and many other places, which will be ready for occupation by next spring.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 3, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Resignations.—THE SECRETARY read some correspondence from Dr. George L. Peabody, stating that he was to remain abroad for some time, on account of ill health, and therefore tendered his resignation as trustee. It was accepted with regrets.

Dr. A. Jacobi's resignation as chairman of the board of trustees was read. THE PRESIDENT spoke of Dr. Jacobi's long and valuable services to the academy, and said no explanation had been received for his resignation. Replying to DR. J. P. TUTTLE'S inquiry whether a motion was in order, authorizing the president to appoint a committee of one to wait on Dr. Jacobi and learn whether his resignation was unalterable, he said it certainly was; and, on adoption of the motion, appointed Dr. Tuttle on the committee.

Ernst Krackowitzer Library Fund.—A communication in the form of an affidavit was received from Dr. Jacobi, stating that, inasmuch as the Ernst Krackowitzer prize fund had not been competed for, but had been accumulating since it was founded, he would request, as the only surviving member for its administration, that it be converted into an Ernst Krackowitzer library fund. The matter was referred to the trustees of the academy, with power.

Nominations.—Dr. Bryant was renominated for *President*, but declined, saying that he thought, unless a special contingency arose, the honor of one term of two years was enough. Dr. E. G. Janeway was then nominated, and on motion the nomination for *President* was declared closed. For *Vice-President*, Drs. Arpad G. Gerster and Everett Herrick; for *Trustee*, long term, Dr. Bryant; short term, Dr. F. R. Sturgis; for *Committee on Library*, Drs. C. H. Knight and Achilles Rose; for *Committee on Admission*, Drs. Dessau, Ewing, Satterthwaite, Brill.

The Management of Pneumonia Patients.—DR. SIMON BARUCH, in presenting this paper, said his reason for doing so was the continued high mortality from pneumonia and the desire to give a *résumé* of his experience in country and city practice for a third of a century, together with what he thought was the management most likely to save life at the present time. The teaching of the schools and the practice in the army at the commencement of the civil war was clearly antiphlogistic, including bloodletting and purging. Seeing a vigorous young soldier practically recover from an attack of pneumonia and also from a relapse, then to die of exhaustion attributable to such heroic treatment (directed by another physician), he was himself deterred thereafter from imitating the example. Afterward, it became almost the universal practice to combat heart failure by such drugs as digitalis and strophanthus; and, finally, the temperature received chief attention, leading to the employment of the coal-tar series of antipyretics. The view was that pneumonia was a local disease, and it was only recently coming to be regarded as a constitutional affection with a local expression in the lung, just as in typhoid fever there was local manifestation in the intestine. At this point Dr. Baruch pointed out analogous conditions relating to typhoid and pneumonia, and their bearing upon treatment, particularly hydrotherapy. Both diseases were due to germ infection, the micro-organisms entering the mouth, and going in one instance to the intestine, in the other to the lungs: but in both running a definite life course, during which

they produced constitutional symptoms, which ceased with the death of the micro-organisms, although local lesions might still remain. In pneumonia, however, the diplococci had a life history of only about a third duration of the Eberth bacilli, and they were more likely to reach the meninges and other structures, as well as the lungs, adding further symptoms to those depending upon toxin circulating in the blood. But the chief blow in both diseases was upon the nervous system. It was not until he had learned the true principle of the Brand method in typhoid fever that he had come to feel a sense of security in treating this disease, and he suggested that in hydrotherapy would be found a like positive treatment for pneumonia.

The following was, in brief, Dr. Baruch's management of pneumonia patients: Complete rest of body and mind. Thorough ventilation of the sick-room. Diet restricted to milk and farinaceous broth, four to six ounces every two hours. Plenty of water. Since pneumonia was a disease of short duration, he did not believe in "stuffing" the patients. Alcohol was not necessary, as a rule. He used few medicinal agents, but gave a good dose of calomel at the outset, not repeating it. Its effect was twofold: Placed dry upon the tongue, it destroyed the diplococci in the mouth; it removed the ptomains which might have lodged in the gastro-intestinal canal. Further, it probably was of benefit in indirectly relieving the engorged lung by acting upon the portal circulation. The patient was directed to rinse the mouth frequently with chlorate of potassium. Strychnine was used hypodermically for the heart.

The author then spoke of hydrotherapy, dwelling upon its importance and explaining its mode of action. With children, the tub bath could be readily applied; but for adults he preferred the wet compress, because it was much less disturbing. When tubbing was used for children, one could begin with a temperature of 95° F., and reduce it according to the case. It should be continued a shorter time than in typhoid fever, say ten minutes, and repeated in three or four hours. The cold compress used for adults covered the back and front of the chest, was wrung out of water at 60° F., and was repeated every half-hour or hour, according to the case. A higher temperature than 60° F. might be used if there was much jactitation and excitability. If there was delirium with depression, the compress could be preceded by dashing on of cold water. The author attributed much of the benefit to the tonic effect of the cold compresses upon the nervous centres, and to relieving the heart by dilating the surface capillaries. It also acted by reducing the temperature and increasing elimination, whereby the toxins were cast out of the circulation. The action was very different from that of warm poultices. Under special conditions, oiled silk was placed over the flannel coverings, which converted the compress into a poultice. Only about forty per cent. of the cases treated in this manner had terminated by crisis; the remainder by lysis, or gradual clearing up of the physical and subjective symptoms.

Dr. Baruch said he had not lost a case of uncomplicated croupous pneumonia in private practice since he had adopted the cold compress and general management outlined in his paper. It was more difficult to judge of the method by hospital practice, where one seldom saw the patient in the early stage of pneumonia. The method of applying the cold compresses must be as exact as that of drug administration. The general statement to use cold water might mean, in the summer, water at 75° F.; and in the winter, below 45° F.—certainly a great difference.

Cold Bath in Thirty-Six Cases of Pneumonia.—DR. CHARLES B. FOLSOM, of Boston, expressed the strong conviction that pneumonia should be treated by

boards of health and by the public as an infectious disease. He then related his experience with cold baths, and said it had been limited to thirty-six cases in the Boston City Hospital. It was given very nearly as in typhoid fever, only not quite so long and the temperature was not quite so low. Three classes of cases were excluded: 1, The moribund and those not likely to live more than a day or so after admittance to the hospital; 2, cases in which the temperature did not rise above 102.5° F.; 3, cases of simple, mild, uncomplicated pneumonia, involving perhaps one lobe, in young people who were likely to get well without much interference on the part of the physician. Of the 36 patients, 28 recovered, 8 died—a mortality rate of 22.2 per cent. During the last year, 355 cases of croupous pneumonia had been treated without baths, with 124 deaths—mortality of 34.9 per cent., which was about their average mortality for all years. Of his eight patients who died under the bath treatment, one had typhoid fever and one kidney disease, and if these two were excluded, it would leave a mortality rate of less than 18 per cent. Judging by this experience, Dr. Folsom thought the bath treatment in pneumonia, as in typhoid fever, gave a better chance of recovery, even in seemingly desperate cases. It was clear to him that it had done no harm, and he was well pleased with the results. The patients themselves felt comfortable under the treatment, whereas in typhoid fever about one-third of them disliked the baths. They were given plenty of fresh air and other treatment as indicated. In Boston they gave little medicine for pneumonia, except when directly indicated, and this occurred less frequently under the bath treatment. The baths acted beneficially by moderating the fever, mitigating the pain, lessening the cough, quieting restlessness and delirium, relieving distress in breathing, and inducing sleep.

Adapts the Treatment to the Case, Not the Case to the Treatment.—DR. E. G. JANEWAY opened his remarks with the statment that pneumonia was a broad subject. There was not only a toxic agent, not only inflammation of the lung, but the individual reaction to these two things. In old people pneumonia might attack one or both lungs, prove fatal, and yet not be attended by fever. There one could not employ the cold bath nor the compress. Yet he dreaded the afebrile pneumonia of old people more than he dreaded the highly febrile pneumonia of young people. In the former all treatment had for its object to keep up the strength of the patient.

In young people we saw pneumonia result in recovery under almost any plan of treatment. One week he saw four subjects, all of whom recovered on the third day; in each case the attending doctor had pursued a different course of treatment, and with equally good results. If he had seen but one of the cases, the good result might have been attributed to the treatment.

There was trilobar pneumonia, in which a *sine qua non* to recovery was oxygen. There was cyanosis throughout. We could not look upon pneumonia simply as a toxic disease. The lung was inflamed, the breathing capacity was diminished, and to meet this indication he regarded oxygen as the best agent. Then we had to consider maintaining the heart's strength. Different doctors had different ways for doing this, some preferring digitalis, some strophanthus, others sparteine, camphor, strychnine, nitroglycerin. A good deal might be said about the size of the dose. Nothing varied more than the dose of digitalis and other heart tonics. He remembered a case of Dr. Duncan's, in which the pulse was very bad at the outset of the pneumonia. Dr. Duncan gave a dose of a teaspoonful of tincture of digitalis and repeated it once; the pulse improved, the patient recovered, no more digitalis was required. The case showed that we had

to meet contingencies. He had seen some patients treated with the cold compress as recommended by Dr. Baruch, some treated with a wet flannel, some with oiled silk over the chest. Of the different plans, he thought the compress laid across the chest had acted as well as any. For himself, he did not feel like adhering to any iron rules, either as to external applications or internal medication. More important than any plan was the individual under treatment.

Dr. Janeway was not one of those who decried the coal-tar series of drugs. He had given patients a great deal of comfort at times by their use. In one case, in which the temperature rose to 106° F., cold compresses did not reduce it and the attendant restlessness, while phenacetin did. This experience was repeated twice in that case. The phenacetin reduced the temperature and also induced sleep, as morphine might; but it did not, like morphine, cause constipation, tympanites, and derangement of the liver. Discouragement of the coal-tar series, on account of depressing effects, came from Germany, where they gave very large doses of everything. It was Dr. Janeway's custom to give the smallest dose which would accomplish the purpose, and not to give the largest dose which the patient could stand.

Abortion of Pneumonia.—Dr. Janeway thought it was possible to abort pneumonia, but the opportunity seldom presented itself when the physician was called soon enough, and it was very difficult to prove that without the physician's interference the patient would have had pneumonia. The method which he thought had aborted an attack in a few cases which he had seen consisted in applying a hot footbath for half an hour, hot drinks, sweet spirits of nitre, liquor ammoniac acetatis, aconite, followed by large doses of quinine.

DR. W. P. NORTHRUP expressed interest in Dr. Janeway's remarks on the varieties of pneumonia, and said that he had at one time seen a good many cases of afebrile pneumonia in old people, and was willing to try something new in the way of treatment, since under the plan adopted all died. Regarding the abortion of pneumonia, he thought he had accomplished that in one case, that of a young man, by very hot water to the feet, heat to the side, and hot drinks. In all cases of pneumonia he gave free ventilation and paid special attention to the digestive tract. Flatulency, with pressure against the diaphragm, was very oppressive to a pneumonia patient. He gave oxygen, but it was through the open window. He related several cases illustrating the rapid improvement in the condition of patients suffering with pneumonia when they were given plenty of air by opening the window, and when cold was applied by ice bag, or, better, by bath. What we found especially good in the bath were improvement in the mental condition, quieting of the nervous centres, improvement of the pulse, depth of respiration, sleep. He felt under great obligations to Dr. Baruch for what he had done for New York in the way of hydrotherapy.

DR. ALFRED MEYER said he had had no experience with the bath treatment, but had employed such remedial agents as seemed appropriate to individual cases. He had not a long list of cases, but his assistant at Mt. Sinai had tabulated twelve treated on the plan named, with only two deaths, a mortality rate of about sixteen per cent.

DR. BARUCH said, in some closing remarks, that he had not met with afebrile pneumonia in the aged, but he had seen high temperature pneumonia in the aged which had been treated with cold compresses. He could not accept the view, prevalent among the profession, that oxygen was of use in the dyspnoea of pneumonia, as it had been shown to be against the law of the diffusion of gases. He believed in Dr. Northrup's way of giving oxygen, namely, by way of the

window. Regarding digitalis, he did not doubt that it was a splendid heart tonic in the early stage of pneumonia, but in the later stages it caused the weakened organ to struggle tremendously against contracted peripheral vessels. Indeed, it did harm in the later stages by contracting the peripheral vessels. Regarding cold compresses, he repeated that everything depended upon how they were applied.

SECTION ON GENERAL MEDICINE.

Stated Meeting, November 17, 1896.

REYNOLD W. WILCOX, M.D., CHAIRMAN.

Anæmia in Relation to Cardiac Disease.—DR. ANDREW H. SMITH read the paper (see p. 852).

DR. BEVERLEY ROBINSON opened the discussion. He thought all must have at times met with difficulty in determining to what extent a patient was suffering from simple anæmia, or anæmia depending upon heart disease, or whether certain physical signs were dependent upon the latter or were anæmic in origin. These difficulties applied more particularly to women and children. For instance, a patient appeared in whom we appreciated a blowing murmur at the apex of the heart; there were pallor and oppression of breathing. It was difficult to say at the moment whether such a patient had cardiac disease. Examination of the blood was probably the chief test, and if it were found to show only from fifty to seventy per cent. of hæmoglobin, relative increase of the white cells, and some change in the red cells, of course we would feel that anæmia was a very important factor. But those were not the cases in which there was most difficulty. It was rather those in which there was but slight change in the blood and there were certain signs of cardiac disease. Modern authors had dwelt less upon the relation of cardiac trouble to anæmia than some who had written a number of years ago, and he might mention Stokes, in particular, as one who recognized the difficulty of diagnosis and the importance of making it. The best advice which he could give was to be judicious in doubtful cases. It might be that the cardiac murmur and symptoms of anæmia would disappear under tonic and hygienic measures. As to iron, while we all had some preparation which we were more likely to give than others, he did not think the organic salts possessed any special advantage over the inorganic salts of iron. There were manganese, digitalis, strophanthus, nitroglycerin, etc. He knew clinically that in a good many cases iron acted better when oxygen was also administered artificially. One of the best tonics, when properly used, was sulphur baths, either artificially prepared or at springs. He believed a good deal of the benefit obtained at Bad Nauheim and the Schott treatment, on which Dr. Heineman had recently read a paper before the academy, was due to relief of anæmia and not to the effect upon what he believed to be irreparable cardiac lesions. But it was not necessary to go abroad for the treatment or to get the information.

Functional Cardiac Murmurs.—DR. WILLIAM H. THOMSON said he had been rather disappointed to hear anæmic cardiac murmurs referred to almost to the exclusion of functional murmurs. The latter were extremely interesting to him, and he was sure that in many cases they were the most important ones which came before the hospital physician and the insurance examiner. Functional murmurs included much more than anæmic murmurs. He had known of more than one man being rejected for insurance because of a murmur taken to be a cardiac regurgitant, but which Dr. Thomson believed was only functional; yet there was no anæmia. He was sure there were some strange

murmurs which were affected by the respiration and which were certainly functional. All functional murmurs were systolic. A diastolic murmur could not be functional, neither could a presystolic murmur. A systolic hæmic murmur, as in chlorosis, was heard loudest at the second interspace to the left of the sternum, and while it was frequently transmitted down to the apex, where one heard mitral organic murmurs, yet it was never so loud there, nor was it transmitted to the left, but rather to the right. He did not doubt that Dr. Smith had, as he had stated, occasionally heard a hæmic murmur in the axilla to the left; but Dr. Thomson personally had never had such experience. When in doubt whether a murmur was functional or organic, the examiner should have the patient lie down, and if it were functional it would be diminished. Further, if it were functional, it would totally disappear while the patient took a long breath and held it. If the murmur were due to a lesion of the mitral valve, it would not diminish on lying down, nor disappear on holding the breath. Then there was a difference in the character of the sound. It was not whizzing, buzzing, or booming, as in functional murmurs. The functional murmur diminished also on quieting the patient, who, when he came in for examination, was likely to be much excited, anxious, and to have a rapid pulse. He believed such functional murmurs to be due largely to the muscular element of a rapidly acting, irritated heart in nervous persons.

There was another kind of functional murmur which was very puzzling indeed. It was heard during certain acts of respiration, but was particularly apt to be heard during inspiration and then to disappear. It occurred at the mitral area and was not transmitted at all. This was one of the most peculiar of murmurs, for he had heard it nearly as far to the right as the nipple, and again on the left side, away from the area of the heart, very nearly at the posterior axillary line. He did not know how it was produced, but evidently it was through the lung. A murmur which was heard at a distance from any of the areas of the heart could be put down as functional.

The question of anæmia was a large one, and he would say but a few words on it. He fully agreed with Dr. Smith, that anæmia in relation to the heart was very important. He believed, also, that it bore a causative relation in many instances to organic trouble in the heart; that there were cases of heart disease which were produced by anæmia in the first instance. Throughout the whole animal kingdom muscular power was in direct proportion to respiration. Muscular weakness tended to produce anæmia. The muscle cell had to breathe more than any other cell, more even than the nerve cell, for it had two functions to perform—to produce muscular contraction and to make heat. The most marked cases of fatty heart found at the autopsy table were in pernicious anæmia. There was a softened heart in chlorosis, and in anæmia connected with muscular debility we found a weak heart. Many cases of cardiac disease had dated from a muscle disease, like rheumatic fever.

Dr. Thomson would take issue with any one who would give iron simply because there was anæmia. In all febrile anæmias it did mischief. Doctors were very apt to give it in the anæmia of acute articular rheumatism, and the result was much harm, for it increased temperature. It was so in phthisis. It would be far better to give cod-liver oil.

Anæmic Murmurs Not Always Systolic.—DR. FRANK W. JACKSON said the point in the paper which struck him as most important was the fact that anæmia might be primary, although associated with heart disease. We were too apt to think it must necessarily be secondary to the heart disease. It would be much

better in the cases named to direct treatment to the anæmia and let the heart alone. The opinion generally prevailed that all anæmic murmurs were systolic, and the same opinion had been expressed to-night, but in reality one who examined many and all kinds of hearts found now and then an exception to that rule. Last year a German author had published three cases of accidental murmurs, and, death having taken place from some other cause, the heart was examined and found to be absolutely normal. Dr. Jackson had himself found a presystolic murmur in several anæmic persons, which disappeared when they regained their normal health. Regarding the influence of the recumbent posture on anæmic murmurs, he had seen some cases in which it made no difference. He used the hæmoglobinometer, and if the percentage of hæmoglobin fell below seventy-five there was good reason to suppose that the murmur was anæmic, if there was no definite evidence of organic disease. As Dr. Thomson had said, a large number of murmurs were functional, some were intermittent; at times the diagnosis of their nature was easy, at others very difficult.

DR. LEONARD WEBER had observed, in a small number of cases of progressive disease of the coronary arteries, more or less rapidly developing anæmia, in conjunction with general disturbance of nutrition connected with disturbance of nutrition of the cardiac muscle. The anæmia was one of the signs and consequences of cardiac degeneration, from blocking up of the coronary arteries in the course of the cirrhotic change in their walls. A second point was the development of anæmia from aortic regurgitation. He had seen several such cases in which the anæmia, depending upon mechanical causes, preceded other constitutional symptoms. A third point was that he had seen several cases of diffuse disease of the cardiac muscle and disturbed heart action, without there being any valvular disease—a condition which might occur in gout or old syphilis, causing disturbance of the general health, with more or less profound anæmia. Lastly, while anæmia might give rise to fatty degeneration of the heart, yet there were cases in which fatty degeneration began in a previously dilated heart and caused secondary anæmia.

DR. HEINEMAN thought it was about time the profession abandoned the method which was prevalent when he was a student, of basing a diagnosis of cardiac disease on a few data. The murmur was always the least important thing; the pulse next; then the size of the heart in a moderate number of cases. But, on the whole, the diagnosis was made in a perfunctory way, and when we came to difficult cases we found our methods failed us. If the anæmia, the sphygmographic tracings, and all known facts were taken into consideration, he thought there would be much less doubt than existed in many instances to-day. It was especially important to bear in mind that the intensity of the murmur bore no relation to the extent of the lesion. Regarding baths, he did not agree with Dr. Robinson that we could well judge of a health resort without going there. For instance, he had had no idea of the Hot Springs until he visited them. As to cardiac disease and anæmia in cases treated at Bad Nauheim, the anæmia was the smallest factor. The anæmia had improved, but it was the smallest part of the benefit.

DR. A. H. SMITH closed the discussion. He had heard the murmur to which Dr. Thomson alluded, on the right side, perhaps about the fourth interspace, not connected with anæmia, but rather with muscular prostration. It disappeared with the disappearance of the muscular disturbance or restoration of the capillary circulation in the muscles. He had occasionally heard the harsh sounds at a distance from the heart, present during inspiration, absent during expiration.

He was also unable to explain them. He agreed with Dr. Thomson regarding iron in fever, that it ought not then to be administered. Regarding Dr. Jackson's remarks on having occasionally heard diastolic or presystolic anæmic murmurs, Dr. Smith did not believe much in such murmurs. They were systolic, or he might say that the explanation of presystolic murmurs was that in nine-tenths of the cases the valves did not close on the instant.

Original Contribution to the Anatomy of the Blood Supply of the Heart: Its Bearing upon Angina Pectoris Treated by Physical Methods.—DR. H. NEWTON HEINEMAN read a paper with this title. It was based upon some pathological and histological investigations, begun in Paris, in 1895, and finished in June, 1896, and also upon some clinical facts. As was well known, it had been disputed for many years whether the coronary arteries on the two sides finally anastomosed. There had been a good deal of accepted anatomy in this connection, but very little proven anatomy. His experiments had been on the hearts of various animals, as turtles, rabbits, etc.; and on the human heart, obtained as soon as possible after death. Injections were made with gelatin and Prussian blue. Carmine stain was not suitable, because it injected the surrounding tissue. The facts brought out were that the blood supply of the heart was principally capillary, but what was rather unusual was that in the heart the capillaries came off directly from the large branches, so that one saw a trunk and suddenly on all sides numerous capillary vessels, and very soon venous capillaries and large veins. Further, here and there the capillaries were seen to form what appeared like little reservoirs, the object of which was, no doubt, to receive the blood in systole when contraction of the heart drove it from the vessels. The muscle shortened, and these reservoirs were between the muscular fibres. The two coronaries did anastomose, but it was not through large branches, but through the capillaries. Regarding angina pectoris, he preferred the term stenocardia, and would include under this head all degrees of cardiac pain. Even microscopically we could not always recognize changes in the heart at post-mortem. Consideration of the blood supply of the heart made it evident that even moderate changes in the large branches must make a great difference in the capillary circulation. The prognosis would depend upon the question of cardiac lesion, the condition of the blood supply of the heart, and the severity of the attacks. Cases which showed themselves amenable to treatment offered a better prognosis. The author mentioned the various symptoms sometimes connected with those referable to the heart, and the numerous exciting causes, many of which seemed to act reflexly.

The Treatment of Stenocardia.—The point which the author wished to make with reference to treatment was—after having determined as far as possible the condition of the heart, of the arteries, and of the spleen and liver—to relieve the heart by lessening the circulatory resistance in the organ, and then to strengthen the cardiac muscle. The potent factors were to unload the congestion of the liver and spleen by calomel and salines, and strengthen the heart by saline baths and resistance exercises—a course of treatment which he had described before the academy in his paper on the baths at Bad Nauheim combined with the Schott physical treatment. But one could not make much headway if he resorted to the baths and exercise alone, and failed to relieve the engorged viscera. In addition to these measures, one found aid in such remedies as strychnine, nitrites, etc. Attention must also be given the diet.

DR. F. W. JACKSON expressed his agreement with the author, that we ought not to make the minute divi-

sion of cases of angina pectoris which it had been the custom to do. He also agreed with the choice of name, preferring that of stenocardia. He did not, however, think we could exclude the possibility of some cases being only pseudo-angina. In other words, he thought there might be a cardiac pain which was not true angina.

Treats the Circulation Rather than the Heart.

—DR. CHARLES E. QUIMBY expected anæmia to occur sooner or later in all cardiac cases. It preceded dilatation. This malnutrition might be slight at first, but should be combated, which he did by giving tonics, especially iron; and if the patient was unable to assimilate this, he made it possible by differential breathing. The important thing was to increase the capillary circulation, instead of giving drugs intended alone to increase the heart beat.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Annual and Stated Meetings, November 23, 1896.

E. D. FISHER, M.D., AFTERWARD L. C. GRAY, M.D.,
IN THE CHAIR.

The Medical Directory.—DR. DANIEL LEWIS, editor of the medical directory published under the auspices of the society, presented his report. The first edition, nine years ago, was very small compared with the present volume, and, of course, contained much less information. At present the addresses were given of nearly eleven thousand physicians, including those in the States of New York, New Jersey, and Connecticut, and in the volume of five hundred pages was much information useful to the profession. The next volume would contain one hundred additional pages. The expenditures for the last volume had been \$3,721; the income, \$3,980.

Advertisements in the Directory.—DR. A. Y. REID wished to be informed as to what could be done regarding such advertisements in the medical directory which members would not be willing to endorse individually as physicians, but which apparently had the endorsement of the county society because printed in this book.

After some discussion, which took place in executive session, Dr. Reid offered a resolution which received the approval of Dr. Lewis and the society, providing for the statement in the preface that the society did not hold itself responsible for anything contained in the advertisements.

Address of the Retiring President.—DR. E. D. FISHER, in retiring from the presidency, cast a brief retrospect over the work of the year. It had not been characterized by any departure from the usual course of scientific advancement. The question of the organization of hospital boards had arisen, and could safely be left to the sober common sense of the profession. The various standing committees had done efficient work. The committee on hygiene in particular had had under consideration some important questions relating to the public health and well-being. Among these was the proper care of the poor, the founding of public baths and of convenient lavatories. Dr. Fisher had himself given some study to the system of lavatories in London and other European cities, and hoped to see something done in New York for the sake of the public health and to do away with the necessity for entering saloons or hotels.

Address of the President-Elect.—DR. LONDON CARTER GRAY, in his address, said: "When I look over the long list of presidents of this society, and perceive

such names as Hosack, Cock, the two Rogers, Delafield, Bulkley, Taylor, Fennell, Hubbard, Peasley, the two Elliots, Jacobi, Sands, Peters, Bumstead, Purdy, Sturgis, Webster, Vander Poel, Lewis, Grandin, and Fisher, I cannot but feel that I have received a great honor in being chosen as a successor to these gentlemen.

"In the great changes that have taken place in this city between 1806, when this body first came into existence and the population was about 90,000, and the present year, during which it is estimated that the dwellers within our corporate limits number 1,851,060, medical societies have multiplied, not only for scientific but also for social, topographical, and collegiate reasons, and the County Society no longer occupies the same relative position that it did for years after its foundation; and this has too often caused those not familiar with its work to overlook the fact that it is possessed of great powers, which would make medical men instinctively turn to it in time of war or epidemic. It has at the present time a membership of fourteen hundred and eighty-four. It is the official, or authorized, or representative society of the medical profession in the county of New York; while through its delegates, who can become members of the State Society by the simple process of attending for two successive years, it has an intimate affiliation with the larger organization, and, by this intermediary, with every medical society in the State. It has three standing committees of great importance. By means of the one upon ethics it regulates the professional conduct of its members with an authority that very few men would care to dispute. By its committee on hygiene it keeps a watch upon the public health; and the committee upon prize essays gives an opportunity for generous recognition to many a struggling man of talent. It has a large and active comitia minora acting as councillors to the president. It has a salaried counsel of the law, standing ready to protect the interests of the profession against imposture and injudicious legislation. It is in the metropolis, and its incentives, its opportunities, and its dignity are those of the greatest city of the country, so that what it does (provided it be worthy of notice) is known of all men throughout the broad American nation of physicians. I do not need to remind you of how effectively these powers have been used in the past, and are being employed in the present, for the historian of the battles that have here been fought and won for a higher standard in medicine would need more than an evening to chronicle these achievements.

"It would seem, from what information is at my disposal, that the members of this society are not aware of the fact that section 41 of the consolidation act, chapter 410, laws of 1892, disqualifies a physician from being the president of the municipal board of health in these words:

"The head of the health department shall be called the board of health. Said board shall consist of the president of the board of police, the health officer of the port, and two officers, one of whom shall have been a practising physician for not less than five years preceding his appointment. The commissioner of health, who is not a physician, shall be the president of the board, and shall be so designated in his appointment. The commissioners of health shall, unless sooner removed, respectively hold their offices for six years and until their successors shall be respectively appointed and have qualified."

"I am told that this clause was copied from the charter of 1873, but I am at a loss to understand the reason for disqualification of physicians for an office which one would think peculiarly required medical skill and experience.

"But I would like to ask your especial attention to

the abuses of medical charity—a subject which has been so often discussed and rediscussed that our souls have become weary, and I should hesitate to allude to it but for the seeming opportunity now offered to us in the power recently given to the State board of charities to revoke the charter of any institution proven to dispense medical charity improperly. This clause was introduced into the new constitution by Mr. Tunis G. Bergen, president of the State board of charities, to whom the profession should be under a lasting debt of gratitude; and I never fully appreciated what this gentleman has attempted to do for us until I obtained accurate figures upon the subject, through the kindness of our distinguished colleague, Dr. Stephen Smith, who is a most energetic member of the same board. From these statistics it would seem that the county of New York has, at the present time, 26 hospitals and 114 dispensaries. In the former, during the year 1895, 75,368 patients have been treated free, and in the latter 661,803, making a total of 737,171. Just stop for a moment to think of it, gentlemen, that 737,171 patients have been treated gratuitously in the last year in this city, of which the population is only 1,851,060. In other words, the proportion of such free patients to the whole community is 39 per cent. There have been 92,529 free visits of patients to hospitals in 1895, and 1,387,170 free visits of patients to dispensaries. Out of 1,104,381 prescriptions that have been dispensed, there is no means of knowing exactly how many have been without charge, because 52 of the dispensaries have made no report to the State board of charities, while of the 62 that have reported, 16 make no charge for their medicines, and 46 make nominal charges of from five to fifty cents, or nothing when the patients are unable to pay. Of these 114 dispensaries, 60 take certain precautions to weed out the unworthy, such as making inquiries, questioning the patients, judging by their appearance, and by the statements of physicians sending them, while the remaining 54 either make no inquiries or have made no report. In attendance upon these 114 dispensaries are 949 medical men, which is 27 per cent. of all the physicians in the city, who number 3,430. Efforts were made to ascertain how many of these patients were non-residents, but the answers were usually very indefinite; one institution stating 'very few, if any,' others 'from one to ten per cent.,' while 10 had treated 2,124. The foregoing summary does not include institutions under the charge of the local commissioners of charity, one of whom, Mr. John P. Faure, has kindly informed me that there are 8 city hospitals, containing 7,089 patients, and that the out-patient branch has treated 49,620 patients during the year ending June 30th, 1895. Although it is probable that these cases are really worthy of charity, yet, in strict logic, the figures should be added to those given above, which would swell the total of patients treated in this city in one year to 793,880.

"These statistics confirm the rumors that have been rife among us for many years, such as that the president of one of the largest municipal railroad corporations was discovered to be a regular attendant at one of the dispensaries; that patients come occasionally to the clinics in carriages; that practices can almost always be obtained from certain clinics in a large dispensary, such as those of general medicine or gynecology; that the neighborhood of large dispensaries is bare of physicians' residences; that patients come to town from distant cities with a physician, occasionally with a relative, put up at a hotel, seek a clinic for medical advice, and, when told in one dispensary that they are not fit objects of charity, speed away in hot indignation to another: that patients are frequently sent to a clinic with a letter from the attending phy-

sician containing a modest request for diagnosis, prognosis, and treatment, inquiry eliciting that their intention is to go back to this gentleman's office and pay him for treatment; that patients in the country towns for miles around New York are quite appreciative of the excellencies of our city dispensaries for different diseases; and that patients constantly go to dispensaries in order to ascertain the best physician for their particular disease. The reasons for this enormous increase in our charity work is plain to any one who has witnessed the development of our hospitals and dispensaries of late years. The public must be appealed to for money; the larger the number of patients, the more need shown for money; and no effective general regulations being strongly enforced, the growth of the abuse has been so stupendous that all methods of restriction have proved utterly ineffectual. The intentions have been altruistic in the extreme, on the part of both lay and medical members of hospital boards; indeed it is questionable whether any one has known the full extent of the evil.

"It will not be denied for one moment that a certain, nay, a liberal amount of charity work is a necessity to the medical profession, distinguishing it in this respect from all others. The lawyer, for instance, the engineer, the minister, the architect, the *litterateur*, the journalist, can each perfect himself in the art of his calling without proffering his services gratuitously, but the physician must study types of disease only to be adequately observed in such large numbers of human beings as are incidental either to a large practice or to hospitals and dispensaries—indeed, it may be doubted whether the fullest practice, in the harvest time of a successful physician's life, will offer him such opportunities for familiarizing himself with maladies as do our hospitals and dispensaries. It must be remembered, too, that relatively few men obtain great practices, and that they can hold them only by means of the knowledge of ailments acquired in the previous years of attendance upon hospitals and dispensaries, so that these institutions are the training-schools of our profession, inestimable to the men whom they bring into contact with each other in their varyingly eager and mutually stimulating pursuit of the same ideal, aided by the assistants, the instruments, the nurses, the housing, and the organization of such corporations. Then the thousands of students who come to this city must be taught, and this cannot be done without the clinical material of hospitals and dispensaries. Any unwise restraint would therefore imperil the existence of New York as the medical centre of the country, and no man in his senses would dream of such restriction. But such manifestly indiscriminate charity does not seem necessary to these purposes. It is trite to say that no suffering person should fail to receive the medical aid that may be needed in the emergencies of life, but in this city there really does not seem to be much likelihood of such a grievance when 949 physicians, out of a total of 3,430, treated 737,171 patients in one year, made 1,479,699 free visits, and wrote 1,104,381 prescriptions, besides paying due attention to the other duties incidental to attendance upon 26 hospitals and 114 dispensaries.

"In our medical profession there are gentlemen who have been so favored by fortune that it has not been their lot to come in contact with the seamy side of practice; there are others to whom fame has brought its attendant success; and there are still others whose special branches obviate the necessity of practice. To these medical men this statement of facts may seem exaggerated, but the great body of practitioners and those who are broad-minded enough to realize this grave violation of the first principles of a wholesome political economy will feel, as I do, that prompt and

just measures should be taken to regulate our medical charities. For my part, I have a most thorough appreciation of the needs of those upon whom we should bestow charity, but my sympathy is broad enough to embrace the medical as well as the lay poor. I should therefore recommend to this society that a special committee be appointed to obtain such facts about this subject as may be necessary to just conclusions, and that the results of this investigation be submitted to the entire society for such action as it may think proper. I would suggest that this committee consist of eleven members, namely, the chairman, five members to represent respectively the five medical schools, and the other five on behalf of the profession in general."

Committees.—THE PRESIDENT appointed the following committees: On ethics, A. M. Jacobus, chairman, James P. Tuttle, John Beach Knapp, Henry S. Stearns, William S. Dennett; on hygiene, W. H. Katzenbach, chairman, Egbert Le Fevre, Charles North Dowd, J. Harvie Dew, Robert C. Myles; on prize essays, William Stevens, D. Bryson Delavan, John E. Weeks; on auditing, V. P. Gibney, George Woolsey.

Notes on Appendicitis and Exhibition of Type Specimens.—DR. ROBERT T. MORRIS read the paper. The specimens, arranged in rows in bottles on a card-board, began with a normal appendix, which he explained was obtained post mortem. Next was an appendix in a state of acute exudative appendicitis, with desquamation of the mucosa and compression anæmia of the coats. The specimens then successively led up to the more chronic pathological changes. They showed how some cases might cure themselves, at least for that attack.

In order to estimate the number of cases of appendicitis occurring annually in the United States he had asked eight physicians who were in the habit of diagnosing the disease the number of cases they had encountered for the year ending July 1, 1896. The number would have to be much greater in order to form a reliable opinion, but the following estimates were thought to be quite within the bonds of truth: twenty-five per cent. of cases of appendicitis not treated surgically finally proved fatal of that disease, but not necessarily in the first attack; a liberal estimate of his own death rate from surgical treatment gave only two per cent.; the number of physicians in the United States was probably about one hundred and three thousand, each of whom saw probably two cases of appendicitis annually, giving a total number of cases for a year of two hundred and six thousand. If this number were treated not surgically, the total number of deaths would be over fifty thousand.

Regarding the origin of appendicitis, it was frequently due to trauma inflicted by the right psoas muscle. This occurred oftener in man than in woman, because, as pointed out by Dr. Robinson, of Chicago, the appendix in the latter more frequently hung in the pelvis out of the way of trauma by the psoas. But whatever the cause of the trauma, the appendix frequently contained a fecal concretion and infectious bacilli ready to attack the mucosa as soon as this was injured. The form of the tube was such that it did not allow the lymphoid tissue to swell equally: the inner layers of the tube suffered from compression anæmia and became a prey to bacteria.

The diagnosis was objective and subjective. Dr. Morris placed stress upon the value of palpation when the appendix was not in a state of acute inflammation, for by palpation the condition of the organ could be recognized, whether healthy or diseased. In acute inflammation there was a board-like condition of the belly, which was a valuable differential sign from salpingitis. No doubt catarrhal appendicitis might exist

with catarrh of the colon and cæcum, but in all cases in which the diagnosis of appendicitis was made the case had passed beyond the catarrhal stage.

Years ago he had laid down the rule to operate in all cases in which the diagnosis of appendicitis was well established, during or after the attack, for it was impossible to say what patients would not die under medicinal treatment, or how soon a fatal attack would occur if the patient recovered from the first. His statement on this point had led to his having been misrepresented, as he had been on other points, but surgeons, nevertheless, had come to adopt the propositions which a few years ago they had combated. He had been represented as even removing the normal appendix in case the abdomen were opened for some other purpose, while in fact he was opposed to such practice. He had also been misrepresented with regard to the inch-and-a-half incision. He did not recommend it to those in whose hands the patient's life would not be safe without an opening six inches long. Gauze should be avoided if possible, for it tended to the development of ileus. Iodoform gauze was not an infrequent cause of some seemingly unaccountable rise of temperature and wandering in mind.

The paper was discussed by DR. MCENROE, who spoke of medicinal treatment, including opium; by DR. B. S. TALMEY, who thought it was not twenty-five per cent. of all cases of appendicitis which resulted fatally, but rather of the operative cases; by DR. SAVIDGE, who thought those who spoke of medical treatment versus surgical had done so without discrimination; by DRS. COLE and COLLYER, both of whom approved of the position taken by the author. Dr. Cole would attach more importance to the pulse and also to the temperature than was done in the paper.

DR. MORRIS concluded his reply with the statement that those who were not willing to turn cases over to the surgeon, but preferred to turn them over to the bacteria, must allow the decision to be made upon the pathological condition. There were some surgeons more dangerous than some bacteria, and some bacteria more dangerous than some surgeons.

Committee on the Abuse of Medical Charity.—DR. BURTENSHAW, in accord with the suggestion contained in the president's inaugural address, moved that a committee of eleven members be appointed to report on the abuse of medical charity. The motion was adopted. The committee will be composed of the president as chairman, and of five members to represent the medical colleges and five to represent the general profession.

Committee on Legislation.—On motion of DR. FRANK VAN FLEET the president was authorized to appoint a committee on legislation, to act with the committee of the State Medical Society, and see that no bills pass the legislature detrimental to public health. It was because nobody was present to oppose it that the chiropodists had secured the passage of a bill permitting them to practise minor surgery on the feet. No doubt the opticians would try again this winter to have their bill passed.

A Humiliating Law.—DR. D. B. ST. JOHN ROOSA moved that the comitia minora be requested to draft a bill, and have it presented in the legislature, for the abolition of that clause in the present law which prohibited a physician from being president of the board of health. Adopted.

Tight Lacing. according to Einhorn, is accountable for the large proportion of ptosis of the stomach and intestines with movable kidney found in the female subject.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Ninth Annual Meeting, Held in Nashville, Tenn., November 10, 11, and 12, 1896.

E. S. LEWIS, M.D., OF NEW ORLEANS, LA.,
PRESIDENT.

First Day—Morning Session.

THE association met at the Nicholson House, and was called to order by the president at 10 A.M.

Address of Welcome.—This was delivered by the HON. JOHN BELL KEEBLE, of Nashville, and was responded to by PRESIDENT LEWIS.

Vaginal versus Abdominal Section for Pus in the Pelvis.—This paper was read by DR. W. D. HAGGARD, JR., of Nashville, in which the author recounted the transitional periods in the treatment of pus in the pelvis—vaginal puncture, superseded by abdominal section and removal of pyosalpinx, total uterine castration per vaginam by the French and through the abdomen by the American school. These operations had given way to modern vaginal section and evacuation and drainage of all pus pockets. The abdominal route affords visual inspection of the field. The attack on morbid masses could be made with safety to visceral integrity. If pus accumulations were multiple, rupture and peritoneal soiling were inevitable; that is the supreme disadvantage of abdominal incision. The author had often seen the pelvis deluged with pus with impunity. He had also seen patients die within twelve hours from fulminant sepsis from peritoneal contamination. The writer referred to a mortality of 18.5 per cent. in a series of collected cases of laparotomy for pus, done in five metropolitan hospitals in the last year, and asked, What must it be in the "unheard-from precincts," and in the hands of the great unwashed? The abdominal method offered the best approach in tuberculous inflammation of the ovaries and tubes and in small unilateral pus tubes. The author referred to the advantages of exploring the pelvis for retro-uterine tumors and disease of adnexa by vaginal section.

The geography of pus in the pelvis in most cases made vaginal incision extraperitoneal, a minor procedure giving major results—no shock, no risk, no disturbance in convalescence. In prolonged sepsis from large abscesses, posterior section and drainage were a life-saving procedure. The special indications were in (1) early cases of acute suppurating salpingitis; (2) incipient post-puerperal peritonitis; (3) large pyosalpinx and true pelvic abscess. The first group included early gonorrhœal and abortion cases. In puerperal cases, incipient peritonitis and puddles of pus in Douglas' space imperatively demanded incision. Should simple pus-letting in any of these cases not effect a cure, subsequent operation for removal of the relics of previous ravages can be done without the dangers incurred in the presence of pus. The field of vaginal section is to prevent suppuration in early cases, to anticipate it in puerperal cases, and to save life in desperate cases. Its application to the pelvic inflammatory processes and to pus in the pelvis was one of the greatest surgical triumphs of the age.

Discussion.—DR. JOSEPH TABER JOHNSON, of Washington, D. C., said that while the vaginal method had a great many points in its favor and was being resorted to more and more in cases of large pus collections in the pelvis, yet those who had been familiar for a considerable time with the abdominal route could operate more conveniently and dexterously by this method and with greater safety to the patient than by the vaginal method. He could not agree with the speaker that the vaginal operation may be done with-

out any risk to the patient. Sometimes in operating through the vagina for the purpose of removing the uterus and its adnexa, or for large pus collections high up in the pelvis, where it was necessary to manipulate the parts a good deal and to do a thorough enucleation, the surgeon was likely to tear the intestine, the bladder, the ureter, or rupture a large vessel which was out of sight. In such cases the abdominal was much safer than the vaginal route.

DR. CHARLES P. NOBLE, of Philadelphia, did not feel that either the abdominal or the vaginal method possessed all the advantages, but if restricted to one or the other he should prefer the abdominal rather than the vaginal route. An objection formerly urged against the abdominal route was the large percentage of hernias which followed this method. Only a week since he had tabulated the operations he had done in four years, which amounted to 397 abdominal cases, in which he had used the buried suture in closing the abdominal wound. In this number 7 of the wounds suppurred, while 390 healed by primary union. Of the 7 which suppurred, 1 had a hernia. Of the 390 cases, 1 had a large umbilical hernia. Aside from these two cases, he had not had any hernias in his operative work for the last four years when the buried suture was used. If the patient was in a condition to permit the surgeon to do ideal work, he thought the question of hernia was such an insignificant one that it might be left out of consideration.

DR. HOWARD A. KELLY, of Baltimore, said that, whenever possible, pus in the pelvis should be treated by vaginal puncture or section posterior to the cervix, without sacrificing any of the uterine appendages. A large percentage of the cases thus treated would have no future discomforts. Illustrative cases were cited. One of the principal arguments advanced by advocates of the vaginal route in removing the uterus, tubes, and ovaries was the excellent drainage that could be secured by this method. In Dr. Kelly's opinion it was unnecessary to take out the uterus to get drainage.

DR. L. S. McMURTRY, of Louisville, said a deep impression had been made upon the profession in the last two years by the vaginal method of operating for pus in the pelvis. This procedure, however, was by no means a new one. Battey, in his original operations upon the ovaries, attacked the pelvic organs through the vault of the vagina. The method of attacking accumulations of pus in the pelvis by vaginal puncture and drainage was the universal practice of abdominal surgeons for a long time. The sacrifice of the uterus in the majority of cases of suppurative pelvic inflammation was unnecessary. Surgery should be confined within the limits of removing only such diseased tissue or organs as were necessary for the complete cure and restoration of the patient.

DR. J. WESLEY BOVÉE, of Washington, D. C., objected to anterior colpotomy in dealing with pus cases unless the accumulation of pus was on top and in front of the bladder. He thought these cases could not be drained through the anterior vaginal route, and the pus could not be reached in many cases. He believed it was not necessary to remove the uterus at the same time pus tubes were taken out. He did not want to be understood as being opposed to the vaginal route in very urgent cases.

DR. R. B. MAURY, of Memphis, had, during the last two years, made it his duty thoroughly to study the subject of vaginal hysterectomy, as he had done quite a number of these operations without any mortality, without any accident, and without unpleasant result. But he would not undertake to say that we ought to substitute it for laparotomy. Both abdominal and vaginal hysterectomy were operative measures that surgeons must avail themselves of according to the circumstances of the case. Dr. Maury then cited the

histories of two cases that he had treated within the last thirty days, which beautifully illustrated the advantages of the two methods.

DR. W. E. B. DAVIS, of Birmingham, Ala., said the practise of incising pelvic abscesses was so old that it hardly required discussion, but the method of attacking pus tubes by vaginal section was comparatively recent. Unquestionably vaginal incision for pus confined to the tubes and ovaries would save these important organs in a good proportion of cases. In all cases of large pus collections in the pelvis, nothing more should be done than to incise the abscess and drain, and then later on the surgeon should be prepared to do an abdominal section, if necessary, but he thought the surgeon would rarely have occasion to do this. Total ablation of the uterus and its adnexa was unnecessary in the many instances in which it was practised by some surgeons.

Cholelithiasis.—A paper on this subject was contributed by DR. A. M. CARTLEDGE, of Louisville, in which the author reported several interesting cases. He dwelt upon cholecystostomy and cholecystenterostomy, pointing out the indications for each operation. He considered cholecystostomy as the only operation that was applicable to the cases cited. In his opinion there were no cases that primarily demanded cholecystenterostomy.

DR. JAMES MCFADDEN GASTON, of Atlanta, agreed with the essayist that in ordinary cases of gall stones in the gall bladder with obstruction of the cystic duct, the simplest procedure was to lay open the abdominal wall, attach the gall bladder to the incision, and remove the gall stones. But in a large proportion of cases of complete obstruction he doubted whether there would be restoration of bile through the cystic duct into the gall bladder. With reference to the comparative value of cholecystostomy and cholecystenterostomy, the two operations were applicable to entirely different conditions. No one would operate and expect benefit from a cholecystostomy except to establish drainage for the bile in a case of permanent occlusion of the common duct, and this was the only condition in which the advocates of cholecystenterostomy had ever claimed anything for it.

DR. JOHN D. S. DAVIS, of Birmingham, emphasized the point that patients frequently had gall stones without the manifestation of symptoms, particularly the symptom jaundice. He did not believe that it was ever wise to resort to cholecystenterostomy as a primary procedure. The surgeon should first resort to drainage, and then, if relaxation did not take place and the flow of bile was not effected, a cholecystenterostomy should be done.

DR. GEORGE BEN JOHNSTON, of Richmond, Va., spoke of the diagnosis of gall stones. He was convinced that if examinations of suspected cases of gall stones were as careful and minute as they should be, surgeons would frequently find them. It had been his experience that enlargement of the gall bladder did not always occur when a gall stone existed, but that a condition which simulated enlargement of the gall bladder frequently did exist, this condition being due to the presence of numerous dense adhesions found in the neighborhood of the gall bladder, gluing it to every tissue with which it came in contact. One thing which struck him as very singular in connection with the presence of gall stones was that the size of the stone or stones seemed to make no difference in the production of symptoms. In regard to hemorrhage, it was generally admitted that in cases in which cholæmia was profound, they were the ones in which we were to expect hemorrhage, and by no known method could this hemorrhage be successfully controlled. The cholæmic condition seemed to invite a fatal hemorrhage. The experience of operators in

this field of surgery was that when cholæmia was profound, hemorrhage of a fatal character was to be expected. He considered cholecystostomy a proper procedure in all cases, except in those in which the obstruction was in the common duct and could not be relieved.

DR. W. E. B. DAVIS said surgery of the gall bladder for the removal of gall stones had given brilliant results, but there were still questions in regard to operative procedures on the ducts that were not as yet definitely settled. He did not believe the essayist referred to cholecystostomy as being the choice of operation in cases in which the obstruction of the duct could not be removed; that he must have had in mind the procedure advocated by Murphy of resorting to this operation in a case of gall stone in the gall bladder when there was no obstruction in the duct. Murphy resorted to cholecystenterostomy instead of cholecystostomy, and he thought the essayist did not intend to convey the idea that he would not do a cholecystenterostomy when the obstruction in the duct could not be removed. Cholæmic cases were bad to operate upon. Perhaps in not more than five or six per cent. of the cases was the obstruction found in the common duct. Some years ago the author made experiments which conclusively showed that the surgeon could incise the duct and drain with gauze without peritonitis following. A paper on this subject was read by him before the American Medical Association in 1892, since which time he had done further experimental work in which sutures were not used after the stone was removed from the duct, and while several of the subjects were at the time very nearly dead from profound cholæmia and eventually did die, yet in the cases in which this method was resorted to the abdominal cavity was walled off and peritonitis did not result.

DR. GEORGE A. BAXTER, of Chattanooga, directed attention to the frequency of gall stones unattended with the ordinary symptom of colic, and cited an illustrative case in which there were found post-mortem three large stones in the gall bladder.

DR. F. W. MCRAE, of Atlanta, reported a case in which there were repeated attacks of colic with profound cholæmia. An operation was undertaken with the idea that the obstruction was in the common duct, and that there were stones in the gall bladder. On opening the abdomen in the presence of several physicians, the liver was found much enlarged and reaching almost to the umbilicus. Instead of finding the gall bladder enlarged, he found a fibrous cord not larger than his index finger. The common duct from disuse was reduced to a mere cord. A calculus was found in the hepatic duct extending up into the transverse fissure of the liver. He did not know what to do for a case like this, and after consultation with his colleagues closed the abdomen. The patient died five days later from exhaustion. If anything could be done for such patients he would like to know it.

First Day—Afternoon Session.

Mental Complications Following Surgical Operations.—DR. JOHN T. WILSON, of Sherman, Tex., read this paper. He said the subject of mental disorders produced by or following surgical operations had not been discussed to any great extent, and until within the past two years only a passing notice had been given to it. It was a strange fact that while surgical operations would sometimes cause serious mental disturbances, on the other hand those same operations would sometimes cure them. Especially was this the case with some melancholiacs. Many females laboring under attacks of melancholia caused by some disease of the genital apparatus had been cured when relieved of the physical defects by operation; others

had been much improved, and yet some had received no benefit. The question might very properly be asked why a surgical operation should produce an attack of insanity. This could no more be answered in every case satisfactorily than could the question why some persons became insane from the many other causes to which insanity was attributed, for in most cases the mental complications were a surprise and no good reason could be given why they should follow. In others, however, a logical explanation might be had. If the patient was a high-strung, nervous individual, easily excited, unable to bear pain, the great and increasing dread of the anæsthetic, the operation, or both, would so affect him that he would lose control of the will power and the explosion would come after the operation and reaction from the anæsthetic. In many of these cases, probably a majority, there was a hereditary taint or a strong neurotic tendency.

The author quoted Mairret, who thinks (1) that it is in those individuals who are predisposed by heredity or other grave causes—alcoholism, infectious diseases, etc., that surgical operations give rise to insanity; (2) in the constituent elements of an operation that may act on the brain the two most important ones are the anæsthetic and the degree of surgical traumatism, with its after-effects, of which disturbed nutrition plays a very important part; (3) when predisposition also is considerable, the anæsthetic alone may produce insanity, or it may result even after minor operations. It is, of course, necessary to take into consideration the mental state of the patient prior to the operation, especially in those graver ones in which frequently questions of life or death are involved.

Discussion.—DR. E. S. LEWIS, of New Orleans, related the case of a woman, forty years of age, very hysterical, upon whom he had operated for laceration of the perineum. She had manifested no evidences of insanity prior to operative interference, but during convalescence the hysterical manifestations increased and were associated with delusions. Her condition became so serious that on different occasions she threatened to commit suicide. She was transferred to an insane asylum, and after a thorough examination by the physician in charge an unfavorable prognosis was given. Investigation of the family history showed traces of insanity.

In another case, that of a woman sixty years of age, he removed a very large adherent ovarian tumor, the operation being attended with considerable shock. For a few days subsequently the patient did well, but she later became perfectly insane. These were the only two cases he vividly remembered, although he had seen after operations cases of temporary insanity which had passed off in the course of a few months.

DR. W. E. PARKER, of New Orleans, had seen in men two or three cases of insanity following surgical operations, but had never been able to trace any history of the disease in the family. The insanity occurred in alcoholics. Two of the men were either cocaine or morphine habitués. In the management of such cases the particular drug to which the patient was addicted should still be continued in very small doses, being cut off gradually, for the reason that great prostration often followed the sudden interdiction of a habit that had been continued for many years.

DR. R. B. RHETT, of Charleston, S. C., had met with three cases of postoperative mental aberration, two of which occurred in old women after removal of the breast for cancer. A third case occurred in a young woman who had had puerperal insanity prior to operation. In two cases the insanity lasted for three days, in the other for three weeks.

DR. A. M. CARTLEDGE, of Louisville, said the question of postoperative insanity led us to discriminate as to the probable etiology in many of the cases. He

thought the author of the paper had in mind to deal with those cases of postoperative insanity that were functional in character, rather than those in which patients suffered from the mental impression produced by the operation in general. He was quite sure most of the cases, except those characterized by hereditary tendencies and traits, could be traced to some organic lesions. The history of the case should always be thoroughly investigated. He had encountered what he considered pure postoperative insanity in only two cases.

DR. JOHN D. S. DAVIS considered the subject of interest from a medico-legal standpoint. No surgeon was absolutely free from such mental complications occurring in his operative work. He had encountered four cases. In the case of a certain young man there was no history of insanity, but an analysis of the urine before operation showed a great many casts and a slight trace of albumin. Operative interference was followed by acute mania, which lasted seven days, then disappeared, and the patient recovered. He would like the essayist, in closing, to touch upon the responsibility of the surgeon in this class of cases.

DR. JOSEPH TABER JOHNSON said that in talking with Drs. Kelly and Noble, he learned that the latter had met with eight cases of insanity following perineal operations. He asked the essayist to state whether operations upon the perineum were more frequently followed by insanity than others.

DR. WILSON in summing up said he had seen a number of cases of various forms of insanity following surgical operations, but did not think the disease occurred more frequently after perineal operations and operations upon the genitalia than upon any other part of the body. In reply to Dr. Davis' question, he did not think the physician was any more responsible for the death of a patient from insanity following an operation than he was for death following any other operation. He had never heard of a suit for malpractice being brought against the practitioner for a case of mental derangement following a surgical operation.

Splitting the Capsule for the Relief of Nephralgia.—DR. GEORGE BEN JOHNSTON, of Richmond, Va., read a paper with this heading, in which he drew the following conclusions: (1) Nephralgia is not always associated with a demonstrable lesion. (2) When other evidences of kidney disease are wanting, the pain is due to a too tight capsule. (3) Nephralgia may and frequently does simulate symptoms of gross tissue changes or mechanical irritation. (4) When severe and persistent pain in the kidney exists without other evidences of renal disease, exploratory operation is indicated. (5) When inspection, palpation, and needle puncture fail to disclose a condition sufficient to account for the pain, the capsule should be freely opened.

Uretero-Ureteral Anastomosis.—DR. J. WESLEY BOVÉE, of Washington, D. C., read a paper on this subject and reported an interesting case. The author dwelt at length upon the literature of the subject, quoting from the contributions to the surgery of the ureters by Van Hook, Fenger, Kelly, and Cabot in this country, and the classical works of Glantzenay, Liaudet, Tuffier, and others in Europe. He drew the following conclusions: (1) Uretero-ureteral anastomosis is a perfectly feasible procedure. (2) Uretero-ureteral anastomosis, whenever possible, is far preferable to any other form of ureteral grafting, to nephrectomy, and to ligation of the ureter. (3) It should be done preferably by lateral implantation or by oblique end-to-end anastomosis, though the transverse end-to-end, or the end-in-end methods may be safely employed. (4) Constrictions of the calibre of the ureter do not usually follow attempts at suturing in closure of complete transverse section of the duct.

(5) Nephrectomy for transverse injuries of the ureter, *per se*, is an unjustifiable operation. (6) Simple ligation of the ureter to produce extinction of the function of the kidney is too uncertain to justify its practice. (7) Drainage is not necessary if the wound be perfectly closed and the tissues are aseptic.

DR. HOWARD A. KELLY was very much interested in this subject and said every abdominal surgeon should be familiar with uretero-cystotomy or uretero-ureteral anastomosis, because in doing abdominal operations the surgeon was liable at any time to injure the ureter, when he would be confronted with the necessity of doing something to repair it. Dr. Kelly then pointed out the various ways in which the ureter might be cut during operations and described the method he pursued in repairing such injuries.

DR. CHARLES P. NOBLE cited a case of neglected extra-uterine pregnancy complicated with an intra-ligamentous ovarian tumor. In operating, the intestines were apparently adherent over a mass of blood and a large fleshy adhesion ran upon it. To save time this was clamped, cut through, and the pelvis cleaned out. It was necessary to do a hysterectomy in order to get anything to tie, as the anatomical landmarks were obliterated on both sides of the pelvis. Furthermore, the broad ligaments did not come down in the usual way. When the operation was completed the patient was in collapse, and it was found that what was supposed to be a fleshy adhesion was really the ureter and thickened peritoneum. The ureter was cut off almost up to the kidney itself. The lower part of the ureter was taken out with the mass of blood, there being only the upper three or four inches of the ureter left. Dr. Noble thought that if any attempt had been made to prolong the operation with the patient in collapse death would have resulted. Although the remainder of the ureter was short, it was dragged up into the upper end of the abdominal incision. It was impossible to do a uretero-ureteral anastomosis, likewise to switch the ureter into the bladder, because it did not reach anywhere near the brim of the pelvis, much less the bladder, and there was nothing else to do but to remove the kidney, which Dr. Noble did, and the patient recovered.

The Treatment of Pregnancy and Labor Complicated by Fibroid Tumors of the Uterus.—DR. HENRY D. FRY, of Washington, D. C., read this paper. He advanced two propositions: First, that the production of abortion is unjustifiable. Second, that labors presenting serious difficulty to delivery are best treated by abdominal section and removal of the child and tumor. By maintaining this position the interests of the mother are not relegated to second place. While saving the life of many infants, the maternal mortality will also be diminished. After making a few brief remarks on the natural history of fibroid tumors complicating the pregnant state and reporting a few cases that had come under his care, he considered the treatment.

DR. A. J. COLEY, of Alexander City, Ala., reported a case of cyst on the right side with a left uterine tumor, low down, involving the body of the uterus, which was firmly fixed in the pelvis and complicated pregnancy. The woman, forty years of age, suffered so much pain that it was thought advisable to resort to hysterectomy, but it was not insisted on. The woman had been married a little over a year. She was closely watched, and, as pregnancy and labor advanced, the tumor was pushed above the brim of the pelvis. The woman was subsequently delivered naturally of a child, and is now attending to her household affairs. Dr. Coley counseled against operative interference in many of these cases.

DR. R. R. KIME, of Atlanta, had encountered a case some two years ago of a debilitated patient with evi-

dences of infection before labor. In introducing the hand a tumor was felt in the posterior uterine segment, crowding the cervix apparently above the symphysis pubis, and it looked as if the patient could not be delivered. However, by waiting and placing the patient in the exaggerated Sims position and elevating the growth, delivery of the child was effected.

DR. HOWARD A. KELLY agreed with the conclusions of the essayist. There was a tendency on the part of the profession to interfere too much in cases of pregnancy complicated by fibroid tumors of the uterus. He had been called in consultation to see a number of such cases, but the indications were not such in some of them as to warrant the induction of premature labor. In many instances a consultation had been the means of postponing operative interference. When fibroid tumors complicating pregnancy were situated in the upper part of the uterine body, unless large and multiple, they were comparatively unimportant. If situated in the lower part of the uterus, and it was found as pregnancy advances that they could be pushed up, this should be done in order that labor might proceed naturally. On three occasions he had opened the abdomen and had done a myomectomy for tumors complicating pregnancy, the woman subsequently going to full term and being delivered normally.

DR. W. D. HAGGARD, SR., of Nashville, mentioned a case of uterine fibroid complicating pregnancy which came under his observation a few years ago. Hysterectomy was advised by the consultants but not resorted to. The woman was subsequently delivered of a child, and the tumor six months later had entirely disappeared. Dr. Haggard reported another similar case.

DR. JAMES A. GOGGANS, of Alexander City, Ala., had observed during the last twenty years a number of cases of pregnancy complicated by uterine tumors. He had seen the case referred to by Dr. Coley. He thought it was unwise in a great many cases to resort to hysterectomy, believing that the tumors could be pushed up and delivery effected without surgical interference.

DR. JAMES MCFADDEN GASTON cited a case of dermoid tumor which complicated pregnancy. The obstruction was so great that it was utterly impracticable to undertake to deliver the woman by forceps, and it was concluded to lessen the obstruction by aspirating the tumor. This was done, and a little more than one quart of grumous material was drawn off, after which the woman was delivered with forceps of a dead child. Dr. Gaston believed that the woman would have to be subjected to a radical operation for the removal of the dermoid before perfect relief was afforded.

DR. GEORGE A. BAXTER referred to the danger of post-partum hemorrhage in cases of fibroids complicating pregnancy and related an interesting case. The fibroid tumor interfered with the natural contraction of the uterine fibres, and on this account it was exceedingly difficult to arrest hemorrhage. This was a complication which endangered the life of the woman.

DR. E. S. LEWIS said it often fell to the lot of some physicians to meet with a series of anomalous cases, such as those that had been reported by the essayist, while other physicians with probably quite as large experience would pass through life without meeting some of the complications that had been mentioned. During an experience extending over thirty-four years he had never met with a fibroid tumor which justified interference before labor, that is, a fibroid occupying the lower segment of the uterus and impinging upon the pelvic cavity. Within the past year he had delivered two women having large fibroids.

In one case in which pregnancy supervened, after suspension of menstruation for two months he was unable

for several months to determine the existence of pregnancy. The uterus then reached above the umbilicus, but the woman was found pregnant and was delivered at full term with forceps, but with no extraordinary difficulty. The other woman had an abdominal tumor the size of a six months' fetus. Although she had been married a number of years, she was about forty when she became pregnant. The tumor occupied the upper portion of the body of the uterus, but she was delivered without the use of instruments. He could conceive that in a case of fibroid situated in the broad ligaments or occupying the lower segment of the uterus, seriously impinging upon the cavity of the uterus, hysterectomy would be inevitable, but it had been his fortune to escape such cases.

DR. FRY, in closing, was glad to note that the general trend of the discussion was favorable to conservative work in the treatment of pregnancy complicated by fibroid tumors of the uterus, and of permitting women to go to full term and trying to deliver them naturally. Some of the cases in the paper, which he did not read, exemplified the wonderful resources of nature in overcoming uterine obstructions. Post-partum hemorrhage was one of the serious complications of labor under these circumstances and was common. If the placenta was attached to the fibroid tumor hemorrhage was free. If it was found necessary to operate, Cæsarean section ought not to be resorted to, as the mortality following this procedure was fully as high as eighty-four per cent. The best thing to do was to resort to hysterectomy, either the complete or supravaginal method.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PERICARDITIS—FRACTURED RIBS IN OLD AGE—HERNIA—CLUBBING OF FINGERS—GASTRO-ENTEROSTOMY—CURIOUS DEFORMITY OF JAW—FRAGILITAS OSSIUM—TUMOR OF SACRUM—GENERAL MEDICAL COUNCIL—ANNUAL MEETING OF COLLEGE OF SURGEONS—DR. CULLINGWORTH'S DEFENCE.

LONDON, November 20, 1896.

SOME very interesting cases were related at the last meeting of the Clinical Society. Thus, Mr. H. Besham Robinson described a case of suppurative pericarditis treated by resection of the sixth rib and drainage, in a lad aged sixteen years. The lung was fixed by recent adhesions. All fibrinous coagula as far as possible were cleared out from the cavity by the finger, and over two quarts of pus were evacuated, but irrigation was decided against, owing to his feeble condition. A large drainage tube was introduced into the pericardium and was stitched to the margin of the wound. His recovery was uninterrupted but protracted, and the tube was removed on the sixty-first day after the operation, the wound soon healing, and the patient, although not taking very strong exercise, can walk ten miles. There are very slight enlargement of the superficial cardiac area upward and no retraction of the spaces with the systole. Very few such cases have been recorded during the larger part of a century, less than a dozen, but they show a large proportion of successes (five out of eight).

Mr. R. H. Mills-Roberts related a case of an old man, aged seventy-three, who was knocked down by a falling rock and crushed by two boulders, between which he was jammed by the rock which fell on him. On admission he was nearly moribund; he rallied, but on the sixth day he developed pneumonia.

He again got better and steadily improved for six weeks, when he had a fit and died suddenly, apparently of syncope. Post-mortem revealed, on the left side, comminuted fracture of the sternal end of the clavicle; fracture of all the ribs, including the first; the second, third, fourth, fifth, sixth, seventh, and eighth ribs were broken at angles, and the second, third, and eighth at the sternal end. The ninth, tenth, eleventh, and twelfth each had a single anterior fracture extending through the inner plate only. On the right side there was single fracture of the third rib at the sternal end; of the fourth, fifth, sixth, seventh, two fractures, sternal end and angles; of eighth and ninth, single fracture. The right kidney showed a blood calculus in the lower part. All other organs were normal. There appeared to be very little lung injury.

Mr. W. G. Spencer described two cases of a rare form of inguinal hernia, each presenting three peculiarities, viz.: absence of an internal ring, the deep epigastric artery lying across the front of the hernia, and close above the pubic spine an extraperitoneal protrusion of a bladder pouch, closely adherent to the sac.

Dr. Samuel West related two cases of "clubbing of the fingers" developing within a fortnight and four weeks," respectively: (1) In a gentleman, aged thirty-six years, with right-sided empyema between the base of lung and the diaphragm. The patient recovered of the empyema, and by the end of three months the clubbing had completely vanished. (2) In a healthy woman, aged fifty years, who came under treatment because she had taken ammonia by mistake and had a troublesome gastritis in consequence. Her fingers were extremely clubbed, and had become so four weeks before without apparent cause, while she was in perfectly good health. Her attention was first drawn to their condition by her gloves ceasing to fit her. This seems a unique case.

Mr. Richman Godlee remarked that however chronic the clubbing might be, it cleared up if the disease causing it were cured. He remarked that the nose often suffered as well as the fingers, etc., but this was apt to escape notice, as there was no orthodox type of human nose. He had a little child under his care in whom only one finger was clubbed, and there was nothing wrong with the bones. Well-marked clubbing might certainly occur without any disease to account for it, though perhaps it was more frequently met with in association with bronchiectasis than any other disease.

At the clinical evening of the Medical Society Mr. Lockwood showed a successful case of gastro-enterostomy performed on an elderly man for cancerous obstruction of the pylorus. He insisted on the importance of furnishing the artificial opening with a complete lining of mucous membrane, thus rendering it less liable to subsequent contraction. Mr. Battle had had a somewhat similar case of rapid onset in a young man, aged thirty, in whom, at the operation performed within six weeks of the onset of the symptoms, extensive secondary growths were found. He used Senn's bone plates reinforced by a Lembert suture, and the patient promptly recovered from the operation with relief of all his urgent symptoms. Mr. G. R. Turner showed a lad with a curious bilateral deformity of the lower jaw, which the mother believed to be congenital, but which the father stated had commenced after an attack of measles at two years of age. There was no ankylosis of the temporo-maxillary articulation, but the vertical ramus of the jaw projected lower than the horizontal so that there was considerable prominence at the angle. The lad could open his mouth only a little way and was unable to protrude his tongue. Mr. Bruce Clarke said he had never seen this deformity in the bilateral form, as in this instance, but had had a unilateral case, in which it was neces-

sary to perform tracheotomy to prevent asphyxia caused by the tongue falling back into the throat.

Dr. F. de Haviland Hall showed a young man who had developed progressive enlargement of the cervical and supraclavicular glands, followed by the development of a mass of enlarged glands over the upper part of the sternum. The enlargement decreased for a time under large doses of arsenic, but there was a marked pigmentation, probably due to the drug. There was now dulness all over the left lung behind, and he raised the question how much of this was due to enlarged glands and how much to pleuritic effusion. Dr. Outtersen Wood pointed out that arsenical pigmentation displayed a curious tendency to vary in intensity from day to day without obvious cause.

Mr. Clinton Dent showed a very remarkable and pronounced case of fragilitas ossium in a man, aged twenty-nine years, whose stature did not exceed thirty-six inches. He had in all sustained twenty-seven fractures, principally of the limbs, but his intelligence was unaffected. He had been brought up on his mother's milk exclusively until four years of age. Mr. Dent showed some very interesting skiagraphs of the bones. The first fracture (of the femur) occurred when the child was four months old.

Mr. Goodsall showed a large pelvic tumor which had grown from the sacrum. He removed the tumor, taking away at the same time the lower portion of the sacrum to which it was attached, and the result was most satisfactory.

The General Medical Council meets next week, when the fate of the Dublin Apothecaries' Hall will again be in the balance. Meantime the electioneering for seats in the council is being energetically carried on.

The annual meeting of fellows and members of the College of Surgeons took place yesterday; Mr. Macnamara, vice-president, presiding in place of Sir W. MacCormack (president), whose progress toward recovery is still slow. In the report submitted the finances are stated to be satisfactory. A resolution was passed after full discussion in favor of voting money toward the effort of Mr. Anderson to appeal to the House of Lords for the restitution of his rights as a fellow and member, of which he has been deprived by judge-made law. You will remember his gallant defence against the oppression he suffered at Tobago and that a British jury decided in his favor, but that decision was overruled by the court. The council opposed the resolution, as a grant of the kind would probably injure the cause they are supporting—to be exempt from certain taxes, on the ground that they are only a scientific body. Nevertheless, the resolution was carried by forty-seven to two.

Another resolution was carried, requesting the council of the college to instruct their representative on the General Medical Council to forward in every way feasible the principle that the representatives of the licensing bodies should effectively represent the holders of all their diplomas. Corporation reform is in the air and must come, in spite of the opposition of the few in possession.

Dr. Cullingworth, of St. Thomas', has successfully defended the action brought against him by a woman on whom he performed double ovariectomy. She alleged she consented to have only one ovary removed, but he said he could undertake to operate only on the understanding that it must be left to his judgment to do the best he could for her. He has vindicated his procedure, the jury adding to their verdict that the action ought never to have been brought. But no doubt he has been put to great expense and endured some four years of worry. It seems as if operators would be well advised to insist on consent in writing. Sir S. Wells and Dr. Bedford Fenwick were called for

the plaintiff, but their evidence, founded on notes of the case, did her no good, and it is a pity they should have appeared and so illustrated the prejudice as to doctors disagreeing. It is very hard on Dr. Cullingworth, after a successful gratuitous operation, to have to defend his conduct in court. He will certainly lose a considerable sum, as there are numerous items in costs which do not pass the tax master. Drs. Herman and Galabin, as well as Mr. Lawson Tait, agreed that it was necessary to remove the second ovary. Professional responsibilities are heavy enough without the terrible risks of lawsuits to decide whether a patient has consented to a procedure which may prove necessary in the course of an operation.

THE CURE OF SEASICKNESS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Notwithstanding the large circulation of the MEDICAL RECORD in Europe, I did not until quite recently have an opportunity of reading Dr. Rockwell's article on seasickness published in the spring or early summer. The doctor was kind enough to mention my work on the subject, but was also frank enough to intimate that he did not believe in the results I obtained by my method of treatment of seasickness.

Since my chief desire is that the sea-going public may benefit by my former researches in that direction, I beg that you will here permit me to reaffirm the exactitude of my statements as to results in treatment. I also might venture to observe that a physician who has barely crossed the ocean and back, with all the upholstered comfort of a first-class passenger, is hardly in a position to pass judgment upon the work of another man who, as a regularly appointed ship's physician, has travelled his sixty thousand miles in all latitudes and has as conscientiously treated his seasick emigrants as he has the first-cabin passengers. In the eighty-seven written clinical records upon which I based my conclusions as to the efficacy of my mode of treatment, there were no flights of the imagination, but only carefully considered facts. Other physicians have tried my method with marked success, although the writer of the above-mentioned article in the MEDICAL RECORD may never have heard of them. The doctor is without doubt a first-rate authority on electro-therapeutics, and also able to fill four columns of the MEDICAL RECORD on the well-known properties of the bromides in seasickness, but that hardly qualifies him to characterize as "mistaken" a fellow-practitioner who has had a comparatively large experience in the matter. I am not disparaging the mode of treatment by bromidization as a means of prophylaxis, for I dwell upon it sufficiently in my own treatise on seasickness, but I simply claim that the results obtained by my method are fully as favorable as stated, and that that treatment will reach desperate cases which other means fail even to alleviate.

W. W. SKINNER, M.D.

LUZERNE, November 16, 1896.

THE JUDGING OF COMPARATIVE RESULTS IN THE SURGICAL ARENA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: With all the presumption of the ancient shepherd boy going out to meet the giant with pebble and sling, with not the remotest idea of criticising the surgery of any person or institution, with neither standing nor right to pose as champion of Roosevelt Hospital—the writer ventures comment on some recent surgical statistics given to the profession.

Dr. Gaillard Thomas, in an address at the Woman's

Hospital, drew comparisons between several city hospitals as follows:

Abdominal Sections done in 1894, at	Number of Cases.	Re-covered.	Died.	Percentage of Deaths.
Roosevelt Hospital	66	50	16	24.24
New York Hospital.....	67	52	15	22.37
New York Cancer Hospital....	104	86	18	17.3
Mount Sinai Hospital.....	55	46	9	16.36
Woman's Hospital.....	153	130	23	15.03

Dr. Morris, in a recent paper, cited a series of 100 cases of appendicitis in which he had operated, with a mortality of two per cent.

Péan, of Paris, recently reported 584 cases of vaginal section (non-suppurative), with a mortality of less than two per cent.; and 816 suppurative cases of vaginal section, with a mortality of less than five per cent.

Jacobs, of Brussels, reports 403 cases of vaginal section, with less than three per cent. mortality.

These statistics, without analysis or qualification, prove logically that surgery in the Woman's Hospital is almost doubly as successful as in Roosevelt Hospital. Those of Morris, when compared with surgeons who have a ten or a twenty per cent. mortality, prove logically that he is five or ten times more skilful than they, and is justified in deducing that it is all a matter of "individual art," and that "some surgeons are more dangerous than some bacteria." The figures of Péan and Jacobs prove logically that they have five or ten times more "individual art" than the principal surgeons at New York hospitals.

But does anybody who knows the whole ground believe these logical deductions? Such unqualified statistics are, to the unthinking, a standing criticism upon more conservative men in the profession.

Suppose that surgeons with fancy statistics meet a dozen desperate cases in their respective lines, each with one bare operative chance for life in a hundred. Would these gentlemen have regard for their statistics and refuse the patient the one poor chance by operation? Or would they rule out from their statistics these "practically moribund cases"? In either event, while the operators themselves may be soberness and truth itself, their figures are vainglorious cheats as a test of comparative skill.

As low mortalities cannot be had from desperate cases, we must seek another standard to test a surgeon's worth, namely, the character of his cases. The conservative man who operates only on grave cases, will necessarily have a shorter list and a larger mortality than another who operates on everything coming into his hands. Life-saving is a higher ambition than record-making. And low mortalities mean many easy cases to help the average up—cases that the conservative man would not subject to risk of operation.

EUGENE COLEMAN SAVIDGE, M.D.

66 WEST FIFTIETH STREET, NEW YORK.

An Exception.—In an examination of sanitary inspectors one candidate answered the question relating to the wilful exposure of a person suffering from an infectious disease: "He must not ride in any public conveyance, excepting a hearse, without first informing the driver."—*The Medical Times and Hospital Gazette*.

Eye Strain.—The long continuance of eye troubles may be the unsuspected source of insomnia, vertigo, nausea, and general failure of health. In many cases the eye trouble becomes suddenly mischievous, owing to some failure of the general health, or to increased sensitiveness of the brain from moral or mental causes.—*The Medical Times and Hospital Gazette*.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 5, 1896:

	Cases.	Deaths.
Tuberculosis.....	136	85
Typhoid fever.....	45	14
Scarlet fever.....	98	5
Cerebro-spinal meningitis.....	3	3
Measles.....	86	3
Diphtheria.....	263	35
Small-pox.....	1	0

A New Use for Patent-Medicine Literature.—It is a favorite axiom of the optimists that everything has its uses, but it has remained for the New Mexico territorial board of health to find a use for the patent-medicine almanac. In a recently issued circular on the prevention of consumption, among other things, it is advised that "every person so affected should spit into some receptacle and should see that the sputum is soon destroyed by fire. About the house there is no better way than to spit between the leaves of patent-medicine almanacs—to be had freely at all drug stores—and after a half dozen or more spittings burn the book."—*Journal of the American Medical Association*.

Sixpence for medicine and attendance was the charge of a lady doctor in Fulham, England.

Oxytoxins.—The subject of the oxytoxins is one that will require long-continued experiment upon animals and cultures before we shall know its limitations. For the present, however, it would be unwise to expect miraculous cures of patients in the last stages of consumption.—HIRSCHFELDER.

Paté de Foie Gras.—Instances of illness following the free use of this delicious product of the fatted goose may have at times a *raison d'être* in the fact that some goose farmers have been found to possess a secret of securing enormous livers in their stuffed fowls by administering the acid oxalate of potassium, a powerful poison.

The Night Lunch Wagon.—Mr. John F. Hurley, president of the water board, of Salem, Mass., who has been indefatigable in promoting a good water supply, has now called attention to a matter which affects the public health in a different degree. Disclaiming any intention of needlessly interfering with any person's means of livelihood, he has protested against the licensing of night lunch wagons, on account of the liability of the spread of disease by this means. These wagons are familiar sights in the cities and larger towns. Either they are driven about the streets or they occupy a stand, night after night. Mr. Hurley has interested himself to inquire into their operation and finds that when ready for customers the water supply of a wagon consists of about two gallons of water in a bucket. During the night several hundred cups of coffee and mugs of milk are sold and emptied into mouths many of which are dirty and diseased, some foully so. The cleansing of the mug or cups consists of a rinsing in the bucket of water and a wipe with a towel that does duty for the entire night. We must agree with Mr. Hurley that probably no better method of spreading disease can be found than the practices he describes, and the subject is one which should receive the attention of the board of health in the cities where such a menace to public health exists.—*The Engineering Record*, October 24th.

OBSERVATIONS ON VESICAL STONE AND PROSTATIC DISORDERS, BEING THE BRADSHAW LECTURE DELIVERED BEFORE THE ROYAL COLLEGE OF SURGEONS OF ENGLAND ON DECEMBER 9, 1896.

By REGINALD HARRISON, F.R.C.S.,

MEMBER OF COUNCIL; EX-VICE-PRESIDENT, AND FORMERLY HUNTERIAN PROFESSOR OF PATHOLOGY AND SURGERY, ROYAL COLLEGE OF SURGEONS; PRESIDENT OF THE MEDICAL SOCIETY OF LONDON.

WE are met by reason of the beneficence of the widow of the late Dr. William Woods Bradshaw, a physician who practised first at Andover and subsequently at Reading, and who was a fellow of this college, for the purpose of endeavoring to promote in one direction or another the scientific objects for which this college was originally founded. I shall best mark our respect to the memory of the founder of this lectureship, and my appreciation of the honor conferred upon me, by at once proceeding to attempt to discharge the duty I have thus undertaken.

If, for any purpose, we look at the surgery of to-day, as exemplified, for instance, by the work of many of those who either have been, or are, associated with this college, and compare it with what existed at the commencement of this century, or even later, it is impossible not to recognize the marvellous progress that has been made all along the line. Though in some directions it may be more apparent or practical than in others, yet it is at once obvious that it is the outcome of the development of principles which are applicable not merely to subdivisions artificially arranged for convenience of study or of practice, but to the whole field over which the science and art of surgery may be said to range.

It will be my endeavor in noticing certain advances that have taken place in work which circumstances have brought more immediately under my notice, to give prominence to some aspects of a large and an important subject which appear to deserve further consideration and expansion. In this way I venture to hope I shall best fulfil the objects entertained by the beneficent founder of this lectureship.

In bringing under your attention some points connected with the surgery of the urinary organs it is impossible to refrain from noticing the important changes that have taken place in the operative treatment of the affections of these parts within the recollection of most of us present on this occasion. Lateral lithotomy has practically disappeared from the scene; suprapubic and perineal cystotomy, more especially in their application to calculus, have undergone important modifications and have been revived; the older methods of removing stone from the bladder by crushing have been supplanted by Bigelow's process of litholapaxy, and the surgery of the kidney, with the various methods this includes, now occupies a permanent and prominent position in our text-books. Nor is it improbable that the range of renal surgery may not be still further extended with advantage. The outcome of these changes in and additions to our methods of

dealing with urine stones alone represents a saving of life and suffering which it would be difficult, if not impossible, to estimate by figures.

The almost entire disappearance of lateral cystotomy, using this term in its more extended application to various affections and injuries of the urinary apparatus, is a turn of affairs which I venture to think cannot be viewed entirely with satisfaction. Some of us may remember how marvellously this operation was utilized by the late Sir William Fergusson for the rapid and successful removal of certain forms of stone from the bladder. It was in this theatre and before a distinguished audience of the kind gathered here to-day that he referred to this process in terms of eulogy as "the master handiwork of surgery."

In thus dissenting from the tendency existing at the present day to relegate lateral cystotomy to the surgical shelf, the suggestion comes to me in a measure from reading some remarks in a review relative to certain observations of which I happened to be the author, in which I was rather severely taken to task for being so old-fashioned or so eccentric as to reproduce for the use of my readers, at the close of the nineteenth century, a somewhat carefully prepared description of this operation. It seemed to me that such a criticism was a little premature, for, though the use of this operation in stone cases was daily becoming more restricted by reason of the substitution of other methods, the fact that lateral cystotomy possessed essentials in treatment peculiar to itself must forever command for it a place in the records of operative surgery.

By what other means that have yet been devised, may I ask, can a surgeon, by an opening from the perineum in the male, secure the removal of a stone, the incontinent and dependent drainage of a diseased bladder, without the use of apparatus, together with the necessary infliction of a wound on the prostate which, there are reasons for thinking, has not unfrequently been the means of arresting its growth, if not of inducing its atrophy when enlarged? Nor can it be doubted for the reasons just assigned that in certain forms of injury involving the neck of the bladder, complicated as this sometimes is with fracture of the bones constituting the pelvic arch, as in instances of extraperitoneal rupture of the bladder, an incision as for lateral cystotomy has frequently been the means, by at once establishing free and untrammelled drainage for the urine, of alone bringing about a successful termination to the case. For reasons such as these, I should be sorry to think that the mode of performing lateral lithotomy has either ceased to be taught in our schools or to be tested by our examiners.

Lateral cystotomy has to a large extent been displaced by the revival of the suprapubic or high operation on somewhat altered lines, and with this substitution I am not disposed to find fault. By this method an easy access to the bladder for the purposes of exploration and drainage not requiring a dependent opening, for the removal of growths from the interior of this viscus as well as pendulous excrescences from the prostate, is provided. In the case of small stones, both in the adult and the child, its substitution for crushing, in uncomplicated cases, is often unnecessary, while in the instance of very large calculi, though

no other course may be open to the surgeon, the risk to life, it must be remembered, is considerable.

Time, however, will not permit me to traverse opinions and practices relative to an operation which has undoubtedly justified its revival and has proved of much service in connection with the general surgery of the bladder. Its selection relative to the treatment of stone will be found mainly to turn on individual experience, rather than upon those hard and fast lines which lecturers are sometimes disposed to lay down.

Turning to the crushing operation for stone, as now generally practised on the lines laid down by Bigelow in 1878, we shall find much connected with it of interest to discuss without encroaching upon historical and personal controversy. There can be no doubt whatever that the anticipation expressed by the author of the term "litholapaxy" as to the crushing and evacuation of stone from the bladder by an uninterrupted and completed process, with hardly any reference to its size or constitution, being followed by a largely diminished mortality has been more than realized.

In connection with Bigelow's method of operating I may perhaps be excused in saying what pleasure it afforded me in being present at the Massachusetts General Hospital and witnessing some of the cases which formed the earliest portion of the important series that Bigelow subsequently published¹ in illustration of his work. The instrument I am showing you is one of his original evacuators with the catheters, which I brought over with me from Boston in 1878 and subsequently used.

I do not, however, think it would be right in thus referring to the greatly diminished mortality that has followed successive improvements in the crushing operation for stone, or by whatever name we may call the proceeding, were I to omit to refer to the impetus given to this direction of work by Civiale and Guyon in France, and by Sir Henry Thompson in this country. By the latter the museum of this college has been greatly enriched by his gift of a collection of calculi which is unique in its extent and clinical history, while our library and our literature have largely profited by his pen.

I must, however, turn, as I have already indicated, to another aspect of my subject. In his Hunterian lectures delivered before this college in 1886, Mr. Cadge observed that, "although the immediate and direct mortality of lithotripsy is small, the recurrence of stone is lamentably frequent." In illustration of this statement he referred to figures which indicated this as then amounting to about one in seven. It must, however, be remembered that this calculation was based to a considerable extent upon cases operated upon by the processes of crushing, with very imperfect means of artificially evacuating the fragments from the bladder which preceded Bigelow's time.

A decade has now elapsed since this criticism was offered, and, without troubling you with figures which might be open to objection for this purpose if not drawn from sources in actual parallelism with those which formed the basis for the conclusion Mr. Cadge arrived at, there can be no doubt that within this period, and directly arising out of the further development and more general adoption of Bigelow's work, the liability to recurrence after these operations has greatly diminished.

Improvements in the construction of lithotrites or breaking machines, so far as relate both to trituration and speed, the more general substitution of fenestrated for smooth-bladed instruments, the use of evacuating cannulae permitting of the more ready withdrawal and escape of the broken-up fragments from the bladder, and the employment of aspirators or wash bottles more capable of sluicing the bladder and any irregular

pouches it might possess, are the means which have chiefly contributed toward this end.

It would be an interesting study, and not without some prospect of promoting further developments in this direction, to trace, if occasion permitted, the various advances that have been made from time to time in the construction of the mechanical appliances used in crushing and evacuating stone in the bladder. I am disposed to think, however, in the further application of chemistry and physics in this direction (I refer more particularly to the extension of such investigations as Rainey's, "On Molecular Coalescence Relative to the Formation of Calculi") to all forms and positions of urine stones that further improvements in practice will eventually come.

Reverting to stone recurrences, it must still be recognized that even with the best appliances and skill they not unfrequently occur, and it is to such instances, in relation more particularly to some recent investigations in collateral directions, I would desire now to direct your attention for a few moments.

If we analyze the causes of stone relapses after crushing operations, there can be no doubt that a failure to remove all the fragments from the bladder in the first instance is by far the most frequent one. It is in reference to this very important matter that lithotomy, however performed, irrespective of the question of mortality, shows to an advantage, and at the same time suggests an explanation why this distinction should exist. This is a point which I think requires further analysis and consideration.

The general experience of crushing operations as now, and for some years past, almost universally practised under the name of "litholapaxy," in this country at all events, seems to indicate sufficiently clearly that the liability to recurrence after this operation increases considerably as age advances. Recurrences before sixty years of age are rare and are usually traceable to some exceptional circumstance, such as urethral stricture, or obstruction attended with pouching or trabeculation of the bladder. Hence we may conclude that hypertrophy of the prostate and the structural complication arising out of this in conjunction with atony or imperfect powers of urine expulsion are frequent concomitants, in by far the larger proportion of stone relapses after lithotripsy. This is the view which I believe now finds general acceptance.

This explanation of course applies only to those instances of recurrence in which the calculus is mainly phosphatic and of vesical origin, in contradistinction to those in which a fresh descent from the kidney takes place, and accidental arrest and growth in the bladder secondarily ensue. Instances are occasionally met with in which the operation of crushing has been followed within a few days by an attack of renal colic. Here a diathetic stone is either spontaneously expelled in the course of normal micturition, or, being too large to get over the bar caused by an enlarged prostate, requires pulverizing with the lithotrite before its evacuation can be effected. In cases in which persons have been in the habit of passing renal calculi for years, it is frequently found when the prostatic age is reached that the ureters, no doubt much dilated by previous attacks, allow stones of considerable size to descend into the bladder, comparatively painlessly, which are subsequently trapped by the enlarged prostate. Otherwise they might, as previously, have been spontaneously voided. Recalling, however, the ordinary circumstances under which stone recurrences after lithotripsy most frequently occur, I am brought to consider, not the necessity for imposing other restrictions upon the employment of an operation by means of which so much has been achieved at so small a risk to life, but how far progressive surgery permits us to remove or mitigate complications in structural defects which

¹ "Litholapaxy," Wm. Wood & Co., New York, 1878.

tend to provide mechanical difficulties, sometimes insuperable, in the way of complete evacuation of the fragments, and subsequently furnish favorable conditions for repeating the process of stone making when once the nucleus is there.

We may therefore proceed to inquire: (1) What means have we, if any, of diminishing the enlarged prostate? (2) To what extent are they applicable to cases complicated with recurring vesical stone? (3) What alternative measures have we for litholapaxy under exceptional circumstances of this nature? If the question were put to a student under examination, What surgical measures have been followed by atrophy or shrinkage of the hypertrophied prostate? I think he would be justified in replying somewhat in this way:

It has followed cases of simple incision into the prostatic ring, as in the second stage of lateral lithotomy. It has supervened upon puncture of the bladder through the enlarged prostate with retention of the cannula for some weeks.¹

Shrinkage of the enlarged prostate has followed upon double and single castration and upon double and single vasectomy or division of the vas deferens. This answer would of course not be regarded as including cases of partial or complete removal of the prostate gland, now known under the name of prostatectomies.

The second question which necessarily arises out of the preceding statement, namely, How far are these several methods of inducing shrinkage applicable to cases of hypertrophied prostate complicated with recurring vesical stone? is not so easily or so briefly answered, and will, for the latter purpose, require some expansion.

Prostatic incision, or puncture as first referred to, apart from the limited nature of the observations of cases in which atrophy seems to have followed it, would hardly be applicable in cases otherwise suited for lithotripsy. I will, therefore, without further comment, pass on to notice the adoption of castration and vasectomy in respect to the question now under review.

Reference to these proceedings opens up a subject which, so far as it relates to the practice of surgery, is new, though from an anatomical and physiological aspect it has previously received some attention, which must not be entirely overlooked. John Hunter² appears to have experimented on animals in reference to this point, and more recently Griffiths³ has added importantly to these researches. Decimus Hodgson,⁴ of Glasgow, remarked in 1856, "in persons who have been castrated the prostate dwindles down almost to a rudimentary condition."

The inference, however, that what is true relative to the normal state of these parts also applies in varying degrees to the hypertrophied prostate does not appear to have been utilized systematically for practical purposes, until Dr. William White, of Philadelphia, drew attention to it in 1893.⁵ Since this paper appeared, the operation of castration and other proceedings arising out of the same train of thought relative to the enlarged prostate have been somewhat extensively employed, and to some of the results obtained and the considerations suggested I purpose now referring.

From the records of this operation, now covering several hundred cases, which from time to time have been drawn up by various surgeons, I do not think there can be any doubt in arriving at the conclusion that in a certain proportion of cases castration has undoubtedly been proved to have been speedily

followed by shrinkage of the prostate and abatement of the symptoms attending this condition.

Taking one of the most recent communications on the subject, of which Dr. Cabot,¹ of Boston, is the author, and which includes about one hundred well-authenticated cases in illustration, on reading it I was struck not so much with the somewhat high death rate as with the uncertainty as to the kind of result, physical as well as mental, the surgeon is likely to expect. Will the patient recover completely or imperfectly when the risk of the operation is passed, whatever this may be? is a question which naturally arises and is apparently at the present stage not very easy to answer. In the expression of opinion by Dr. Cabot that castration seems especially efficacious in cases of large tense prostates, when the obstruction is due to the pressure of the lateral lobes upon the urethra, and is of but little use in cases of myomatous and fibrous glands, he is warranted, I consider, by the records to which I have referred.

I have hitherto been addressing myself more particularly to the application of castration to prostatic hypertrophy generally. Scattered, however, through the cases which have been recorded are some few in which it has been utilized with advantage for recurrence of stone after crushing operations, when this complication was prominent. I cannot quote a case of my own in illustration, as I have not had occasion to resort to it under these circumstances, but I am acquainted with one in which it well served this purpose.

It was that of a male, seventy years of age, who after lithotripsy had stone recurrence on three occasions, at intervals of a year or so. The fourth time of relapse the urine and bladder were in so foul a state from cystitis and great enlargement of the prostate that a suprapubic cystotomy was performed, by means of which another phosphatic stone was removed and the bladder was drained for some time. The patient, however, was intolerant of all the methods that were tried with the object of keeping the wound open by various drainage appliances, and eventually it closed before the latter process was completed. This was followed by a speedy return of all the symptoms of cystitis and the commencing formation of more phosphates. To meet this condition the bladder was again cleared by means of the lithotrite and the aspirator, and double castration was performed. The relief was now complete and is, I believe, permanent, as the patient has been free of his stone and of his symptoms for nearly two years, and has no need of either his catheter or his irrigator.

It is under circumstances such as these that castration may occasionally find a place in the treatment of recurring stone complicated with enlargement of the prostate. In selecting it, however, apart from other considerations, the surgeon must be reasonably clear in his opinion that the case is not one either of encysted or pouched stone, otherwise, as castration affords no opportunity of making either a digital or ocular examination of the interior of the bladder, a suprapubic prostatectomy would, in the face of these presumed complications, be preferable.

After reading Dr. White's first paper, to which I have already referred, I took an early opportunity of raising the question as to whether somewhat similar results, so far as the enlarged prostate was concerned, could not be induced by dividing either one or both of the excretory ducts of the testicle. I based my suggestion partly on a case² in which some years previously, under somewhat exceptional circumstances, which I narrated, I had casually, though at the urgent desire of a patient, divided the vasa, with good results after a considerable interval of time. Further I drew

attention, in connection with the subject of injuries to the vas deferens, to certain cases recorded by Hilton and Birkett,¹ in which atrophy of the corresponding testis was proved to have followed the accidental division of this tube either by section or laceration. My contention was that if division of a vas brought about atrophy of the corresponding testis, it was logical to conclude that atrophy of the prostate would follow to a like extent—that is to say, the division of one vas would be followed by unilateral atrophy, first of the testis and afterward of half of the prostate—whereas, if both vasa were divided, both testes and the whole of the prostate would subsequently undergo shrinkage. I think I may claim that this has now been proved to be the case.

It must, however, be stated that one of the objections I have put forward against castration applies, as matters at present stand, with equal force to vasectomy. I refer of course to the uncertainty that exists as to what kind of results will be obtained.

In the course of a discussion that recently took place² in reference to the treatment of prostatic hypertrophy by these means, I took the opportunity of saying that from some experience of my own the results of vasectomy depended very much on attention to certain details connected with the operation, which I ventured to enumerate and which I will briefly repeat.

In the first place, I do not think it is well to operate on both vasa at the same time, as any risk connected with the proceeding is increased, and mental effects of a serious nature may follow, such as have been observed after castration. I have not met with an instance in which any ill effects resulted when a sufficient interval was allowed to elapse between the two operations. I think the interval should be not less than a month. I have seen instances in which the relief following the division of one tube was so sufficient as to render division of the opposite one unnecessary. In some of my cases I found that after one vas had been divided the prostatic symptoms subsided at once, and then, after an interval of three weeks or so, began to reappear coincidentally with some hypertrophy of the testicle of the opposite side, where the tube had not yet been divided. The second operation was then proceeded with, and it was in the group of cases in which this incident was observed that I obtained the most satisfactory results.

It must, however, be remembered, as I have endeavored to put it, that in bringing about prostatic atrophy by section of the ducts it is through the medium of a double process, or rather by the induction of an atrophy by an atrophy. Hence the effects of vasectomy upon the prostate are longer delayed and more gradual than when the testes are primarily removed. In some of my cases of double vasectomy it was observed—though in all instances the effects were properly explained to the patients beforehand—that the division of these ducts was not immediately followed by cessation of sexual desire and power, and months sometimes elapsed before these sensations finally ceased and atrophy of the testes was marked. I am not aware, however, of an instance in which these effects, though delayed, were not finally attained. Though vasectomy must be regarded as a slower process than castration, relative to prostatic changes, in this, I believe, lies its comparative safety and advantage.

In the next place a portion of the vas must be resected and not merely ligatured. Pavone,³ who has recently reported twenty-eight cases out of thirty-four in which the patients were either cured or improved after vasectomy, advises that in addition to excision the ends of the canal should be twisted, so as to insure

complete closure. The possibility of the restoration of the occluded vas when a ligature only has been used has been illustrated by Dr. Bransford Lewis.⁴ Here, on the return of prostatic symptoms, it was found that the continuity of the duct had been re-established after the ligature had come away.

The simplest way of performing the operation seems to consist in exposing the vas by a short linear incision over it, and protruding it between the finger and thumb. An aneurism needle is then slipped under the isolated duct, by means of which a loop about an inch in length is withdrawn. The latter is then included in a silk ligature, when the free portion is removed by scissors. The small wound usually heals quickly. Apart, however, from some failures arising from want of attention in operating to details such as these, there appear to be other reasons requiring consideration, and which apply with equal force both to castration and to vasectomy. I have already stated that when the prostate has passed into a fibrotic condition, or when the obstructing third lobe represents in structure a fibrous tumor, the prospects following either operation on the sexual apparatus are unpromising. Here McGill's operation is usually indicated. There are, however, other conditions of the prostate which must be taken into our reckoning.

I am inclined to believe that if the consideration and discussion of these two operations relative to prostatic hypertrophy did no more than lead us to reconsider many points connected with the pathology of this part much will have been accomplished. I have long thought that slowly progressive carcinoma of the prostate, resembling in some features the more ordinary forms of hypertrophy, is far more common than is generally believed to be the case. My attention was first called to this matter in 1886, when I recorded a case⁵ which I will briefly refer to.

It was that of a man, aged fifty-nine years, whom as a private patient I had the opportunity of watching for two years, up to the time of his death. In the first instance he suffered from some irritability of the bladder which he could not completely empty. He was losing flesh, becoming pale, and, though the mental faculties remained vigorous to the last, he constantly complained of pain in the loins, nates, and thighs. In the course of a few weeks he became entirely dependent upon the catheter. His prostate, as felt from the rectum, was hard, nodular, and almost insensitive to the touch, though it was not much enlarged, nor were any neighboring glands found to be involved. As his general health slowly declined, minute petechial spots appeared on various parts of his body, and his feebleness gradually increased. Occasionally he passed a small quantity of blood with his urine. He appeared to die of exhaustion, the result of prolonged blood vitiation. After death his prostate was examined by Mr. F. Paul, who reported it to be an unmistakable example of carcinoma. There was no evidence to show that this was other than the primary disease. I remember Mr. Paul remarking to me at the time that the precise nature of the disease would probably have been undiscovered had it not been carefully looked for, as there was apparently to the naked eye but little to distinguish the specimen from one of ordinary hypertrophy. I have since met with many instances of this kind in practice and have been able occasionally to confirm the diagnosis by pathological examination.

Clinically this group of slowly progressive carcinomata may be distinguished by the following indications: In the first place, they are generally met with in persons who are rather under what I would speak of as the prostatic age, that is to say, they chiefly occur

¹ Holmes' "System of Surgery," 1st ed., vol. ii., p. 739.

⁴ Journ. Cut. and Gen.-Urin. Diseases, New York, 1896.

⁵ Op. cit., p. 509.

in males of fifty-five years or thereabouts. When felt from the rectum the gland is found unusually hard, bossy, and rather insensitive to the touch. They seldom bleed much or ulcerate, unless damaged by a catheter or sound. Though the use of the former is generally required more or less constantly before the case terminates, there is seldom either sudden or complete retention, or even distention of the bladder. Reflected pain in various parts, such as the thighs, nates, and rectum, is often complained of, in addition to much painful irritability of the bladder. Death is usually caused by blood vitiation and exhaustion, with well-marked signs of what we used to speak of as a cachexia.

I have referred to fibrous and carcinomatous prostates for the purpose of remarking that for such growths as these neither castration nor vasectomy is at all likely to be of any avail. Together they represent a by no means uncommon condition of this part, and their treatment must be conducted on the principles which are applicable generally to growths involving the interior and neck of the bladder. In going over the recorded cases of castration and vasectomy, it is not difficult in reading between the lines to see that among them are included instances of the two conditions to which I have just referred and in which experience shows that no good was likely to accrue from what was done. These we must endeavor to exclude, and then I think we shall find that division of the vasa deferentia will be found an efficient means for curing or relieving advanced forms of prostatic hypertrophy, without incurring the additional risk, not to mention other drawbacks, which naturally attend such an operation as castration.

I must not here forget to mention that I have in three instances employed division of the vasa in recurring stone with cystitis due to much enlargement of the prostate, with great and, I believe, permanent advantage. Apart from the non-recurrence of the stone after fair intervals of trial, a general improvement in the function of micturition has been maintained, and this is in correspondence with what other surgeons have illustrated in the records to which I have referred.

It will of course be understood that the expedients I have drawn attention to as worthy of consideration are applicable only to grave varieties of prostatic disease, whether complicating vesical stone or not. When we consider how considerable a number of well-matured brains carry on long and useful lives with advantage to those belonging to them, as well as to the community at large, and who are more or less dependent upon the aid a catheter affords, it is unnecessary to say that such measures as those I have been discussing can apply in any degree only to the exceptions and not to the rules. The latter are already, I believe, adequately provided for, while in the interests of the former all proved methods, either of cure or relief, must receive, as they always have done, our careful and unbiassed consideration.

I will now pass on to offer some remarks in reference to perineal lithotomy. Among the variations that stone cases present a small proportion will be met with in which, by reason of the condition of the bladder and the urinary apparatus generally, the ordinary operation of crushing is not applicable. In these cases not only must the stone be removed but provision made for the drainage of the bladder; and for the latter purpose lithotomy in no way adequately provides.

When the stone is large, and I am speaking now of calculi between two and three ounces in weight, and the prostate and bladder are more or less involved in supuration and chronic inflammation, various substitute proceedings are adopted which have to be considered. Suprapubic cystotomy under these circumstances is

attended with a high rate of mortality. Guyon and others have estimated it in males of advanced age, who are generally the subjects of these complications, at somewhere about fifty per cent., and my own impression is that this is about the case.

Such a mortality as this takes us back to some of the worst days of lithotomy and contrasts unfavorably with other forms of suprapubic cystotomy, as, for instance, when applied to younger persons, and even with suprapubic prostatectomy, which Mr. Mayo Robson¹ has shown to be a much less risky proceeding. It is now some years ago since I had this point under careful consideration in connection with one or two cases of septicæmia after lithotomy, arising under the conditions I have just referred to.

On reviewing the various operations employed for removing stone from the bladder, other than by crushing alone, it appeared that there was much in Dolbeau's² method of perineal lithotomy to recommend it. The objections against it chiefly centred in the employment of forcible dilatation of the prostatic urethra and the neck of the bladder, and in the instruments used in crushing and evacuating the stone fragments. Further, no provision appears to have been made by Dolbeau for draining the bladder systematically, after the stone had thus been withdrawn. These objections, however, seemed to be capable of removal, and I proceeded to practise this operation from time to time, as suitable cases presented, in the following manner:

In the first place an ordinary boutonnière or median perineal cystotomy is practised on a grooved staff sufficient to admit the introduction of the finger into the bladder, as for digital exploration. This represents all the dilatation of the prostate or neck of the bladder that is attempted. The next step is to withdraw the index finger and substitute a pair of crushing forceps specially made for this purpose, though in other respects resembling an ordinary pair of lithotomy forceps, either straight or curved. These have been constructed for me by Messrs. Krohne and Sese-mann, and by Messrs. Tiemann, of New York. They are made in different sizes, the most powerful having a screw at the handle by which the full crushing power is brought into play. In circumference the combined blades correspond in size with an average index finger, and contain well within cover a strong cutting rib running down the centre of each, by which the fragmentation of the stone or stones is chiefly accomplished. By means of these forceps the stone is sufficiently reduced in size to be either easily withdrawn in fragments from the bladder by these instruments or to be sluiced out with a cannula and an ordinary wash bottle as used for litholapaxy. Straight cannulæ will be found the most convenient for this purpose.

After the stone has been withdrawn and the bladder and prostate have been carefully examined, either with the sound or with the finger, the drainage tube is introduced and retained for as long as is necessary, in accordance with the nature of the case. Here is a specimen of the hardest kind of urate stone, the fragments weighing over three ounces, which was broken up and withdrawn in this way in something like five minutes, a process which would have occupied an hour or more had it been expedient to substitute lithotomy. I also removed with my finger quite easily a grape-like third lobe which was in my way. The patient made a rapid and complete recovery. I show this specimen merely as illustrating what these forceps are capable of effecting and what may be withdrawn through a wound only sufficient in extent to admit the introduction of an index finger. I have in one or two instances tried a short lithotrite, such as Surgeon-Major Keith has described, passed into the bladder through the perineal wound,

¹ Brit. Med. Journ., April 25, 1894.

² "De la Lithotritie Périnéale," Paris, 1872.

instead of crushing forceps, but find the latter more effective and convenient for use in this position.

I have selected this method in fifteen instances out of considerably over three hundred cases of lithotripsy and have so far had no deaths or recurrences of stone following it. The chief points in its favor are these: (1) It enables the operator to crush and evacuate large stones in a short space of time. (2) It is attended with a very small risk to life as compared with other operations, such as lateral or suprapubic lithotomy, and is well adapted to old and feeble subjects when for any reason crushing is inadmissible. (3) It permits the operator to wash out the bladder and any pouches connected with it more effectually than by the urethra, as the route is shorter and the evacuating catheters employed are of much larger calibre. (4) The surgeon can usually ascertain, either by exploration with the finger or by the introduction of forceps into the bladder, that the viscus is cleared of all debris. (5) It enables the surgeon to deal with certain forms of prostatic outgrowth and obstruction complicated with atony of the bladder in such a way as to secure not only the removal of the stone but the restoration of the function of micturition. (6) By the subsequent introduction and temporary retention of a soft-rubber drainage tube states of cystitis due to the retention of urine in pouches and depressions in the bladder wall are either entirely cured or are permanently improved. To lock up unhealthy ammoniacal urine in a bladder that cannot properly empty itself after a lithotripsy is to court the formation or recurrence of a phosphatic stone. Hence it is well suited to some cases of recurrent calculus. I have never known the wound to remain unhealed except in those instances in which, for some reason or other, it has been desired to construct a low-level urethra. It is well adapted for some cases of stone in the bladder complicated with stricture in the deep urethra, as it enables the surgeon to deal with both at the same time.

In a recent paper by Mr. Herbert Milton, of Cairo,¹ I see that the operation of perineal lithotripsy figures prominently and successfully among the two hundred cases of stone he records. He has employed it, much on the same lines as I have described, in twenty-one instances with one death. Though speaking of Bigelow's operation as the more brilliant of the two, he evidently has reason to regard perineal lithotripsy, as now revived, as the more generally useful. A specimen made by Messrs. Down, of London, of the breaking forceps Mr. Milton employs is submitted for inspection. Taking Mr. Milton's twenty-one cases and fifteen of my own, we have a total of thirty-six with one death, which, considering the size of many of the stones and the complications that were present, gives, I think, a very satisfactory result and one that will compare favorably with those obtained from other operations, either crushing or cutting used in the treatment of stone. I have a growing impression that in countries where by reason of the great age that is often attained by persons suffering from stone in the bladder, and where the opportunities for practising litholapaxy are not very frequent, perineal lithotripsy will be more generally utilized.

Before leaving subjects connected with the treatment of vesical stone by crushing, I would briefly allude to a change in practice for the better, which is a direct outcome of the excellent work in the application of this operation to male children. I refer more particularly to the successful employment of litholapaxy in this direction by our distinguished fellow, Dr. Keegan, work which has been importantly supplemented by my colleague, Dr. Freyer.

Sudden retention of urine in young males is most frequently caused, as we are all aware, by the impac-

tion of a small stone in the urethra. Such an incident, apart from the extreme urgency of the symptoms thus produced, has not unfrequently led to ulceration of the urethra and serious, if not fatal, extravasation of urine into the neighboring tissues. In fact, it may be stated with hardly an exception that it is under these circumstances alone such a calamity is met with in these young subjects. In earlier days when the catheter detected that a stone was thus impacted, the practice universally was either to cut down and remove the calculus from the position it occupied in the urethra, or if possible to push it back into the bladder and then to extract it by some form of lithotomy or cutting operation. Though either proceeding was usually successful, it entailed an operation which necessarily required a period of convalescence to follow. Among some of my earliest lithotomies in male children were cases occurring under these circumstances. In illustration of the importance of this change in practice I may be permitted to mention very briefly the particulars of a recent case. It was that of a boy, aged four years, whom I saw, with urgent retention of urine due to the lodgment of a stone in the urethra just behind the scrotum. I pushed the stone back into the bladder and the retention was at once relieved. On the following morning I had the child placed under an anæsthetic and crushed the stone. As I found at the moment I had not an evacuating catheter sufficiently small to enter the bladder without more force than was desirable, I contented myself in more completely pulverizing the calculus with the lithotrite than I should otherwise have thought necessary to do. The debris was discharged in the natural course of micturition and the patient was practically well without any delay, as the urine was never even tinged with blood. Sir William Roberts was kind enough to examine the fragments of the calculus and reported that it consisted of uric acid with a coating of oxalates and weighed a little over five grains. A short time ago the patient would undoubtedly have been submitted to a cutting operation. I may incidentally mention that I reported¹ a very similar case, in which I practised lithotripsy in a male child, aged eleven years, in 1881, and I have since from time to time successfully adopted this proceeding. I believe this was one of the first recorded examples in so young a subject, a circumstance I had forgotten until recently reminded of it by my friend, Dr. Keegan, and some small lithotrites were then made for me by Messrs. Weiss.

In bringing my observations to a conclusion I shall ask your indulgence for a few moments while I engage in some speculations in contradistinction to the subject matter I have hitherto ventured to bring under your notice, in the belief that it has been sufficiently demonstrated to warrant me in doing so. I refer to the application of the Roentgen or x-rays to this branch of surgery. I feel that I am justified in doing so, partly for the reason that if these anticipations eventually fail to be realized, they may still possibly serve to indicate in what directions assistance from collateral science is required and may be expected, and partly because Sir Joseph Lister, the distinguished president of the British Association, in his recent address in Liverpool, emphasized the belief that in the near future surgery had much to gain by this method of investigation. As to the truth of the latter statement there can be no doubt.

To what extent this means may be utilized in matters which have occupied a considerable portion of this lecture has yet to be demonstrated. In its application to the diagnosis of calculus situated within any portion of the male or female urinary apparatus from the kidney downward, I am not aware that it has been sufficiently successful in indicating either the form or

¹ Lancet, April and May, 1896.

¹ "Surgical Disorders of the Urinary Organs," 4th ed.

the position of the stone. From some experiments made chiefly outside the human body (I refer to such as those of M. D'Arsonval,¹ in Paris, and of Mr. Henry Morris² and others) it is quite possible by the shadows thus cast to distinguish various kinds of calculi. At present I do not think more than this can be said or has been sufficiently demonstrated. Though I have had several patients skiagraphed, I have not yet succeeded in obtaining results which were of help to me in making a diagnosis independently of such means as we are in the habit of using.

In thus referring to this method of investigation it is with the hope that in its further development and application it will among other aids enable us to dispense with the use of the sound as a means of diagnosing stone in the bladder. I cannot call to mind an instance in the child, woman, or young male adult, extending up to what I could call middle age, who was ever seriously damaged by the judicious use of this instrument, but in males of a more advanced age, in whom the prostate was large and access to the interior of the bladder by means of a rigid instrument by no means easy, we have seen, when a stone had been discovered as well as when one had not, serious and even fatal consequences ensue. A cystitis, for instance, has thus been aroused, with considerable general disturbance which has sometimes taken a long time to overcome, not to say anything of being the means of postponing a necessary operation indefinitely, by reason of the acute septic conditions under which it would otherwise have been undertaken.

Nor is this all. How few surgeons, in whatever degree they may be engaged in work of this kind, can feel that the skilful employment of the steel sound is an absolute guarantee against the possibility of a stone escaping their vigilance. When we look at the shape the diseased bladder and prostate often assume, it is astonishing to me that this somewhat primitive mode of examination so rarely fails us. But it is in just this particular class of cases that we rely upon it most, and as to which our disappointment is the keenest if it falls short of our expectation, whatever the explanation may be.

Under these circumstances I have for some time past been in the habit of including under one process, with great advantage, the administration of an anæsthetic, the use of the sound for the first exploration of the bladder, and the immediate removal of the stone, by crushing if practicable, if one is discovered. Just as in earlier years a preliminary paracentesis of an ovarian tumor was often found to be an unfavorable antecedent to an ovariectomy, so may the passing and use of a sound be a preface, which we would avoid, to the subsequent removal of the stone, however this may be effected. No more desirable object can be wished for in connection with the practical use of these rays than their application in determining the presence, position, and constitution of the various stony concretions that have their habitat in the human urinary organs.

I have every confidence in expressing the belief that the time is not far distant when, under the circumstances I have mentioned, these Roentgen rays will enable us to see the stone instead of feeling it, just as in a recorded case³ in which a Murphy's button, lost in a remote corner of the intestines, was found in this way by my old friend and colleague, Mr. Mitchell Banks.

Infantile Colic.—Tincture of lobelia, one drop in an ounce of water. Dose, one-half teaspoonful warmed. —*Cal. Med. Journal*.

CLEANSING AND CLEANLINESS IN ABDOMINAL SURGEONS' OPERATIONS.

By LAWSON TAIT, M.D. NEO EBOR. HONORIS CAUSA, M.D. ST. LOUIS, LL.D. ALBANY, ETC.

A FEW days ago I read the detailed description of an operation for the removal of a bullet lodged in the brain, the operation being done by one of our best-known European surgeons and a pronounced follower of the school of Lister. He first removed the dressing and exposed the scalp, which looked like a huge billiard ball, excepting for one ominous black spot where the bullet had bored its unkindly way. Then he took a scalpel which was dripping with antiseptic, a precaution which had not been taken with the foregoing bullet, and deftly incised the scalp. Almost all the time an assistant allowed a fine stream of warm water—sterilized by being boiled and allowed to cool to a safe temperature—to play from an irrigator upon the field of the operation. Then instrument after instrument was used, all evidently the subject of fear, for they all dripped with antiseptic, though the track of the wound and the locus of the infected bullet were left to the prey of the germs which had been carried there, and had been working about for forty-eight hours before the operation. The operator had not read Mr. Leedham Greive's interesting papers on how difficult if not impossible it is to sterilize the hands of the operator, for he consistently made no attempt in the direction, and yet he closed the wound with a parcel of cotton wool feebly impregnated with corrosive sublimate. He then addressed his surroundings on the marvellous results obtained in modern times by antiseptic surgery. In the museum of the Royal College of Surgeons is a large iron bar, technically known as a jumper, which went, under the influence of a charge of gunpowder, from below the chin of the user and straight upward through the head and out at the vertex, carrying into the wound a lot of germs and leaving them there. No sterilized water was used about the superficial wound, and no corrosive sublimate was then employed, about the end of last century; yet the patient got well and remained so for years. The museums of this country and of others literally swarm with ancient specimens, which prove the receipt of serious cerebral injury with complete and permanent recovery, so that the belief, now seemingly established in the minds of surgeons for the present moment, that a stream of sterilized water and a few grains of corrosive sublimate in the superficial dressings give any greater security for recovery, has no foundation in fact and is a mere temporary mental aberration.

Some few months ago I read a paper by the same surgeon as I have already quoted, on the subject of the influence of germs; and, in the short space of a column and a half of an ordinary medical journal he used in thirteen instances such phrases as: "It is now fully established," "It is beyond dispute," "It must be universally acknowledged," "Smith has proved," "Jones' remarkable observations have established," and "A complete result of Robinson's original researches we must believe;" though in not a single instance would I, for one, admit anything of any one of the single assertions. It happens that those indicated as Smith, Jones, and Robinson are three frequent contributors of papers on the application of the ever-advancing, ever-developing, ever-changing, and never-ending conclusions of the bacteriologists to the practical work of the surgeon; and such men, always anxious for second-hand novelties, forget in one week what they said the week before. In their writings it is an easy matter to picture in detail the extraordinary phases of the evolution of the practice and principle of Listerism, though it is only fair to say that I use Lister's name here with this qualification, that he,

¹ Bull. de l'Acad. de Méd., Paris, June 2, 1896.

² Lancet, November 14, 1896.

³ Brit. Med. Journ., October 24, 1896.

while the originator and still the chief advocate of the doctrines so various and so varying, is not responsible for more than about half the nonsense which has grown round the original antiseptic religion. There have been a large number of surgical "Pauls," who have freely disseminated perplexing epistles to the various surgical churches of the world, and thereby much and very acrimonious differences have arisen.

The antiseptic generation has now sped its cycle from 1866 to 1896, and we have come back to the figure of the clock at which we started. The time exactly embraces my own surgical life. In Glasgow and Edinburgh I saw patients die of the same terrible infliction, no matter what had happened to them. I saw removal of breasts end with a fatality which seemed to rival that of amputation at the middle of the thigh, and yet in my own practice during the cycle, out of many hundreds of cases of removal of breasts—how many I could not venture to guess—I think it pretty certain that the mortality has been a long way under five per cent., and probably not been one per cent. In fact, I can call to mind only two fatal cases. The crowded wards, the deficient ventilation, the one saluting-dish and the one sponge in each ward, the want of ordinary lavatory cleanliness were the causes of the terrible results. The carbolic oil, the putty, and the lac plaster may have had some countervailing influence under the circumstances of these horrible old pest houses, but in practice outside such influences they were useless. These details, together with others which ended finally in the harmonious logic of the spray, marked the first epoch of the antiseptic cycle, a time during which it was devoutly believed that every germ was potent for evil and every resting spore was a surgical pest. Every germ, every spore, every scrap of harmless dust must, therefore, be submitted to a process of destruction by some potent chemical agent. This chemical agent was constantly changed. As soon as one was contrived, adopted, beloved, and trusted, it was found by some new observers to be wanting when weighed in the clinical balance. The chemical manufacturers were nearly wild, and many of them were ruined by the continual changes, and the antiseptic market rate for years was something more variable than that of African gold shares.

When the spray was introduced, I was led, by circumstances altogether outside my own conviction, to range myself once more as a follower of the chemical antiseptic school, though I did not for a moment forget or neglect my old methods. I performed a hundred consecutive ovariectomies with a full and complete adoption of all the antiseptic precautions of the Listerian school of the period, and I published a paper in the Transactions of the Royal Medical and Chirurgical Society, contrasting the details of that series with those of a consecutive hundred in immediate opposition to them (and the contrast was not in favor of the antiseptic practice).

By this time I had become thoroughly persuaded as to the future progress of the antiseptic doctrines and practice, and I expressed my prophecy in what I called an experiment, though it was more of the nature of a satire.

I went through all the ceremonious observances with gradually diluted solutions, until I used nothing but boiled water, and then that was dispensed with. Finally, I used only ordinary tap water, and then I gave up the spray. This is precisely what has happened all round. The poisonous solutions were weakened bit by bit: the spray was abandoned, with an expression of shame that it had ever been introduced; rigorous hunting for germs was slackened, and the antiseptic belief so modified, that it was at last accepted that not every germ was hurtful, but only such as might yet be identified.

But, on the other side, we found the cubic space allowed to each patient rapidly increased; new hospitals were built, and, above all, the segregation of surgical patients was enormously advanced by the erection of cottage hospitals all over the country. For my own part, between 1878 and 1880, I secured an accommodation of about forty beds, for the occupants of which had each a separate room; in fact, practically they may be said to have all had separate rooms. The effect was at once apparent, for my mortality went down from about thirty per cent. to less than five; and I had long runs of fifty, sixty, eighty, and once as far as one hundred and forty-six consecutive operations, without a death. Even hysterectomy, the most obstinate of all abdominal operations in yielding satisfactory results, has, within the last ten years, given me runs of thirty, forty, and even forty-five consecutive successes. What are the explanations of all this? The answer is, that though I cannot produce anything from which I can "absolutely prove" or "make it apparent beyond doubt," or anything of the cocksure order, yet I can give basic conclusions which will be with difficulty upset; and those who neglect them will have to bear serious responsibility in the criticism of the future.

The first conclusion at which I arrived concerning abdominal operations was, and it remains the strongest now, that the more the patients submitted to them are separated the better. For this purpose and for the greater part of my practice I adopted, as I have said, a room for each patient. Sometimes with a press of work I was tempted to "pack," as we used to call it—that is, put two patients in one room, after the first six or seven days; but I had so frequently to regret this that I ultimately abandoned it.

I am quite sure that there is much truth in one conclusion I have often advanced, that time has much to do with what will happen in the septic infection of an abdominal section. The fourth night is the critical night with all save hysterectomies, and with them that period is not to be so definitely fixed. If an ovariectomy is all right on the fifth morning, the chances of the patient going wrong are small indeed. But if you "pack" them, they will have hamatocetes, stitch abscesses, pulmonary complications, mumps, and all sorts of secondary troubles, in a proportion far greater than if you keep them absolutely one in each room. These complications do not affect the mortality much, but they prolong the convalescence in a fashion of the most annoying kind. This has been still more impressed on me during the last three years, in which I have far more widely adopted the plan of operating in the houses of the patients, and leaving the subsequent treatment of them to their private medical attendants. This is now possible, seeing that I sedulously avoid anything in the shape of gratuitous work, whereas for more than twenty years I did not get payment of any kind for more than one-fourth of my clientèle, and not more than costs out of pocket for one-tenth of them. I am now, therefore, working solely in a class among whom it is possible to have all that is requisite in the way of accommodation in the houses of the patients, and after the operation is over I am seldom required to see the patients again, recoveries are so little interrupted. All this experience points out to me the extreme importance of segregation, and the uniform results of the work at the Sparkhill Hospital, not in the hands of one man but in the hands of all to whom it has been intrusted, prove this, as far as proof in surgery can go: for there segregation is carried out almost as completely as it can be carried out in the best houses, while the perfection of the sanitary arrangements provided by the committee of management is almost absurd in its completeness of detail.

All this, and the necessity for it, were enforced on

my mind coincident with the complete banishment of any fear of germs, either wholesale or individual, though there still remained with me the wholesome dread of certain specific poisons, the nature of which I do not know—and I think I may safely say that their nature is equally unknown to everybody else. First of all of these, as deadly beyond all things known to me, is the poison begot in the peritoneum and uterus of the puerperal woman, and in some subjects who have died after abdominal sections.

This brings me to speak of the third phase of the slowly developing Listerism or antiseptic doctrines of surgery, when it had begun to call itself "aseptic," and to adopt some of the minor doctrines and practices which I have been preaching and practising since 1881. All that I have been saying up to now leads me to that condition which, after segregation, constitutes my second general condition essential for success in abdominal surgery, and going a long way to explain our modern success—I mean cleanliness.

Cleanliness in surgery may be divided into general and specific. General cleanliness, such as close attention to cleaning wards and all in them, the cleanliness of all linen bedclothing, etc., and the personal cleanliness of the surgeon and the members of his staff, are matters I need not waste time over. The details of specific cleanliness are matters much more in need of discussion.

For a long time in the earlier part of my practice, I allowed all properly introduced and qualified practitioners to visit it, and they came in great numbers, chiefly from America. But I soon had to stop this kind of hospitality and to limit admission to such as came as serious-minded students, prepared to see and understand what they saw. The reason for this was simple. The "globe-trotter" came and saw one or two operations, and departed without understanding anything he had seen; and, if he published, he perversely misrepresented the facts. To this misrepresentation are due two misstatements, which even now appear at intervals in the medical journals of the continent and America. The first is that I really am a devoted disciple of the chemical-germ-destroyer school, but that I have some substance in use which I will not disclose. The second is that my secret is "water sterilized by boiling;" and this ridiculous blunder recurred only a few months ago at one of the great congresses of America, and, strange to say, from the mouth of one of my old pupils, Dr. Ricketts, of Cincinnati, who spent six months with me.

It is now fourteen years since I have used sterilized water for any purpose save to raise common tap water to the temperature required, so that the mixture would be probably five parts common tap or well water, and one part water which had been boiled and possibly sterilized. The mixture would have a temperature of about 102° F., for my hands will not stand much more with comfort. I have yet to learn that such a mixture deserves the term of "sterilized."

My attention to specific cleanliness is as close as can be given. It may be divided between the instruments and hands of the operator and the abdomen of the patient.

I hail with great satisfaction all the wonderful inventions and devices of the modern operating-theatre for securing general cleanliness, for that cleanliness can be secured only by the work of women, and women in themselves have not the slightest idea of cleanliness save on the surface, and unless they belong to the really well-educated classes. This is a fact which no one knows so well as he who has gone through the filthy drudgery of a gynecological outpatient department, where fifteen out of sixteen of the patients have lice or fleas upon them, and often both. This is the material from which the great bulk of the

so-called trained nurses are obtained, and with their training, unless most especially well looked after, they alter their habits only in the sense of the smart cap and an attractive uniform. They remain as dirty as ever, and it is therefore necessary to give them shelves and boxes of plate glass.

All instruments with sliding tubes, screw, or Clendon joints ought to be abandoned; every joint should be capable of being unshipped, and after every operation every instrument used should be scrubbed with raw turpentine and a brush, and then well washed with soap and water. If this is done, simple immersion in cold tap water at the next operation is all that is wanted. Sponges—ah! they want a paper to themselves. They are and ought to be the terror of the operating surgeons, and I cannot stay now to say what I have to say about them, save that new sponges are bad, old sponges dangerous, and that none of them should ever be boiled. The Americans will have it that I boil my sponges; but I never did such a thing but once, and that ruined the lot.

Now I come to the real subject matter of my paper—the cleanliness or cleansing of the patients.

I see that a number of superstitious observances on this subject are still recommended, such as the application of an antiseptic pad to the abdominal wall for twenty-four hours before the operation.

I have never employed any such plans, being quite content with a soap-and-water washing of the skin to remove the dead fat and epithelium with which women are always coated, and generally thickly. If there were any real poison in the skin, no antiseptic pad would remove it in twenty-four hours. The real poisons known to me as absolute realities, such as those which I have spoken of as occurring in puerperal peritonitis, cannot be removed by any known germicide from the hands of the surgeon infected by them. Mr. Leedham Greives' experiments seem to show that it is impossible to cleanse the hands from the ordinary spores of decomposition, and yet we know that nowhere is epithelium reproduced and shed at so rapid a rate as it is on the hand. My knowledge of the terribly infective power of the puerperal poison, from my own experience and that of others, has been so emphatic and the lessons so disastrous, that I am persuaded that the poison, whatever it be, permeates at least the whole epithelial layer and cannot be got rid of save by efflux of time and skin, and that it is not safe for any one so infected to operate till at least a fortnight or three weeks have elapsed. Have there not been lessons enough in the same direction by the spread of puerperal fever from the hands of the accoucheur?

I am not alarmed by the conclusion to which Mr. Leedham Greives' observations point, for I do not fear the ordinary germ poison at all. But still, I take the precaution of keeping my nails short and clean, and washing my hands in raw turpentine the last thing before performing any operation, and then washing off the turpentine by ordinary soap and water. My reason for this may be seen in the simple experiment of washing the hands three or four times in the ordinary way, and then in perfectly fresh water repeating the process with the previous employment of turpentine. After this last water has stood for a few minutes, there will be seen on its surface evidence of dirt of a very convincing kind. That dirt must be either in the clear turpentine or it must be a layer of dirt removed from the hands by the turpentine, after having resisted the previous efforts with soap only. The latter conclusion is that accepted by me, and it accounts for my using turpentine on the patient's skin and my own, as well as on the hands of my assistant, in the rare cases in which I need one.

The final cleansing, and I think by far the most im-

portant of the lot, is the cleansing of the abdominal cavity during and after operations.

All the other details of every operation performed by me are conducted, as I have said, by the use of plain cold water, taken immediately from the tap or well and raised when necessary to the desired temperature by the addition of the water from the kettle or boiler; nothing whatever is added to that water for instruments or sponges.

A careful search through the records of abdominal operations, particularly those for the removal of ovarian and other tumors, has not revealed any but the slightest and most casual allusions to any cleansing process, till we come to the work of Charles Clay and Baker Browne, who freely mopped out the pelvic cavity with sponges through their large incisions. One of the most interesting recitals, for many reasons, is that of the first ovariectomy of which we have any record, that by Houston, of Glasgow, when he removed the glairy contents and cystic fragments of a ruptured and half-digested tumor with gelatinous contents. He makes no allusion of any kind to a process of cleansing, and yet it is certain that the contents of this ruptured cyst must have spread themselves throughout the peritoneal cavity and have coated every viscus contained within it, as I have seen on many occasions. In my earlier experience I thought such a case was that of all others which required a full peritoneal toilette, and it was to one such in the year 1875 that I owed the initiation of the process of washing as largely a substitute for, and certainly a great addition to, the process of sponging. Now I am quite sure that this is not the case, and for the reason that the gelatinous cyst contents are not dead material, but endowed with just that degree of vitality as to be able to resist the germs of decomposition unless overdosed with them, just as Lister's blood clot did. In a properly aseptic operation, therefore, as Houston's must have been, the peritoneum will absorb what is left with perfect safety, and here it is that sponging is most especially dangerous and washing particularly safe. The moment a sponge touches such material, the surface of its framework is clogged and it will not absorb, while the gluey material is readily soluble in warm water. In the same way, coagulated blood is not dead so long as it is safely locked up in living tissue and protected by it from the access of the germs of decomposition, when it speedily dies, decomposes, and becomes a source of danger. Clot adherent in layers becomes slowly organized, and after a period of weeks or months comes to have a system of full nutrition, progressing in this direction till removed or so altered as to be recognized with difficulty from original tissue. This is fully proved by the history of clot layers in cases of recurrent hemorrhage in ruptured ectopic pregnancies, and in the process of cure of aneurism by arrest of the current through the sac. Bearing the fact in mind, therefore, that the displaced substances we have to deal with in cleansing the abdomen have different degrees of vitality, and therefore different degrees of resisting power, it will help us much in deciding not only how much cleansing is required, but as to the particular method in which the process should be carried out. These, at least, are the principles on which I have worked for over twenty years, and there has not yet been heard any utterance of weight against the almost uniformly admitted fact that my methods of cleansing have not only materially assisted the surgeon in his work, but that they have greatly diminished its mortality.

My early publications on this subject were met with claims for priority by others, as by Keith, who did not, however, advance any evidence on the subject, nor did others. But it would not matter if it were the fact, as it very likely is, that some one else or many others

had poured out a jug of water into the peritoneal cavity before 1875; but certainly no one made any attempt to systematize the processes of peritoneal cleansing until I did so, or to show how best it could be done and which methods to choose under particular circumstances. All this I reviewed in a paper published in the *British Gynecological Journal* in August, 1887, and therefore I need not repeat it here.

First of all, let me say that if an operation, such as the removal of an ovarian tumor, has been conducted so well and so fortunately that nothing has entered the peritoneal cavity, the wound ought to be closed at once without sponge or anything else entering it. If, on the contrary, a mess has been made inside, it must be cleansed out; and the question is to decide on the best method, and the weight of argument should always be against the use of sponges—they are so inherently dangerous, yet their use is often essential. Thus, in separating adhesions of the omentum to a tumor, nothing displays the ability and dexterity of a surgeon so much as the rapid folding up of a dry sponge in the damaged apron. Or, if the adhesion of the appendages to the pelvic wall bleed freely, the pelvis must be packed, and the packing will probably remove much dirt with it. Until two years ago, I always used sponges for this purpose, and would often have six or eight sponges squeezed tight down in the pelvis. Now, I use iodoform gauze for this purpose. Who it was who led us into this important advance, I do not know; but it is one of real value, for iodoform gauze stops oozing from parietal and visceral surfaces in a way that nothing else will do, save perchloride of iron. If, however, a ligature has cut through a rotten parietal, or a vessel has escaped the forceps and ligature and cannot be found, these washings out with a stream of clean water will speedily display the source of the bleeding and enable the vessel to be secured. I do not combine the two processes if I can help it, for they do not generally aid one another.

As I take it that pus is a substance already dead and generally decomposing—as Miller very characteristically defined it from his common-sense surgical pathology, "effete matter, a foreign body"—I take the utmost care to cleanse it all away, or anything which from my view more or less imitates it, such as loose blood clot and blood in solution. The method to be employed in this case is the continuous stream. The handiest method to serve this purpose is simply to reverse a stream of common tepid water through one of my ovariectomy trocars, and I use a large or small one according to whether I wish to dislodge and wash out loose clots by means of a large volume of water issuing from a large tube; or, on the other hand, if I want to wash carefully every inch of the peritoneal surface, I use a small tube with a gently flowing stream. If the tubes are not handy—and in our worst emergencies, like ruptured pregnancy, they may not be—a very efficient substitute is to open the wound as widely as possible, pull up the parietals, and to pour in with cautious violence one or more jugfuls of tepid water, insert the right hand into the abdomen, and with the left close the wound round the wrist as closely as possible. The process of washing may then be carried out as fully as is considered desirable.

If a tube of my kind can be obtained, it is better to use it, for it can be carried into every one of the complex interstices of the peritoneum, and the washing be thereby made most thoroughly. But let me caution the inexperienced operator against using a double tube for entrance and exit, as has recently been recommended in *The Lancet*. This is no new proposal, and when such is used the stream does not get spread but returns at once, short-circuited, as the electricians say, and without doing much cleansing. Care must be used to have the temperature of the water streams not

lower than 100° F., and not higher than 103° F., and it must be borne in mind that few women, and none whatever of the nurse type, have any sense of temperature in their hands. To them, "blood heat" may be anything between 75° and 120° F.

The further or secondary cleansing of the peritoneum is secured by the use of the drainage tube, to be considered at length in another chapter. So far as I have gone I have laid down the lines on which have been developed the wholesome and aseptic surgery of the peritoneum, a system which I have been advocating for over twenty years, for which persistence my reward is now coming, in seeing that it is being accepted all over the world, and my former opponents of the antiseptic school are finding shelter under its roof from their former extravagances.

A FURTHER STUDY OF THE BIOLOGY OF THE GONOCOCCUS (NEISSER), WITH CONTRIBUTIONS TO THE TECHNIQUE: A PAPER BASED ON THE MORPHOLOGICAL AND BIOLOGICAL EXAMINATION OF EXUDATES IN CASES OF CHRONIC URETHRITIS.*

By HENRY HEIMAN, M.D.,

NEW YORK,

ATTENDING PHYSICIAN TO THE OUTDOOR CHILDREN DEPARTMENT OF MOUNT SINAI HOSPITAL.

In studying the biology of the gonococcus in the experiments noted in my first paper,¹ entitled "A Clinical and Bacteriological Study of the Gonococcus (Neisser)," etc., New York MEDICAL RECORD, June 22, 1895, I employed for the gonococcus cultivations chest serum plus agar,[†] believing this to be the best medium. At that time I stated that a sterilized platinum loop was passed into the urethra and some secretion withdrawn. This method was tedious and troublesome, inasmuch as either the infected subject had to be brought to a laboratory or else the culture medium had to be brought to the patient. A second difficulty encountered was that the quantity of pus withdrawn by means of the sterilized loop was scanty. In order to obviate these disadvantages, I decided to employ for the collection of the secretion tubes available for the centrifuge. It is important to state at the outset that in no case did I first cleanse the genitals. The patient was instructed to pass his urine into a sterilized tube. This was then placed in a centrifuge,[‡] where it was whirled for three minutes. On decanting the resulting supernatant fluid, it was found that a com-

plete sedimentation of the pus was obtained, a layer from one-half to one centimetre in height resulting. This sediment was then planted by means of a sterilized platinum loop on chest-serum agar plates (Petri's), as a surface culture. In this manner I was enabled to procure an almost pure culture of the gonococcus. This method I employed in twenty-two cases of acute gonorrhœa in the male, obtaining positive results in all. One of these cases, it is interesting to note, was that of a boy two years old. Cover-glass examinations and cultures in this particular case gave positive results. The "centrifuged" sediment, if I may be permitted to coin a new word, was found to be acid in reaction, while the pus which was obtained by means of the platinum loop from the urethra was found to be neutral or else alkaline. In this connection I would like to cite eight cases of colpitis gonorrhœica of children, from each of whom, without cleansing the genitals, some vaginal pus was placed by means of a platinum loop into the tube accompanying the centrifuge. This tube was then placed in a test tube containing some sterilized water. This procedure was adopted to prevent the pus from drying, a difficulty always encountered when swabs were used. Preserved in this manner, it will be found that even in twenty-four hours at room temperature, a

positive result can be obtained in cultivating the gonococcus on chest-serum agar plates. For the purpose of ascertaining how the "centrifuged" sediment of the urine of acute gonorrhœal urethritis in the male behaved when planted on media unfavorable to the growth of the gonococcus, I planted some of this sediment on gelatin and some on agar plates, and for control purposes on chest-serum agar plates. The result was as follows: Nutrient agar plates, kept at body temperature, showed a considerable growth of bacteria, especially a diplococcus, which did not thrive so well on chest-serum agar plates, while on the gelatin plates the growth was still less than on agar plates.

Media Employed for the Cultivation of the Gonococcus.—Of the various media employed in my experiments, I found that the gonococcus would not grow when planted on the coagulated (by heat) chest serum. I also found that when I employed a culture medium composed of one part of non-sterilized chest serum and two parts of a two-per-cent. prepared nutrient agar, which had been previously boiled, filtered, and sterilized for one-half hour on two consecutive days in a steam sterilizer, and which medium, while still hot, was poured directly on plates for streak cultures, gonococci did not grow. I then attempted to plant the gonococcus according to the method employed by Pfeiffer² in the case of the influenza bacillus. That is, a drop of blood is taken from the finger and smeared on the surface of a nutrient-agar tube. Upon such a smear a pure culture of the gonococcus was planted, with positive results. For further control purposes I transplanted this gonococcus from this same smear on a chest-serum agar* plate after the third day, and obtained typical colonies. Another series of my experiments was based on the method described by Hammer,³ of Heidelberg. The medium employed by him consisted of one part of sterilized urine, containing 1.5 per cent. of albumin plus two parts of nutrient or glycerin agar. This medium, Hammer

* This paper was based on experiments conducted in the bacterial laboratory, department of pathology of the College of Physicians and Surgeons, Columbia University, New York.

† This culture medium consists of a 2 per cent. agar plus 1 per cent. of peptone plus 0.5 per cent. of salt. Of this mixture two parts were added to one part of chest serum (pleuritic effusion) fractionally sterilized between 65° C. and 70° C. Chest serum of neutral reaction is desirable. In case the chest serum should be strongly alkaline, it is desirable to treat the 2 per cent. nutrient agar in such a manner that it will remain slightly acid, so that on the addition of the alkaline serum the medium will give a neutral reaction.

‡ The centrifuge employed in my experiments is my own modification of the Litten apparatus. The improvement consists in the employment of eight Edison Lalande cells with a special motor devised by the Edison Manufacturing Company. This improved centrifuge gives a speed of 1,500 revolutions per minute and is so constructed that the hematocrit (Richards & Co.) can be attached so as to give the required 6,000 revolutions per minute. The battery operating this improved centrifuge can be advantageously employed as a galvano-cautery, and can also furnish an incandescent light of six-candle power. This centrifuge possesses the further advantage that the street wire can be tapped, by interposing a rheostat. This combination centrifuge can be purchased from the Edison Manufacturing Company, 110 East Twenty-third Street. The accompanying print demonstrates the motor and tube carrier of the apparatus; the semilunar-shaped tubes are employed to reduce the weight of the disc.

* To Drs. Alex. Lambert, James Ewing, and F. S. Mandelbaum I am indebted for the chest serum.

claims, gave him good results. His method is theoretically correct, because urine containing albumin in large quantities contains also a large proportion of serum albumin, paraglobulin, albumose, and peptones. I am of the opinion that liquid albumin or its allied products are essential for the successful cultivation of the gonococcus. I followed Hammer's technique in all its details, except that I employed urine containing one per cent. of albumin by Eschbach's test tube, and for control purposes gonorrhœal pus was planted on chest-serum agar plates. My experiments showed a comparatively small growth of gonococci on albuminous urine plus glycerin agar, but an abundant growth on chest-serum agar plates; while, on planting the pure cultures on tubes containing albuminous urine plus glycerin agar, I also obtained a relatively small growth of the gonococcus. It is worth noticing that Hammer does not mention the degree of reaction of his medium. The albuminous urine in my experiments was neutralized by adding 1 c.c. of a solution of sodium hydrate to 100 c.c. of urine. My experiments, in common with those of Hammer, gave negative results on the acid albuminous urine plus agar. Another medium was then tried, viz., a sterilized liquid hydrocele fluid plus two per cent. of nutrient agar for the planting of gonorrhœal pus from the male urethra, and for control purposes chest-serum agar, with the following result: Hydrocele fluid plus agar gave nearly as good a result as the chest-serum on the plate and test-tube cultures. I then tried still another medium, prepared as follows: 500 grams of finely chopped meat were mixed with 1,000 c.c. of water; this mixture was placed for twenty-four hours in a refrigerator and then strained through cheesecloth. The resulting meat infusion was acid, reacting 0.42 per cent. to phenol-phthalein. Some was made neutral, and to a portion of this latter was added 0.5 per cent. of sodium chloride. A portion of this neutral meat infusion was then treated by the addition of 1 per cent. of peptone and 0.5 per cent. of sodium chloride. These media were placed in a refrigerator for twenty-four hours, then filled into test tubes for fractional sterilization at low temperatures, the low temperature being applied to retain the albuminous matter in solution. After the first sterilization at 65° C. for one hour, I noticed a considerable amount of coagulated material, consisting of, as was afterward ascertained, muscle proteids. This latter, according to Halliburton, is composed of musculin, coagulable at 47° C.; myoglobulin, coagulable at 63° C.; myoalbumose, a substance obtained from the coagulum and itself not coagulable.

A second precipitation followed the further sterilization of the meat infusion. At the completion of the sterilization, I utilized the liquid portion with one or two per cent. of nutrient agar, in the proportion of one to three. Planting gonorrhœal pus on Petri plates containing this last-described medium, a negative result followed. This failure might be attributed to the small amount of albumin contained in the meat infusion, as compared with the greater amount of albumin present in the various kinds of serum which are in use for the cultivation of the gonococcus. For example, according to Hammersten,⁴ blood serum contains 8.2 per cent. of solids, of which 6.9 per cent. is albuminous. The rest of the plasma ingredients amounts to 1.3 per cent., of which 0.84 per cent. consists of inorganic substances. He also states that the albuminous ingredients of animal-blood serum consist mainly of globulin and a small proportion of serum albumin. Pure serum albumin, he states, coagulates at 50° C., but in combination with salt solution at between 72° and 75° C. It is a well-known clinical observation that with the increase of the pleuritic effusion the sodium chloride in urine gradually diminishes. This

accounts for the fact that the pleuritic effusion becomes rich in sodium chloride. My experience has been that chest serum (pleuritic effusion) gelatinizes at 75° C. and coagulates at between 80° and 82° C. I found the reaction of sheep and chest serum neutral. The yellow color of blood serum is attributed to the presence of a soluble coloring matter, termed lipochrom (Hammersten), which precipitates in the presence of amyl alcohol. Hammersten also found soaps—lecithin-cholesterin, glucose-sodium-chloride—in predominance in blood serum. Bunge (Neumeister) furnishes the following table of an analysis of horse, cattle, and pig serum: Potassium, 0.026; sodium, 0.435; calcium, 0.013; magnesium, 0.004; chlorides, 0.369; phosphoric acid, 0.022. Total, 0.869 and sodium chloride in solution.

The medium to which I gave preference is sterilized liquid chest serum—1 part (pleuritic effusion) plus 2 per cent. of agar plus 1 per cent. of peptone plus 0.5 per cent. of salt, 2 parts. This is readily obtainable, and upon it the gonococcus grows, according to my experiments, better than on any other medium. My first experiments with chest-serum sterilizations were faulty, as many of my plates became contaminated. I attributed this to the fact that sterilization for one hour at 65° C. for six consecutive days, and then placing the serum in the incubator for control for forty-eight hours, are not sufficient to render the serum entirely sterile. I therefore continued the fractional sterilization for three days longer at 65° C., after having kept the serum at room temperature for three days.

Liquid Media Employed for Gonococcus Cultivation.—It is a well-known fact that up to the present time no liquid medium has been found in which the gonococcus thrives. Bearing this point in mind, I endeavored to find a liquid medium adapted to this purpose. After much experimentation, my efforts were rewarded in finding three media which gave positive results, namely: Liquid chest serum, sterilized at 65° C., plus fermentation broth;* secondly, sterilized liquid chest serum plus Dunham's peptone solution; thirdly, sterilized liquid chest serum plus nutrient broth. That is to say, on planting the gonococcus on fluid chest serum, on fermentation broth, on Dunham's peptone solution, or on nutrient broth alone, it does not thrive; but on adding an equal part of chest serum to any of the other media we get positive results. Knowing that the gonococcus thrives upon sterilized liquid chest serum plus one or two per cent. of nutrient agar, and believing that the agar does not furnish the principal nutriment, I utilized the three above-described media in equal parts, and carefully mixed them to avoid further sterilization. Upon these media I then planted a second generation of a pure culture of the gonococcus from a chest-serum agar tube, placing the liquid media at body temperature. Examining the liquid chest-serum plus fermentation-broth tube twenty-five days later, I found a few gonococci in cover glass preparations. At the same time I planted a portion of the above liquid medium for control purposes on chest-serum agar plates, and obtained a pure culture of the gonococcus. On repeating the experiments on the twenty-ninth day, I found no gonococci on cover-glass preparations, but obtained a pure culture on chest-serum agar plates. On the fifty-first day I was still able to grow the gonococcus contained in the liquid medium on chest-serum agar plates. How

* Theobald Smith, in "Wilder Quarter-Century Book," 1893: "The bouillon was prepared by digesting fresh beef in water at 60° C. for several hours, then filtering and adding 0.25 per cent. of peptone, 0.5 per cent. of sodium chloride, and about 3 c.c. of a normal solution of sodium carbonate for every 100 c.c. of the fluid. This suffices to make it feebly alkaline. To this peptone bouillon 2 per cent. of one or the other of the three sugars mentioned was added and the resulting fluid sterilized in the fermentation tubes."

much longer the gonococcus would retain its vitality in the liquid chest serum plus fermentation broth, I am unprepared to state at present, as my experiments in this direction are still unfinished. Fifty-one days is, therefore, the oldest gonococcus culture known to me. When the gonococcus was first cultivated by Bumm,⁵ in 1885, on solidified placental blood serum, it was necessary to transplant it every sixth or seventh day, owing to the readiness with which it dried. Since then, Finger⁶ was able to demonstrate the fact that the gonococcus could live as long as four weeks upon a sealed beef-serum agar tube. From the liquid chest serum plus nutrient broth containing the gonococcus I repeatedly planted on chest-serum agar plates, finding on the forty-second day that I was still able to grow the gonococcus. In the Dunham's solution the gonococcus was still found on the seventeenth day, when planted on chest-serum agar plates.

Experiments to Determine the Longevity of Gonococci with Gonorrhœal Pus Kept Either at Body or Room Temperature.—Gonorrhœal pus for this purpose was obtained from gonorrhœal urine for the centrifuge. The clear urine, having been decanted, was then placed in the tubes of the centrifuge, and then repositied within a larger test tube which contained a small amount of sterilized water. Some of these tubes were placed at body and some at room temperature. The result of the immediate examination of the gonorrhœal pus intended to be kept at body temperature was positive both in cover-glass preparations and on chest-serum agar plates. After twenty-four hours at body temperature, I was able to find only few gonococci in cover-glass preparations and very many on cultures. Some of the gonorrhœal pus reacted acid and some neutral. Some of the tubes containing gonorrhœal pus, kept under the same condition at room temperature, showed gonococci in the first examination in cover-glass preparations and on chest-serum agar plates. After they had been kept for twenty-four hours at room temperature, I was able to demonstrate the gonococcus on both cover glasses and plates, obtaining the same results after forty-eight hours. In gonorrhœal urine kept twenty-four hours at room temperature, I also found gonococci both in cover glasses and on chest-serum agar plates.

I now smeared gonorrhœal pus on sterilized linen, which was stored in a test tube, and after three hours planted the pus directly from the linen on the agar plates, and made cover-glass preparations. This experiment gave a positive result, but on planting the material directly from the linen after twenty-four hours I could no longer grow the gonococcus, while the pus cells on cover glass appeared to be undergoing decomposition. Some of this pus-smeared linen was examined by me sixty-six days after its preparation, when I was still able to demonstrate the gonococcus with cover glasses. The pus was obtained from the linen in the following simple manner: A drop of sterilized water was placed by means of the platinum hook on the linen, and a cover glass was smeared directly over the moistened surface. Wocholtz and Nowak⁷ found that gonococci, when dried, lose their power of growth. They report results similar to those obtained by me from dried spots of gonorrhœal pus. A. Haberdad⁸ reported that he found gonococci on linen several weeks after besmearing the fabric. He did not, however, make culture experiments.

On one occasion I just smeared gonorrhœal pus upon the inner side of a sterilized test tube, and as late as fifty-seven days after I was able to demonstrate the gonococcus morphologically. Some of the dried pus from the above tubes was planted after twenty-nine days on chest-serum agar plates, with negative results: but I found gonococci in cover-glass preparations. In all instances of my own, Gram's method was employed.

Relative Growth of Other Pathogenic Bacteria on Chest-Serum Agar Plates.—In my experiments to determine the relative growth of some of the other pathogenic bacteria on chest-serum agar, I planted, among others, the staphylococcus pyogenes aureus, the streptococcus pyogenes, and for control the staphylococcus pyogenes aureus on nutrient agar, and found that the staphylococcus thrived better on nutrient agar than upon chest-serum agar. The streptococcus pyogenes grows nearly as rapidly upon chest-serum agar as the gonococcus does. This is an observation of importance, for the reason that it demonstrates that a mixed infection might occur. But granted, still it would be possible to demonstrate the gonococcus with chest-serum agar plates in cases of mixed infection, e.g., when both streptococci and staphylococci are present. In this connection it is proper to allude to the observations of Welch,⁹ of Baltimore, who at the meeting of the Association of American Physicians, 1895, was the first on record to demonstrate the gonococcus in cover glass and culture medium from the blood of a living person. Welch's report was based on a case of endocarditis with general septicæmia following gonorrhœa. Even with this complex of pathological processes the only pathogenic bacteria he found was the gonococcus.

Morphological and Biological Examinations of Chronic Urethritis Exudates.—In reviewing the literature of chronic urethritis, I find that much has been written upon every phase of the subject except upon the bacteriology; especially upon the examination of gonorrhœal threads with culture medium has little been published. It is on this account that my efforts were mainly directed toward the well-known "Tripperfäden." Those who study these threads with the microscope are familiar with the fact that the old method of collecting them is both tedious and uncertain. It occurred to me to avail myself of the centrifuge, for I remembered how useful and successful this apparatus proved to be in collecting urinary sediments. This apparatus was therefore employed in all my experiments for the collection of gonorrhœal threads, and I believe my experiments are the first on record in which the centrifuge was employed in connection with culture media. My method of procuring the urine in chronic urethritis is to allow the patient to void his urine into two sterilized centrifugal tubes. The first tube will contain threads of the anterior urethra; the second tube will be likely to contain secretion from the posterior urethra and from the prostate gland, if, while urinating, the patient's prostate be pressed upon with the finger. Tubes containing such urine are placed in the centrifuge and whirled for three minutes at twelve hundred revolutions per minute: the threads are thrown down. The centrifugal action to which the pus cells are incidentally subjected seems to have no effect upon the bacteria. The "centrifuged" sediment will be found to contain other bacteria, epithelial cells, and at times spermatozoa. Normal urine on being "centrifuged" at this velocity will be found at times slightly turbid at the bottom of the tube. This turbidity will be found on microscopical examination to consist of epithelial cells, a few leucocytes, and some bacteria. A point of practical importance developed by this procedure is the fact that the urine, after having been whirled, will contain a large amount of mucus. This fact would seem to point to the presence of a catarrhal urethritis. The literature of chronic urethritis deals solely with cover-glass preparations. This is probably attributable to the fact that suitable culture media were difficult to procure.

In my former paper, I stated that if I had to examine chronic urethritis cases with cover-glass preparations, I should require three examinations of the

gonorrhœal threads at different intervals. To-day, with my additional experiments, I am led to modify the above statement, in that we should only employ culture media (surface culture) in connection with the cover-glass examinations. I am also forced to discontinue the use of the ordinary staining solutions of the gonococcus, such as methyl blue or the solution recommended by me in my former paper, namely, a two-per-cent. alcoholic methyl-violet solution for differential diagnostic purposes. I look upon the decolorization by Gram's method as the only reliable criterion, so far as known, for the gonococcus, and it is of material help also in determining whether a culture is or is not that of the gonococcus. The examination of gonorrhœal threads with cover glass by Gram's method is a very tedious affair, as in every instance I examined no less than three, and at times as many as ten cover-glass preparations. It would require many hours upon each and every specimen, especially if gonococci are present in very small number, before a reliable and conscientious opinion could be rendered. If, after all, a negative opinion is ventured, we still are under the necessity of proving that the threads which we fished out for the cover-glass examination were free from gonococci, while the remaining ones might contain them. It is a well-admitted fact that the culture medium is more sensitive for bacteria than is the cover glass, and this holds true for the gonococcus, for we are able to plant each and every thread of the sediment in the centrifugal tube. Fürbringer¹⁰ in his work mentions the fact that in certain cases the absence of the gonococcus in many examinations of cover-glass preparations is not a positive proof that the gonococcus is not present, and to illustrate this unreliability he quotes Oberlaender's language: "Verlorene Liebesmühe," "Love's labor lost." I have been able to confirm the correctness of the above allusion, for on one occasion, in examining

threads, when I could not demonstrate the gonococcus in cover-glass preparations I succeeded in growing it on chest-serum agar plates, while in all instances in which I found the gonococcus in threads in cover-glass preparations I invariably succeeded in growing it on chest serum agar plates. The results of other observers in chronic urethritis are open to the objection that Gram's method was employed only in doubtful cases.

I append here the tabulated results of my investigations. They include examinations of gonorrhœal threads with cover glass alone, from chronic urethritis varying in duration from seven weeks to eight years (Table I.). Of these 34 cases 7 positive and 27 negative results were obtained—a percentage of 20.55 of positive results. Table II. covers examinations of gonorrhœal threads in 61 cases of chronic urethritis with cover glass and culture medium. In these 61 cases, 13 positive results were obtained with cover glass and 48 negative results—21.31 percentage of positive results. The same cases examined with culture media gave 14 positive results and 47 negative results, a percentage of 22.95 of positive results.

In regard to the question of infection in chronic gonorrhœa, I am inclined to believe that chronic gonorrhœa can cause only an acute gonorrhœa in another person. This belief is confirmed by Finger and Wertheim¹¹ by inoculation experiments. Of course we cannot always trace the method of gonorrhœal infection in the male urethra, nor even account for it. This latter observation holds true for acute gonorrhœal colpitis cases in which coitus can be excluded, although the infection is gonorrhœal. I cannot believe with certain observers that diplococci may be present in the male urethra or in the vulvo-vaginal tract, which under certain peculiar conditions can become virulent and thus produce a true gonorrhœa. Of course I do not deny that there may not be some

with a culture fifty-one days old, experiments prove that gonococci may be present in gonorrhœal threads, and yet may not be recognizable in cover-glass preparation but only in cultures. I endorse the experiments of Wertheim, who believes that the gonococcus does not lose its virulence in the urethra, but that the mucous membrane which it infests becomes tolerant to this particular gonococcus. A patient who had a gonorrhœa of two years' standing was inoculated by Wertheim with a pure culture of gonococcus obtained from the patient's urethra seven times, with negative results. The same culture was then inoculated into another urethra, with the result that a typical gonorrhœa followed. Wertheim therefore concluded that a spontaneous cure for gonorrhœa is the general rule. A male with chronic gonorrhœa will cause an acute gonorrhœa in a person with whom he cohabits, and the same is true of the female. The probability therefore points to the fact that an acute exacerbation in a case of chronic gonorrhœa is produced in such a way. Another advantage of culture examinations over cover-glass preparations is that with the former we are able to demonstrate the viability of the gonococcus. I am well aware how difficult it is to determine the presence of gonococci in chronic gonorrhœa of adult females. In children with chronic colpitis I found a diplococcus smaller than the gonococcus, which decolorizes by Gram's method and has a different appearance in culture. Bumm in 1885 said that the time is not far distant when the term "latent gonorrhœa" will be dropped by those studying the etiological factors of gonorrhœa with culture media.

The following are the results of the examination of gonorrhœal threads of chronic urethritis with cover-glass preparations of other observers. Goll,¹⁶ according to his elaborate article, examined 1,046 cases of chronic urethritis varying in duration between four weeks to six years or more, finding gonococci in 178 cases, the remainder giving negative result. Neisser,¹⁷ out of 143 cases varying in duration between two months and eight years, found gonococcus in 80 cases. Weinrich,¹⁸ out of 25 similar cases, obtained 2 positive results. E. Noeggerath,¹⁹ in 1887, deplored the fact that on account of the lack of culture media for the gonococcus we cannot always demonstrate them. Bröse,²⁰ in 1893, stated that the culture medium is the only reliable agent for the detection of the gonococcus. This latter statement is certainly applicable to chronic urethritis of the male. Neisser,²¹ in 1893, stated that in chronic urethritis with slight discharge the examination with a culture medium for gonococci will replace the cover glass. Lundstrom²² examined 50 cases of acute chronic urethritis, finding gonococcus in cases of two years' duration. Gabriel²³ examined the secretions of 100 chronic urethritis cases, without finding the gonococcus in any. Kaeufer²⁴ examined 50 cases of chronic urethritis, finding in 15 cases no bacteria, in 7 cases gonococci, in 10 cases bacilli and other cocci, and in 18 various forms of cocci. It is interesting in connection with the results of the last writer to allude to the fact that his cover-glass preparations were stained with solution of the aniline dyes and only in doubtful cases was Gram's method applied.

Clinical Division of Urethral Threads.—Fürbringer²⁵ speaks of two varieties of gonorrhœal threads: firstly, a muco-gelatinous, about one centimetre in length (this variety occurred in most of my cases); secondly, a brittle, yellowish, short thread, slightly tenacious and easily scattered when shaken. Taylor²⁶ describes four varieties of gonorrhœal threads—the purulent, the gelatinous, a variety consisting of pus, mucus, and epithelium, and, last, the epithelial. For clinical purposes this last division of threads is quite valuable.

In conclusion I will submit the following propositions as a summary of my experiments:

I. I believe that in the examination of secretions from urethritis the employment of the centrifuge not only is the most convenient method but also gives the best and most reliable results.

II. The medium employed by Hammer, consisting of albuminous urine plus glycerin agar, does not give so good results as chest-serum agar, as far as my experiments have shown.

III. Fractional sterilization of serum should be continued longer than six days, and after an interval of two or three days it should be sterilized again on three consecutive days.

IV. I recommend fermentation broth plus liquid chest serum, Dunham's peptone solution plus liquid chest serum, nutrient broth plus liquid chest serum, as liquid media for the gonococcus.

V. In the fermentation broth plus liquid chest serum I was able to cultivate the gonococcus after fifty-one days, at which time I discontinued my experiments.

VI. Gonorrhœal pus submitted to the centrifuge and kept moist at room temperature contained living gonococci after forty-eight hours, as proven by culture.

VII. In gonorrhœal pus which had been smeared on linen the gonococcus was demonstrated morphologically by Gram's method after forty-nine days in cover glass, at which time my experiments were discontinued.

VIII. The gonococcus was demonstrated after twenty-nine days in cover-glass preparation made from pus which had been dried on glass.

IX. In chronic urethritis, culture media alone are to be recommended for the detection of the gonococcus.

X. In 34 examinations of gonorrhœal threads with cover-glass alone, by Gram's method, 7 cases showed the gonococcus.

XI. Of 61 cases of gonorrhœal threads examined with cover-glass and culture media, 13 gave positive results with cover-glass and 14 with culture media.

XII. For the collection of the secretions and threads for planting, at least two specimens of urine must be obtained: first that which washes out the urethra; second, that which contains threads of the posterior urethra and secretion expressed from the prostate.

XIII. I believe that a urethra may contain gonococci which lie dormant and may be innocuous in that person for years, but which may at any time excite an acute gonorrhœa in another person.

NOTE.—I cannot conclude this article without expressing my sincerest thanks to Drs. J. K. Hayden and H. Goldenberg, of this city, for material furnished by them from their clinic. To Drs. Prudden and Cheeseman, of the College of Physicians and Surgeons, I am indebted for many acts of courtesy in connection with the pursuit of my experiments at the laboratory.

Progress of Medical Science.

Forceps, Indications for Use.—Dr. A. D. Wilkinson (*Western Medical Review*, October 15th) submits the following propositions. The forceps are indicated and should be employed: 1. In all pelves where the diameters are below the normal measurements. 2. When the head is in an immovable position, with chin fixed over the symphysis pubis. 3. When the head is in the superior strait, with chin to the front. 4. When the head is locked at the pubis, but when flexion is imperfect and fixation of the frontal part of vertex is the result. 5. When the face is fixed anteriorly, with chin locked. 6. When the face is fixed laterally. 7. In transverse and oblique positions of head. 8. When the head is laterally rotated and deeply fixed in the pelvis. 9. In great narrowness and rigidity of the soft parts, when the hand cannot be introduced, or when the fingers soon become exhausted on account of the constriction. 10. In too large heads—as hydrocephalus. 11. In placenta prævia and eclampsia. 12. When the extractive methods have been tried and proved insufficient. 13. When the fœtus is dead. 14. When the head has been torn from its trunk.

Artificial Dilatation of the Cervix at Term or During Labor.—M. Fochier (*La Semaine Médicale*, April 15, 1896, p. 156) says: "Commencing dilatation of the cervix is to be recognized by softening of the cervix and the extent to which the lower uterine segment is thinned. During labor, if the cervix is effaced, thinned, movable, and retracted a little, the head being fixed, by the application of the forceps dilatation can be accomplished either suddenly or gradually, the head in the latter case being allowed to retract with

the pains and the progress of dilatation watched. If the head is not easily grasped by the forceps, version may be performed by the introduction of two or more fingers and bringing down a foot, thus furthering dilatation. In other cases, if these methods are unsatisfactory, good results are obtained by the use of the balloons of Champetier. Rigidity of the cervix due to infection or eclampsia, as a rule, requires incision or hysterotomy. Spasmodic rigidity of the cervix indicates the employment of chloroform anæsthesia. Roughly speaking, dilatation should not require more than half an hour; but if the balloons of Champetier are used, it may require two hours. No one method accomplishes the three results desired—rapidity of delivery, harmlessness, and good results."

The Treatment of Headache with Methylene Blue.—In a recent communication, Lewy (*Berliner klinische Wochenschrift*, November 9, 1896, p. 996) reports a series of cases of headache of varied origin, in many of which relief was afforded by the administration of methylene blue. The beneficial influence appeared to be not merely temporary, but in many instances of a curative character. The drug was given in capsules, in doses of one and one-half grains, in conjunction with an equal quantity of powdered nutmeg, four times a day; and usually ten doses sufficed to effect the desired result, although often less was necessary. The urine became tinged with blue in the course of half an hour after the first capsule was taken, and continued so for from two to eight days. Upon the basis of this experience, Lewy recommends methylene blue in the treatment of angiospastic migraine, the headache attending neurasthenia, and, above all, in purely nervous headaches.

Successful Abdominal Nephrectomy for Rupture of the Kidney.—At a recent meeting of the Clinical Society of London, Wallis (*Lancet*, October 31, 1896, p. 1,229) reported the case of a man, twenty-two years old, who had fallen a distance of twelve feet from a ladder upon a spiked railing. Though collapsed and evidently in pain, consciousness was not lost. The abdomen was rigid and rather distended. On examination it was found that one of the spikes—three inches in length—had pierced the abdominal wall nearly an inch below the tenth costal cartilage on the right side. The opening in the skin ran downward and inward, and the finger passed into the wound could be pushed on into the abdominal cavity. Soon after admission to the hospital, the patient passed a pint of healthy pure blood by the urethra. He was at once prepared for operation, and an incision made from the lower end of the punctured wound downward to the right semilunar line. A lacerated wound of the peritoneum came into view, through which the bruised intestines presented. The peritoneal wound was enlarged and large masses of blood clot were turned out of the abdomen. Sponges were inserted and the sides of the abdominal wound held apart by two long silk ligatures. The under surfaces of the liver and the gall bladder were exposed and found intact. The intestines in the track of the wound were bruised, and one piece of small intestine presented a tear in the external coats, through which the mucosa bulged. At the bottom of the cavity the kidney could be felt, torn almost in two; blood welled up through the wound at a great rate. The left kidney was found intact in its normal situation. The peritoneum was now divided along the outer edge of the ascending colon, and this portion of the gut pushed in toward the middle line. The left hand was passed in behind the colon, the kidney rapidly freed and brought out of the wound. The ureter was clamped, tied, and cut, the vessels were treated in the same way, and the kidney was removed. The deep muscles were considerably lacerated and

bled freely. Sponges were temporarily inserted and the abdominal cavity was washed out with saline solution. The wound was packed with iodoform gauze in strips and dressed with cyanide gauze, blue wool, and bandaged. The patient was greatly collapsed after the operation, but reacted well during the following twenty-four hours. The wound healed without complication, and the ultimate recovery was perfect. For two days following the operation the urine contained blood, and for twelve days albumin. The quantity of urine passed in twenty-four hours averaged between forty and fifty ounces. It was pointed out that in the past, rupture of the kidney has been attended with a mortality of thirty-five per cent.

Surgical Immunization Compared with Susceptibility and Predisposition to Infection.—Dr. Gaston (*Alabama Medical and Surgical Age*, October, 1896) thinks we may draw the following inferences: That various agencies are at work, rendering the human organism to a greater or less extent free from the injurious impressions of surgical procedure. That local and constitutional influences operate in conferring immunity, and that the environments of individuals, with their habits of life, exert great control over the vital powers. Shock may be averted by proper measures in advance, and, in default of precautions, should be corrected by vigorous means of treatment. Germicidal solutions do not give immunity for normal structures, and are admissible only in septic contamination of the tissues. A preliminary examination of all the functions of vital organs should precede surgical operations, and efficient correctives should be resorted to for their derangements. The result depends largely on proper means of preparation. It is not necessary that the patient be placed in a hospital; cleanliness, good nursing, and the ordinary surroundings of the patient may secure satisfactory results. A thorough comprehension of the reciprocal relations of immunity and susceptibility should lead to the adoption of conservative measures in the practice of general surgery, and the use of the most radical and aggressive measures when indicated by the nature of the case. Appliances which promote surgical immunization should be adopted, and those means which lessen susceptibility and predisposition to infection are warranted in all cases of surgical interference. The author calls attention to the law of habit, as, for instance, in victims to the use of opium, whose nerve centres are very materially affected by it. In such cases the habit must be respected.

Successful Treatment of Suppurative Pericarditis by Resection of the Sixth Rib and Drainage.—At a recent meeting of the Clinical Society of London, Robinson (*British Medical Journal*, November 21, 1896, p. 1,504) reported the case of a lad, sixteen years old, who developed right-sided diaphragmatic pleurisy, following a protracted bath in a swimming-pool. On the fourth day there was some pain on the left side, and the left wrist was swollen; and on the sixth day an unmistakable pericardial rub could be heard. Although sodium salicylate was given, the temperature failed to decline. In the third week the area of cardiac percussion dulness was much increased, both upward and laterally to the mid-axillary line, but there was no dulness at the posterior aspect of the left chest. The symptoms pointed to the presence of pus, either in the pericardium or localized to the anterior and lower portion of the left chest. Aspiration in the fifth interspace just behind the anterior axillary line resulted in the evacuation of a small amount of pus. Using the trocar puncture as a guide, the sixth rib was on a subsequent occasion resected and the left pleura opened, the left lung being found fixed by recent adhesions. The bulging pericardium was incised,

and pus welled out freely on introduction of the finger. all fibrinous coagula were as far as possible cleared out of the cavity. Over two quarts of pus were thus evacuated. Irrigation was omitted, owing to the feeble condition of the patient. A drainage tube was introduced into the pericardium and stitched to the margin of the wound. Recovery was slow but uninterrupted, the tube being removed on the sixty-first day and the wound healing soon afterward. There was at no time any collection of pus in the left pleura. The patient was able to walk great distances after convalescence. There remained slight enlargement of the area of cardiac dulness upward, but there was no retraction of the chest in systole.

Treatment of Ingrown Nail by Perchloride of Iron.—The *Gazette Médicale de Liège*, September 24, 1896, p. 644, publishes the following: "There are cases of ingrown nails in which surgical treatment cannot be employed. In these cases we may have recourse to the method set forth by Dr. Reghi in the *Gaz. d. Osped.* This treatment consists simply in a daily application of a fifty-per-cent. solution of perchloride of iron. Direct the patient to take daily foot baths, and when this softens the skin and washes out the pus which has formed, the side of the nail as well as the groove made by the pressure of the nail should be stuffed with cotton soaked in the perchloride solution. The same operation is repeated twice daily, care being taken to remove the blackened crust that forms. When this is done, the toe is to be enveloped in a light dressing. During the first few days the patient should remain in bed. About the tenth day the granular mass disappears, the cavity of the ulcer is cleansed and presents a uniform surface, the end of the nail separates from the skin, and in twenty days the patient is cured. To avoid a relapse, it is necessary to separate the nail from the skin with a little cotton steeped in perchloride solution."

Treatment of Mammary Tumors.—The *Centralblatt für Chirurgie*, October 3, 1896, gives the following: No affection has increased to such an extent in this country. Dr. Williams states that in England and Wales in 1840 there were forty-five hundred cases, while in 1895 there were forty thousand. Should all tumors be operated upon for fear that they may become cancerous, or should they be left undisturbed in women from twenty-five to thirty? Dr. Cow answers these questions in the *Revue de Thérapie*, No. 13, by saying that every mammary tumor is liable to become malignant in a proportion of from ten to fifty in one hundred cases. Even with a proportion of one to one hundred, he considers an operation indicated. Aside from malignancy, he thinks there are other and sufficient reasons to justify an operation—the care and the pains, especially during menstruation, etc. A mild operation puts an end to all these disturbances, if the tumor is not diffuse or malignant. He considers a previous microscopical examination injurious, as it may produce a rapid surrounding growth of the tumor, or may open a passage for the introduction of cancer cells leading to further infiltration. In actually malignant neoplasms, the pectoral muscle and glands, as also the fat in the axilla, must be removed. He recommends to open and excavate the axillary cavity first, thus avoiding infecting the depths of the opened mammary tissue, and then remove the whole in mass. This method diminishes the hemorrhage, as all the blood-vessels that supply the tissue are ligated. Patients with generalized cancerous nodules should not be operated upon, except with the strict understanding that it is only a palliative measure, as otherwise surgery is brought into disrepute, and patients with operable tumors are deterred from applying for relief in time.

ASEPTIC SURGICAL FEVER.

It has long been recognized by surgeons that operations and other forms of traumatism, such as subcutaneous incisions, simple fractures, luxations, and contusions, unattended with suppuration or other complication, may be followed by febrile reaction; and various explanations have been offered to account for this apparently paradoxical phenomenon. In open wounds the possibility of infection cannot always be excluded, despite the most rigid aseptic and antiseptic precautions; and some have gone so far as to attribute the febrile symptoms that appear under these circumstances to the presence of pathogenic micro-organisms of attenuated virulence. Other investigators have sought to place the responsibility for this reaction upon the fibrin ferment set free as one of the results of the traumatism. It has, however, been shown on the one hand that the febrile state may be unattended with the presence of fibrin ferment in the blood, and on the other hand that fibrin ferment may be present in the absence of febrile reaction. While traumatism is often attended with a considerable degree of nervous shock, the attendant febrile disturbance is not to be attributed to this factor, for a variety of reasons. In this connection it is to be borne in mind that general infection may arise from a latent or unrecognized lesion, so that the diagnosis of aseptic surgical fever is not to be made without the most rigid exclusion of all ordinary causes of fever. Such evidence as exists points to the fact that aseptic surgical fever is due to the absorption of substances set free at the site of the injury as a result of the traumatism.

From a careful analysis of the literature of the subject, in conjunction with a series of well-directed and carefully conducted observations, Schnitzler and Ewald¹ have reached the conclusion that so-called aseptic surgical fever is due to a combination of influences, and they adduce evidence to show that nucleins and albumoses are set free through the agency of the traumatism, and that these are, in part at least, to be held accountable for the febrile reaction that takes place in the absence of infection or other tangible cause. It has been claimed that the disintegration of blood corpuscles is attended with the setting free of albumin, and investigation has shown that the nuclei of the leucocytes contain nucleohiston, which is ca-

pable of causing multiple thrombi and breaks up in the process of coagulation into histon and nuclein. As the nucleins appear in the urine in the form of alloxur bodies (including uric acid), the presence of these substances in increased amount would indicate the entrance of the former into the circulation. It has further been shown that the presence of the nucleins in the circulation is attended with leucocytosis. Now Schnitzler and Ewald were able in both animals and man to demonstrate the presence of an excess of alloxur bodies in the urine following manipulative procedures of such a character as gave rise to subcutaneous traumatism together with subsequent febrile disturbance, in the absence of infection. They also found leucocytosis under the same conditions. The inference seems therefore fair that as a result of the traumatism there are set free nucleins, which occasion the presence in the urine of an excess of alloxur bodies and also the development of leucocytosis, and which further may be viewed as one of the factors responsible for the resulting fever.

Having advanced thus far in their investigation, Ewald and Schnitzler proceeded a step farther and confirmed the observations of previous investigators that albumose could be found at the site of traumatisms attended with extravasation of blood. It had already been shown that both nucleins and albumoses are capable of causing death in animals when injected in large amounts and of inducing febrile manifestations when non-lethal doses are employed, and more especially is this the case in tuberculous animals. In the latter, in addition to the fever, evidences of local reaction may be found after death about the tuberculous foci comparable with those noticed after injections of tuberculin. Similar reactions were observed in tuberculous animals subjected to sterile injuries, while they failed to take place in control animals. From this evidence one is forced to conclude that to the albumoses set free at the site of aseptic traumatisms must also be attributed a share in the etiology of the fever that manifests itself. Accepting the foregoing facts as established, we are furnished with an explanation of the elevation of temperature often observed in tuberculous patients following operative interference of varied kind, and also perhaps of the dissemination of the tuberculous process that sometimes takes place in the same way as such dissemination follows injections of tuberculin. The same explanation may apply also to the recrudescence of latent and the lighting up of unrecognized lesions of other nature following operative measures at remote points.

SOME OF THE INFLUENCES OF X, SOLAR, AND ELECTRIC RAYS UPON THE SKIN.

For some time newspaper accounts have told of remarkable effects which the rays from the Crookes tubes have produced upon the skin of those exposed to their influence. Reports of falling of the hair, discoloration of the skin, and desquamation have reached us from various sources. It has long been known that certain of the sun's rays possess for particular indi-

¹ Archiv für klinische Medicin, B. liii., II. 3, p. 530.

viduals the power of calling forth most distressing cutaneous alterations, and experiments upon the supposed power of red light over the efflorescences of variola are still fresh in mind. Indeed, no longer ago than December last the *Gazette Médicale de Liège* presented a lengthy *résumé* of Dr. Finsen's modern and scientific study of light in this connection, based upon the empiricism of the middle ages, which led to the custom of wrapping small-pox patients in red fabrics and surrounding them with hangings of the same color. After the successes reported by Lindholm and Svendsen from exclusion of the chemical rays in variola a certain enthusiasm was created, which, extending over Europe, reached us here, and a series of experiments was carried out at some of the small-pox hospitals. The success, however, was not pronounced. Instances of dermatitis from the effect of light, aside from direct sun action, in certain individuals of susceptible skin are well known.

Dr. Graham, of Toronto, has reported two such cases under the name of hydroa æstivale.¹ The majority of writers attribute the cause of these distressing eruptions to the action of the chemical rays of the sun, and experiments would tend to show that the ultra-violet rays act with great intensity in certain cases.

That the sun's action can be put to therapeutic uses has been demonstrated by Rikli, and, to judge by the following which this individual has secured in certain German and Austrian quarters, the treatment carried out at his institute in the mountains near Trieste should have something to recommend it. Light is here supposed to constitute the essential factor in the cure, and hence the patients expose themselves to it in a state of entire nudity. The sun baths are taken in the open air, so that the body is subjected not only to the direct action of the sun's rays but likewise incidentally to the variations of atmospheric temperature.

The effects of electric light upon the skin have been studied and present some features of interest in this connection. In a paper read before the recent meeting of the American Electro-Therapeutic Society, Dr. Watson stated that in a large percentage of persons whose naked bodies were exposed to the rays of a number of incandescent lights in a room free perspiration would be induced before the temperature of the room reached that of the normal body. This he attributed to the chemic effect of the light. That certain eruptions are called forth by the action of bright electric rays has been known for some time.

Passing now to the Roentgen rays and leaving aside the questions which have been raised as to their probable value in the cure of disease, we find that they exert a most pronounced effect upon healthy human integument long exposed to their action.

In an instance related by Dr. Fuchs² so much pain was experienced in the finger-joints of a hand examined for a lengthy period by the x-rays that the test had to be given up. The skin directly opposite the cathode was colored brown; the hand became swollen and gave the appearance of a frozen member. After the lapse of a quarter-hour bullæ formed, some being

of large size. The contents were similar to those in blisters from burning.

This frozen appearance of exposed parts has been noted in the ear of a man examined for several hours at the University of Minnesota in order to locate a bullet in the head. This patient, while experiencing no pain or disagreeable sensation at the time, lost all the hair from the one side of the scalp. Numerous other instances of temporary hair loss have been related.

Dr. Parker, of New Orleans, has called attention to inflammation of the skin after long exposures, subsiding, however, after a few hours.

In the *British Medical Journal* of November 7th Dr. Drury reports that after an exposure lasting an hour and a half the patient noticed a sunburn-like condition of the skin over the abdomen, more intense in the part which had been directly opposite the platinum plate in the tube. Upon the fourth day small vesicles appeared, increasing in size and number, bullæ forming and rupturing, until upon the eighteenth day after exposure a patch seven and a half by eight and a fourth inches occupied the region. While not painful, the discharging surface showed no tendency to heal for ten days, when it began to cover over slowly from the margins, as in a burn. Two months later there was still an open wound three by three and a half inches, despite attempts at skin grafting. Cautery with silver nitrate produced no attempts at granulation, and a month later the base of the ulcer, which was covered with a thick false membrane, was curetted under ether and the actual cautery applied. Sixteen weeks after the exposure there still existed an indolent ulcer, whose base was covered with an insensitive false membrane and which showed no tendency to heal under any plan of treatment. The patient was confined to his bed during the greater portion of the time. The serious nature of such an unfortunate outcome of a skiagraphic *séance* makes the matter one of interest and importance, and we would direct attention to a very similar report of a case observed by Dr. Barrister of the United States army. Such results should render those who employ this most valuable aid to diagnosis cautious in the matter of prolonged exposure. The patient who, while not securing the satisfaction of seeing a skiagraph of his disordered interior, has to undergo several months of contemplation of a disturbed exterior will not think well of the method nor kindly of the operator. The suggestion of hair removal in an intentional way, for cosmetic effect, seems not likely of successful application, since, so far as we are aware, the hair grows again after a time in the instances so far observed.

Fat Bivalves.—A recent official medical report published in London quotes with approval the words of Professor Conn, that "the public health is placed in jeopardy when oyster dealers, for the sake of producing plumpness, place oysters in the mouths of freshwater creeks in close proximity to sewers."—*Post*.

² Deutsch. med. Woch. No. 35.

INDIANA HEALTH BOARD RULES.

IN "Health Circular No. 5," just issued by the Indiana board of health, the following rule is the first of a series governing the proper conduct of physicians.

"RULE 1.—When visiting patients known to be sick with small-pox, scarlet fever, diphtheria, or other contagious or infectious disease, physicians shall clothe themselves in a specially provided clean linen duster, oil-cloth, or rubber coat, and a tight-fitting cap made of silk, linen, oil-cloth, or rubber. The cap shall well cover the hair. Before leaving the house, physicians shall cleanse hands and face with antiseptic soap and water, and use a disinfectant upon hands and face. The coat, cap, antiseptic soap, bottle of disinfectant, etc., shall be carried in a special glazed leather valise, together with a pad of cotton, which is to be kept wet with formaldehyde.*"

The asterisk calls attention to the fact that the outfit can be obtained from the "— Clothing Store" in Indianapolis. The rule is a most excellent one, and but one it would be well to have adopted generally in visiting small-pox, scarlatina, and diphtheria patients, when it comes to extending the wearing of this costume to "other contagious or infectious disease" the burden placed upon the physician becomes onerous, no matter how attractive the wearer may appear when thus arrayed. Imagine for an instant the evening mental and bodily state of a practitioner who starts out in the morning clothed and in his right mind—of course we assume that this is the way the Indianian does start out.

His first call is upon his best-paying client. The unfortunate lady has contracted pediculosis or scabies, or possibly both, from the stable boy, who has the habit of making a lounging-place of the victoria with its luxurious cushions and robes.

According to rule, on goes the rubber coat and cap. At the next call the disguise must again be extracted from its glazed bag and donned before the gentleman with gonococci concealed about his person can be examined. Then the little girl with pertussis next door gets a chance to wonder at the strange appearance of the doctor, and if he chooses the linen duster and cap in which to visit the man down the street with secondaries it will be dollars to doughnuts that he will be shot for a whitecap before he gets into the house.

If he escapes whole, the agility acquired during his day's experience will lead him to abandon his profession for that of lightning-change artist in a continuous performance, or it will drive him into a neighboring State.

What the Indiana health board needs—and it must be done quickly—is to issue "Circular No. 6," and leave out the words "other contagious or infectious diseases." It should also make provision for bald-headed doctors. As the matter now stands, the cap must be worn so as to cover the hair.

Jefferson Medical College.—Mr. William M. Singerly has been elected a trustee of Jefferson Medical College to succeed the late Mr. Joseph B. Townsend.

COVERT PUFFING OF PROPRIETARY MEDICINES.

It is no secret that much of the pecuniary prosperity of a medical journal depends upon well-filled advertising pages. While the character of the advertisements must depend upon the standing of the periodical, and thus carry with them a corresponding guarantee of the value of the articles named, it is generally conceded that the proper medium for such presentation to the readers is through the pages specially set apart for the purpose. All advertisers have then an equal chance of presenting any special claims for patronage. It is perhaps a natural desire on their part in some manner to obtain some sort of editorial reference. As a consequence, it is sometimes proposed, as a condition of contract with publishers, that an occasional article on a special and well-advertised drug or apparatus, or a covert notice of its value shall accordingly appear in the reading-columns. We have always maintained that such is a very reprehensible practice and one calculated to thwart the higher purposes of independent journalism. Readers naturally expect that an editor shall be perfectly sincere in his efforts to enlighten them on all matters connected with the earnest and honest pursuit of their studies. His opinions must be necessarily untrammelled by any pecuniary consideration, and be above any suspicion of partiality either to advertisers or authors. Hence he is often called upon to decline articles either designedly or innocently written which extol the virtue of certain proprietary articles, in order that his readers may not be deceived. As we know from long experience that it is possible to be absolutely consistent on this point, we are especially pained to observe, in the reading-columns of one of our much-esteemed contemporaries, a barefaced puff of an advertised article in the same number, with the signature of a reputable medical man, and with much of the language of the advertisement in the body of the so-called original article.

What possible benefit can be obtained from such methods it is difficult to determine. They injure the journal, its readers, and really the advertisers themselves. An article having such a transparent aim in view is never of any value to the reader, and in the end lowers the journal even as an advertising medium. The subscribers, who really give the journal its value as an advertising medium, have the right to demand proper scientific reading in its columns. If such is not given them, the true interest in the reading-columns falls off. If the puffing notices are limited, gross partiality is rightly charged by other advertisers; while if all solicitors of such advertising are treated alike in this particular, the journal inserting them must inevitably degenerate to the level of an advertising trade almanac, and no self-respecting medical man will read the trash. The ordinary doctor patronizingly so-called is never such a fool as many take him to be. He does not subscribe to journals for the sake of reading puffs of remarkable remedies, and is always ready to resent such insults to his common sense by refusing to support the journals which tolerate such doings. The best ad-

vertisers appreciate this condition of patronage, and are content to restrict themselves to the advertising pages, trusting to the benefits of legitimate methods for the sale of their wares and to the proper appreciation of straightforward methods in presenting their claims for professional consideration.

Advertising pages are as much an essential part of a journal in respect to a doctor's needs as the reading-matter; they both go to him at the same time, both appeal to him legitimately along different lines. The different departments have their function and place, and the integrity and worth of each are only properly maintained by keeping one absolutely separated from the other. Subscribers never complain of this, and are always generous with fair-minded advertisers accordingly; but they nevertheless hate to be fooled, and rightly resent the covert persuasions of the real fool at the other end, by refusing to read what he has written or to believe what he has said. Furthermore, and this is where some editors are short-sighted, the readers come to look upon every article published in journals which commit such blunders, with a degree of suspicion which ultimately becomes intolerable.

News of the Week.

Another Editorial Resignation from the "Bulletin."—Dr. Samuel Lloyd has severed his editorial connection with the *American Medico-Surgical Bulletin*.

A Deceptive Crank.—A man, aged sixty years, with sandy hair and full beard shot with gray, visits doctors at their offices and offers to engage them at an extravagant salary to attend a millionaire abroad. He is merely the victim of a delusion, says he is the private secretary of the liberal patron, and the physician who cannot make a diagnosis at sight becomes a victim to the same disease.

Department Store Dentists.—On November 12th, the superintendent and two employees in the dental department of Siegel-Cooper Company were arrested upon the complaint of the Dental Society of the State of New York, the charge against each being that he had practised dentistry in New York County without registering therein according to law. All of the accused waived examination and were held for trial at special sessions, wherein several adjournments were granted to them. Finally, on December 3d, all of these cases were set down peremptorily for trial. Counsel for two of the accused asked a further adjournment, upon the ground that the attorneys previously employed by them had abandoned their cases, and that he had just been retained and wished to call witnesses to prove his clients' innocence. The court said that under the rules the adjournments could not be granted against the opposition of the prosecution. Counsel for the Dental Society then said that, although the only defence to the charge of non-registration

would be the proof of registration, which, if it existed, could be procured within ten minutes from the county clerk's office, he would nevertheless consent to an adjournment until the following day, upon the absolute condition that the cases should be tried then. Upon this understanding, Mr. Mingey, the counsel, accepted the adjournment, and forthwith procured a stay of proceedings and an order to show cause why the cases should not be transferred to general sessions. Upon the following day the other defendant was then tried and convicted—one judge, however, dissenting from his colleague's opinion that the examination of a patient's mouth and subsequent advice as to the condition of the mouth and what was needed to be done constituted "practice of dentistry," the dissenting judge being of opinion that some mechanical or operative act should be performed.

Obituary Notes.—DR. CHARLES N. WOOLLEY, of Newburg, N. Y., died at his home in that city on December 11th, after a long illness. He was born in Southampton, L. I., in 1840, and was a graduate of the Long Island Hospital Medical College in 1868. He was for seven years a member of the Newburg board of education and its president two years.—DR. DÉCLAT, of Paris, whose ardent advocacy of the healing virtues of carbolic acid did much to popularize the use of that remedy among the profession, died recently at Nice. He always claimed for himself priority in the discovery with which Sir Joseph Lister's name is associated, as well as in that of certain more recently promulgated therapeutic measures based upon antiseptic or microbicide principles.—DR. LEONARD J. SANFORD, of New Haven, Conn., one of the medical faculty of Yale University, died at his home in that city on December 12th. He was born in New Haven in 1833, and was graduated from the Jefferson Medical College, Philadelphia, in 1854. He received the honorary degree of M.A. from Yale in 1858, and was appointed professor of anatomy and physiology at the same university in 1863. Since that time he had lectured regularly on these subjects and also upon hygiene in the medical and other departments of the university.—DR. C. E. SEGER, of New Hackensack, Dutchess County, N. Y., died at his home in that village, after an illness of two weeks, of typhoid fever, at the age of fifty-four years. He was health officer of the town in which he lived.—DR. GEORGE H. TAYLOR, who devised a mechanical massage treatment, and who wrote several medical works on the results of his experiments, died on December 9th, at his residence, No. 40 Central Park, South. He leaves a widow and two children.—DR. ALFRED J. MARTIN died at Allentown, Pa., on December 8th, at the age of fifty-nine years. He was graduated from the university of Pennsylvania in 1857. In 1878 he was elected mayor of the city of Allentown, and in 1880 served as a presidential elector. He was for twenty years prison physician and for a long time coroner's physician. He was also a trustee and consulting physician to St. Luke's Hospital at South Bethlehem.—DR. C. D. KEENE died at Homeville, Upper Oxford, Pa., on December 8th, at the age of forty years.

The Plague in India.—A telegram from Bombay states that the bubonic plague in that city is spreading, and several Europeans have recently been attacked. Two Englishmen died of the disease early in December.

The Association of Assistant Physicians of Hospitals for the Insane held its fourth annual meeting on December 3 and 4, 1896, at the Eastern Michigan Asylum, Pontiac, Mich. A number of practical subjects were discussed.

The Leprosy Congress.—A call, signed by Drs. E. Ehlers, of Copenhagen, G. Armauer Hansen, of Bergen, R. Koch and O. Lassar, of Berlin, has been issued, inviting those interested in the repression of leprosy to meet in Berlin in October, 1897. The committee states, as its belief, that leprosy, which is now slowly but steadily upon the increase, can be arrested by proper and concerted measures; and it is to discuss these measures and to devise some plan by which they can be made effective that the congress is called. It is unfortunate that the meeting is not to be held immediately before or after the International Congress at Moscow, instead of five or six weeks later. It will be out of the question for many, from this side of the water at least, to take part in the deliberations of both meetings, unless, perchance, leprologists have more leisure and more money than the majority of their confrères.

No More Lodge Work.—The following praiseworthy resolutions have been adopted and signed by the physicians of Santa Clara County, Cal.:

"Whereas, Rendering professional services at a stipulated fee per capita per annum is derogatory to the dignity of the medical profession, we, the undersigned physicians and surgeons of Santa Clara County, Cal., enter into the following agreement:

"First, we mutually, jointly, and individually pledge our word of honor not to enter into any contract or agreement, or renew any existing contract or agreement, either written, verbal, or implied, to render medical or surgical services to any lodge, society, association, or organization.

"Second, we will not render medical or surgical services to the members of the above-mentioned bodies for less compensation than we charge the general public for similar services.

"Third, this agreement shall not be construed to affect existing contracts between physicians and surgeons and the above-mentioned bodies.

"Fourth, these pledges shall take effect and be in force for a term of three years from and after May 22, 1896.

"This agreement shall not apply to hospitals and purely public charitable institutions."

Association of Military Surgeons of the United States.—The following are the officers of this association for 1896-97: *President*, Com. Albert L. Gihon, Medical Director, U. S. N. (retired), New York City; *First Vice-President*, Brig.-Gen. Edward J. Forster, Surgeon-General, M. V. M. (deceased), Boston, Mass.; *Second Vice-President*, Maj. John Van Rensselaer

Hoff, Surgeon, U. S. A., Fort Vancouver, Wash.; *Secretary*, Maj. Herman Burgin, Surgeon, P. N. G., Philadelphia, Pa.; *Treasurer*, Capt. James J. Erwin, Surgeon, O. N. G., Cleveland, O.; *Editor*, Maj. Charles C. Foster, Surgeon, M. V. M., Cambridge, Mass. The seventh annual meeting of the association will be held at Columbus, O., May 25, 26, and 27, 1897. The local committee of arrangements consists of Maj. Henry M. W. Moore, *Chairman*, Assistant Surgeon, O. N. G., Columbus, O.; Capt. James E. Pilcher, *Secretary*, Assistant Surgeon, U. S. A., Columbus Barracks, Columbus, O.

Scarlatina is so prevalent in South Russia that it is proposed that all educational establishments shall be closed at once.

Military Surgery in Germany.—The medical services of the German army and navy are to be separate hereafter, and the privilege of changing from the army to the navy, or *vice versa*, formerly enjoyed by the members of either service has been abolished.

The Admission of Women to Universities in Austria.—In the budget committee of the Austrian Reichsrath on November 7th, the minister of instruction, Baron Gautsch, made a statement to the effect that the government was preparing legal measures for next year to admit women to all faculties of the universities, except that of theology, and also to grant to the women who have obtained medical degrees at foreign universities the right of practising in Austria after having undergone an examination.—*British Medical Journal*.

St. Christopher's Hospital for Babies.—On December 1st there was opened at 283 Hicks Street, near Joralemon, Brooklyn, Saint Christopher's, a hospital for babies. Most physicians practising among the poor have experienced the difficulty of getting hospital treatment for the very young, and it is to meet this want that this hospital has been established. No child suffering with a contagious disease can be received, but all others, sick and destitute, will be taken to the full capacity of the hospital. The hospital staff is as follows: *Consulting Surgeons*, Dr. A. J. C. Skene, Dr. William Maddren; *Consulting Physician*, Dr. Charles Jewett; *Consulting Neurologist*, Dr. William Browning; *Consulting Laryngologist*, Dr. William F. Dudley; *Consulting Ophthalmologist*, Dr. William H. Snyder; *Visiting Pædiatrists*, Dr. William A. Northridge, Dr. John W. Parrish. On the advisory board are Messrs. William G. Low, Edwin Packard, and Francis H. Southwick, and Dr. Edward H. Squibb.

Visitors to the Moscow Congress.—The St. Petersburg correspondent of the *British Medical Journal* writes that, in view of the fact that a large number of visitors to next year's International Medical Congress in Moscow is certain to take the opportunity of seeing St. Petersburg at the same time, Professor Petersen, of the Army Medical Academy, has undertaken to form a local committee in that city, the purpose of which shall be to enable the foreign visitors to see what is worth seeing there (and there is very much worth seeing) with the greatest ease and comfort: A

similar committee has been formed in Brest-Litofsk, a main junction on the line to Moscow, not with the design of showing local objects of interest, but to supply information and perhaps also accommodation to members of the congress who may break their journey there.

Funny Lawmakers.—A bill has been introduced in the Georgia legislature prohibiting the playing of football in the State; also one prohibiting the sale of cigarettes or cigarette paper. If the newspapers report correctly, the same assemblage of Solons proposes to make it a misdemeanor for women to wear bloomers, divided skirts, or shirt waists.

Professor Roentgen was the recipient, on November 30th, of a medal awarded him by the Royal Society of Great Britain, for his discovery of the *x*-rays. Professor Moissan, of France, was similarly honored, for his success in isolating the element fluorine.

Yellow Fever is epidemic in Port au Prince, Hayti, and a strict quarantine is maintained against the place by all the other West Indian ports. The Haytian authorities claim that medical authorities differ as to whether the disease is yellow fever or a pernicious form of malarial fever.

The Morristown (N. J.) Memorial Hospital.—A new building, a memorial gift of a friend, is to be erected, at a cost of \$38,000, on the grounds of this hospital. The proposed building will be, it is hoped, the central portion of a larger future hospital, to be built in three sections, of which this is the first. It will be about forty-five feet front, with a depth of ninety-five feet, three stories and basement, of brick, with trimmings of Indiana limestone, and fireproof. It will be equipped with elevator, baths, toilet rooms, steam laundry, etc.

Sunburn Effects from the Roentgen rays are due, according to Tesla, to the ozone generated by the rays in contact with the skin.

The Tri-State Medical Society of Alabama, Georgia, and Tennessee will hold its next annual meeting in Nashville, on October 12, 1897.

Perfected *x*-Rays.—A sixteen-inch spark in a twenty-inch tube, giving an intensity two hundred per cent. greater than that possible with the four-inch spark in a twelve-inch tube, formerly used, is said to do the work in thirty seconds and do away with long exposures.

Jefferson Medical College.—There has been a strike at the Jefferson. The students refused to attend lectures on December 1st. Dr. Keene had an audience of one, to whom he lectured for the prescribed hour. Dr. Chapman's solitary auditor was assailed with a shower of eggs as he made his exit after the lecture. Other demonstrations of a riotous nature were intended as a protest against the rule which had been posted three weeks ago, requiring all fees to be paid for the first half-term on or before this date. Professor Hare succeeded in gaining an audience in the evening, when a lecture was delivered upon the rights of individuals.

The French Medical Press Association ate its thirty-fourth dinner in Paris on November 9th. Professor Cornil presided.

The British Association for Child Study was recently established at a meeting held in Newcastle-on-Tyne, under the presidency of Dr. Oliver.

A Medical Defence Society.—The editor of the *Lancet-Clinic* calls for the foundation in Cincinnati of a medico-legal society, which shall defray the expenses of any of its members who may be sued for malpractice. The suggestion is called forth by two vexatious and iniquitous suits recently brought against Cincinnati physicians, and also by the editor's personal annoyance in the matter of libel suits brought to discourage him in his fight against quackery.

Brains for the Paris Faculty.—Dr. Luys, of the Salpêtrière Hospital, Paris, has presented the Faculty of Medicine with his collection of twenty-two hundred brains, carefully prepared and catalogued. The collection is the result of thirty years' investigations, and includes the brains of idiots, of blind persons, of persons who had undergone amputations, and of those who had suffered from various forms of mental disorders.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending December 12, 1896: December 9th.—Assistant Surgeon H. F. Parrish, resignation accepted from January 1, 1897. December 10th.—Surgeon E. H. Marsteller ordered to the *Raleigh*; Surgeon H. G. Beyer detached from the *Raleigh*, and ordered to the *Newark*; Passed Assistant Surgeon H. B. Fitts detached from the *Essex*, ordered home, and placed on waiting orders; Passed Assistant Surgeon C. D. Brownell detached from the Puget Sound naval station, and ordered to the *Petrel*, December 16th.

Dr. Jameson's Illness.—We learn from the *British Medical Journal* the nature of the illness which has necessitated the release of Dr. Jameson from prison and his transfer to a private hospital near London. The trouble was one of long standing, which had been greatly aggravated by his enforced confinement. For some time he had been suffering from hemorrhoids, both internal and external. During his stay in Africa he underwent two partial operations for their removal, but since his arrival in England the condition had become so much worse that further interference was absolutely necessary. Recently a serious complication developed, in the form of a very painful fissure. So great and so constant was the pain that sleep was impossible. The operation was performed by Mr. Herbert Allingham. Dr. Jameson was thus in a low state of health when the operation was undertaken, and it is therefore not surprising to hear that he took the anæsthetic badly. After the operation his condition did not improve so rapidly as might have been wished. This was due to the restless condition of the patient, the result of his confinement, combined with the pain attending the dressing of the operation wounds.

Reviews and Notices.

FUNCTIONAL DISORDERS OF THE NERVOUS SYSTEM IN WOMEN. By T. J. MCGILLICUDDY, A.M., M.D., Consulting Physician to the Italian Hospital; Surgeon-in-Charge of the New York Mothers' Home Maternity Hospital, etc. Illustrated by 45 Wood Engravings and 2 Chromolithographic Plates. New York: William Wood and Company. 1896.

WHILE such great advances have been made in operative gynecology, the diseases of womankind which are purely functional and need not the surgeon's knife have been somewhat neglected, or at least have not received the attention which their importance would seem to demand. The author of the present work has attempted to draw attention to this class of affections, and he modestly lays no claim to completeness in his treatment of the subject. The work of three hundred and sixty-seven pages is written from the standpoint of the general practitioner, and it is kept well before the reader that many uterine disorders constitute but a small part of general conditions which require treatment. The experience and writings of other observers have been freely drawn upon in illustration of practical points, and the histories of numerous cases are given in a brief manner.

About eighty pages are devoted to therapeutics. In an appendix is a series of illustrative charts devised by the author to make clear the various reflex neuroses. The volume is neatly bound in conformity with the "Medical Practitioners' Library" series, to which it belongs.

MODERN GREEK MASTERY: A Short Road to Ancient Greek. By THOMAS L. SIEDMAN, A.M., M.D. New York: Harper & Brothers. 1896.

THIS work is intended as an aid to the acquirement of a practical knowledge of modern Greek, and primarily for those who cannot secure the services of a native Greek teacher. One of the aims which the author had in view in the preparation of this work was to demonstrate the possibility as well as the desirability of learning the ancient language through the modern. The book will be welcomed, however, not only by those who desire to study modern Greek for philological purposes, but also by those who regard this as the language best fitted to serve as the common tongue of scientific men of different nations. The method employed by the author differs widely from the traditional one. The teaching of grammar for grammar's sake has no place here. The student is put at once in possession of living Greek phrases, and insensibly acquires the ability to express his thought in this language without the intrusion of English. An appendix contains a list of all the irregular verbs and several specimens of Greek handwriting.

A HANDBOOK OF PATHOLOGICAL ANATOMY AND HISTOLOGY. With an Introductory Section on Post-mortem Examinations and the Methods of Preserving and Examining Diseased Tissues. By FRANCIS DELAFIELD, M.D., LL.D., Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia College, New York, and T. MITCHELL PRUDDEN, M.D., Professor of Pathology and Director of the Laboratories of Histology, Pathology, and Bacteriology, College of Physicians and Surgeons, Columbia College, New York. Fifth Edition. Illustrated by Three Hundred and Sixty-five Wood Engravings; Printed in Black and Colors. New York: William Wood and Company. 1896.

THE editions of this standard treatise on pathological anatomy follow each other in quite rapid succession, attesting not only the numerous and rapid advances constantly being made in the science of pathology, but also the favor with which this work is regarded by the medical profession. The plan of this edition is the same as that of the previous ones, the intention of the authors being "to give to students and practitioners of medicine, first, the knowledge necessary for the making of autopsies, the preservation of tissues and their preparation for microscopic study, and to outline the methods of study of pathogenic micro-organisms; second, to describe concisely, with such illustrations as seem necessary, the lesions of the acute infectious diseases and, so far as they are known, the micro-organisms concerned in their causation, the various phases of degeneration and inflammation, the character of tumors, the special lesions of different parts

of the body, of the general diseases, of poisoning, and of violent deaths." There is little to add to this description except to say that the promise has been more than realized in the execution. This new edition contains many changes which have been made in order to bring it thoroughly up to date, and several new illustrations have been added. The section on the blood has been rewritten by Dr. James Ewing.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Ninth Annual Meeting, Held in Nashville, Tenn., November 10, 11, and 12, 1896.

E. S. LEWIS, M.D., OF NEW ORLEANS, LA.,
PRESIDENT.

Second Day—Morning Session.

Uterine Drainage as a Factor in the Prevention and Relief of Pelvic Inflammation.—DR. R. R. KIME, of Atlanta, Ga., drew the following conclusions: (1) A uterine tampon is not a true drain and even obstructs drainage in many cases. (2) Capillary drainage is secured by carrying a strip of gauze up into the uterine cavity, not packing it, and then it drains for a few hours only. (3) Gauze cannot even act as a capillary drain when either end or centre is constricted, or when coated with mucus. (4) Gauze when saturated with serum, unless it contains an antiseptic, forms a hotbed for germ development. (5) Never tampon the uterus in puerperal septic infection, except to check hemorrhage. (6) The good effect of a gauze tampon in cases of endometritis and after abortion is not due to drainage, but to its effects as a tampon, *i.e.*, checking hemorrhage, stimulating uterine contractions, prolonging medication to the endometrium, and acting as a surgical dressing. (7) The uterine drainage tube is the most essential factor in the treatment of puerperal infection and the best means of securing drainage when demanded in other diseased conditions of the uterus. (8) It will save more lives, prevent or relieve more pelvic complications than any other one factor at our command.

Gunshot Wounds of the Abdomen.—DR. W. E. PARKER, of New Orleans, read a paper on this subject, and reported thirteen cases with six recoveries. In his paper he made the statement that he believed that in the hands of men skilled in abdominal work seventy-five per cent. of cases of wounds of the small intestine should recover if they were seen early, the prognosis being better in this class of cases than in any other. He advised an early and rapid operation in all cases.

In conclusion he made the following general statements: The diagnosis is generally easy, but when there is doubt he would advise enlarging the wound or probing. In doubtful cases he is inclined to attach much importance to pain referred to the umbilicus as a symptom. He stated that he had never seen a case in which this symptom was not present. There is frequently but little shock when grave symptoms are present, and when symptoms of it are present the trouble is generally hemorrhage and not shock. Senn's gas test was not used in any of these cases, and he spoke of it as being unnecessary in at least a majority of cases, uncertain in the hands of those not skilled in its use, and making it more difficult to replace the intestines after sewing the wounds.

As to the technique he said that (1) unless the wound is well to one side it is best to make a median incision, and it should be long enough to enable the operator to make a thorough examination of the ab-

dominal contents. (2) The whole intestinal canal should, as a rule, be examined. (3) All peritoneal wounds should be sutured with silk Lembert sutures. Intestinal wounds should, other things being equal, be sewn in the long axis of the bowel. (4) If the liver is wounded, better results are obtained from packing than from suturing it. (5) If the kidney has been wounded it is best to suture the peritoneal wound and treat the kidney extraperitoneally if necessary. Of course, he did not refer to those cases in which the laceration and hemorrhage are so great that it is necessary to remove the kidney at once. (6) Drainage, except in late cases, is not necessary if all hemorrhage has been stopped. (7) Cases in which the intestines cannot be sutured without great risk of obstruction should be resected. (8) While enough time should be taken to do the work thoroughly, no time should be wasted. (9) Unless the bullet can be felt, search should not be made for it, as it causes unnecessary delay. (10) The superficial wound should be closed with silkworm gut or silver wire, and the author believes that a single suture should include the skin, abdominal walls, and peritoneum.

Prognosis: (1) The sooner the patient is operated upon the better the prognosis. (2) Those cases that have been reported in a series including all cases have shown a mortality of about sixty-two per cent. The prognosis is best in cases of wounds of the small intestine, and he believes that seventy-five per cent. of the cases will recover if seen early. By early is meant in the first two or three hours. (3) Every one knows that alcoholics stood all surgical work badly, and yet most of these patients have been drinking before they come under care. The prognosis in non-alcoholics will be better than in alcoholics. (4) If the stomach and intestines are empty the prognosis is usually improved by this fact.

After-treatment: While not favoring drugging these patients, strychnine and other stimulants, he thought, should be given hypodermatically if necessary. Especially should strychnine and alcohol in some form be given to alcoholics. Much depends on starting these patients well. If they are restless after the operation or suffering, small doses of morphine should be given. If the stomach is quiet and has not been injured, small amounts of water and Duero's elixir can safely be given at the end of twenty-four hours and also small quantities of milk or some light broth. If the stomach has been injured, the feeding should be per rectum. The diet should be liquid for at least two weeks. If there is shock, with the clammy sweat that is sometimes seen, atropine, one-sixtieth of a grain, should be given every three hours as may be necessary. When shall we give a purgative? This is one of the most important questions that we shall be called upon to decide. If we give a purgative too soon our stitches may pull out, and if we wait adhesions may form and give us trouble. The bowels of these patients will usually act by themselves about the end of the fifth or beginning of the sixth day. If they do not, a mild purgative assisted by an enema should be given about the end of the sixth day, or on the morning of the seventh. As a rule, these patients should be kept in bed for at least two and a half weeks.

Discussion.—DR. JAMES MCFADDEN GASTON was not able to corroborate, either from his reading or experience, the favorable percentage of recoveries which the essayist had given in gunshot wounds of the abdomen. The fact that the bullet entered the abdominal cavity, if it did not wound the intestinal tract, was not necessarily a very serious matter, although wounding of the mesentery with hemorrhage was sufficient reason for exploration. As to the Senn gas test for determining perforation of the bowel, it was not used

by very many surgeons to-day. Dr. Gaston was very positive in his conviction of the propriety of laparotomy after gunshot wounds of the abdomen, and the sooner the better.

DR. N. P. DANDRIDGE, of Cincinnati, called attention to the importance of making a distinction between penetrating gunshot wounds and penetrating stab wounds of the abdomen. The latter were much less dangerous. In fact, a very large proportion of these cases, in which it seemed as though the intestines must necessarily have been wounded, get well without operation. In gunshot wounds, however, an exploration should be made in every case in which there is reasonable supposition that the abdominal cavity had been entered. Gunshot wounds were much more serious than stab wounds. He could not agree with the essayist as to the percentage of recoveries likely to take place. Personally, he had never succeeded in saving a case of gunshot wound of the intestine.

DR. A. M. CARTLEDGE said that Dr. Parker's results were the best he had seen mentioned in literature, particularly in penetrating wounds involving the intestines. He had operated on five subjects with gunshot wounds of the abdomen, three of them hopeless from hemorrhage from the beginning, one dying within an hour and a half from a short operation, simply from the enormous amount of blood lost from a wound in the mesenteric vessel. He had never saved a case of gunshot wound with intestinal perforation.

DR. A. V. L. BROKAW, of St. Louis, considered every case of gunshot wound of the abdomen a law unto itself, and that the surgeon had to meet the emergency as it occurred. He agreed with the essayist that a quick operation was absolutely necessary.

DR. W. E. B. DAVIS emphasized the importance of early operation and called attention to the almost hopeless condition that was found if the surgeon operated after twenty-four or forty-eight hours. At the Charleston meeting of the association he said he was criticised for making the statement that at the end of twenty-four or forty-eight hours usually a general peritonitis would develop after a gunshot wound with intestinal perforation. If the surgeon had this condition to contend with, an operation would offer scarcely any hope of recovery, unless done very early.

DR. B. R. RHETT happened to have had three cases of gunshot wounds of the abdomen during the past year. In one case, that of a little boy, there were several intestinal perforations. He was operated on, but died within three hours thereafter. Case II. died eleven hours after the closure of the perforations. Case III. was that of a negro boy, who had six perforations. He was operated on, the perforations were closed, and he made a good recovery.

DR. H. M. HUNTER, of Union Springs, Ala., laid stress on the importance of early operative interference. He held that very few patients would recover after twelve hours if not operated on, no matter how expert the surgeon might be. He had operated on a man, thirty-six hours after the receipt of the injury, who had two perforations of the colon, the ileum being just touched. The man died in three or four hours thereafter of general peritonitis.

DR. JOHN D. S. DAVIS did not believe it was possible to obtain in private practice seventy-five per cent. of recoveries from early operations in injuries of the small intestine. The patients saved by Dr. Parker were operated on two hours after they were shot, hence early operation was the keynote to success. While he was not prepared to agree fully with Dr. Hunter that none of the subjects could be saved after twelve hours, still the majority of them would die if not operated on within twelve hours. The most serious injuries to the belly from gunshot wounds were seldom followed by symptoms.

DR. F. W. McRAE had seen and known of several cases of penetrating wounds of the abdomen in Atlanta, all of which had terminated fatally, with one exception, and this patient was operated on by the late Dr. Armstrong, who found several perforations. A foot and a half of the small intestine was resected and the man recovered. The speaker would have some hesitancy in opening the abdomen when there was apt to be some medico-legal complication.

DR. HOWARD A. KELLY offered the following resolution, which was unanimously adopted:

"*Resolved*, That it is the sense of all the members of the Southern Surgical and Gynecological Association that in gunshot wounds penetrating the abdominal cavity, the proper routine procedure is to make an immediate exploratory incision."

DR. PARKER said, in closing, that the late Dr. Miles in his first series of cases reported thirteen, the percentage of recovery being nearly forty. He had operated on probably twenty additional cases before his death, and the percentage of recoveries was very much better than in the first series. As to the medico-legal aspects of this subject, all surgeons should advocate the early opening of the abdomen, and, if some fellow practitioner should get into trouble as a result of it, the profession should stand together and support him.

The Evolution and Perfection of the Aseptic Surgical Technique.—DR. L. S. McMURTRY, of Louisville, read a paper on "The Evolution and Perfection of the Aseptic Surgical Technique." The author cited cases in which surgeons of world-wide reputation had infected their patients, through some imperfection in the aseptic surgical technique, and said the subject deserved much more study and attention at the hands of operative surgeons than had heretofore been given to it. So far as instruments, dressings, etc., were concerned, surgeons had an absolute guarantee against sepsis; but when it came to the operative field, the hands of the operator and his assistants, they were reduced to mechanical and chemical methods of asepsis, which were certainly far less efficacious and reliable than sterilization by heat. Everything that comes in contact with the field of operation in the form of instruments and dressings was exposed to heat at a boiling temperature; hence the patient was safe against septic infection from this source: but so much could not be said for the hands of the surgeon and those of his assistants nor of the field of operation.

Second Day—Afternoon Session.

The President's Address.—This was delivered by DR. E. S. LEWIS, of New Orleans. Reference was made to the brilliant achievements of the masters of the art of surgery who had passed away and of the galaxy of shining lights who had followed after, who had created an era in the medical history of this century for all future time. How could we wonder that the "magnificent records obtained by experts have proved alluring temptations to the inexperienced and ambitious," and led to abuses which have left a blot on the fair page of abdominal surgery. As a representative body of the surgeons and gynecologists of the South, the society should condemn the reckless and thoughtless plunging in this delicate and difficult work, without knowledge, fitness, or preparation. The statistics of the skilled, who had learned to minimize risk and cope with difficulties, should not serve as an argument with the inexperienced to secure subjects. The responsibility of human life should not be ignored in the craving and struggle for notoriety or fame.

With regard to the relative merits of the abdominal and vaginal operations for the removal of the ovaries and tubes, or of the uterus with the appendages, Presi-

dent Lewis said that divergent opinions are entertained and heated discussions have arisen. For the vaginal method it is claimed less shock is produced, better drainage is obtained, the abdominal walls are not weakened, and the extirpation of the uterus removes a menacing source of infection and of physical and nervous disturbance. For the abdominal operation rapidity of execution is contended, with increased security to adjacent organs and facility of repair when injured, as the structures are always in view. The removal of the uterus is also condemned as complicating and unwarrantable unless justified by the state of the organ. In the modified vaginal method, as practised by Doyen and others, the uterus is not necessarily sacrificed, nor are a sound ovary and tube. It is in touch with the conservative movement of the day, and is in marked contrast with the ultra-radical operation of Péan.

Memorial Address on Dr. Paul F. Eve.—This was delivered by DR. RICHARD DOUGLASS, of Nashville, in which he said a retrospect of the lives of great men inspired us with the spirit of emulation and indicated to the ambitious mind the paths to fame. Prof. Paul F. Eve had three distinguishing characteristics—energy, consistency of purpose, and extreme modesty, and upon them he built for himself an everlasting reputation and secured an imperishable place in the temple of fame. It is not alone as surgeon and teacher that his reputation rests. As a contributor to current medical literature he was a conspicuous authority. In military surgery he was without a peer. His experience in Poland had engrafted a taste for the work, which unfortunately in later years, as one of the chief surgeons of the Confederacy, he had more than ample opportunity to gratify. As the result of his observation and work during the war of secession he recorded many valuable facts which the surgeons of to-day would do well to ponder. As a lithotomist Dr. Eve was pre-eminent. While his preference was for the bilateral method, yet he was not wedded to it, and appreciated the many advantages of the suprapubic operation and often practised it, not, however, with the same success that he achieved by perineal section. Thoroughness characterized every undertaking of his life. When the great and good life of Dr. Eve came to an end, suddenly but peacefully on November 3, 1877, he had reached more than his three-score years and ten, and, dying, left behind him a name that was destined to live on in surgery through many generations.

The Relations of the Tuberculous Diathesis to its Local Manifestations.—A paper on "The Relations of the Tuberculous Diathesis to its Local Manifestations" was read by DR. J. McFADDEN GASTON, of Atlanta. He said that in considering the various forms in which tuberculosis shows itself in different structures, there must be an underlying element pervading the whole organism, which results from a general deterioration of the secretions. Whether there is a predisposition to the development of tuberculosis in certain parts or organs in advance of any constitutional disease or not, this change occurs in connection with the general impairment of the vital forces which characterizes the tuberculous diathesis. While most recent authorities do not make a distinction between scrofula and tuberculosis, there is a fundamental difference in their general and local development. We have different characteristics of tuberculosis when it involves separate organs and structures of the body in a distinctly circumscribed form, or is defined as miliary tubercle in different structures, and yet the dyscrasia which marks the lymphatics under the designation of scrofula differs materially from any of the varieties of tuberculosis heretofore recognized. Dr. Gaston touched briefly on the causes of tuberculosis, and reference was made to the papers that were pre-

sented before the last meeting of the American Surgical Association on important tuberculous lesions. The presence of a condition recognized as a tuberculous diathesis corresponds in some respects with the cachexia of carcinomatous tumors, and is held by many to be hereditary. There has been quite a revolution in the opinions of those best versed in the pathology of tuberculosis as to the transmission of this disease from parent to child, and also in regard to the communicability from one individual to another by ordinary contact in social relations. It is fair to conclude that great caution should be observed in putting restraints upon the marriage of those suffering with pulmonary consumption, and the association of those laboring under this disease should be limited as far as practicable. Finally, the predisposition to tuberculosis cannot be relieved by a surgical operation upon the diseased structures, but must be corrected by remedial agencies acting through the absorbent and secretory organs.

—
Second Day—Evening Session.

The Rational Treatment of the Diseased Appendix by Operation.—DR. A. V. L. BROKAW, of St. Louis, read a paper with this title. He said the question had been vigorously discussed, Is appendicitis a surgical disease at all times, or surgical only at times? He wished to be put on record as favoring the first proposition. He was aware that some ultra so-called conservative practitioners claimed that the surgeon who advocated the removal of the appendix in every case when diseased was a dangerous faddist, an extreme sufferer from an inoculation of the bacillus operativus. He earnestly advocated early operation as soon as the diagnosis was made. He would always operate when there was even a slight chance of saving a life, regardless of damage to statistics. Invariably operation should be insisted upon in the recurrent cases. With the knowledge of this dread disease evolved from the mortuary chambers and the treacherous clinical course in a considerable percentage of cases, why should the rational treatment of all cases be other than by prompt surgery?

Report of Cases of Appendicitis.—DR. JAMES A. GOGGANS, of Alexander City, Ala., followed with a paper on this subject. The fact that physicians generally took the stand that operative interference in appendicitis was called for only in exceptional instances, when the disease advanced to suppuration, gangrene, and perforation, made the treatment of appendicitis a never ceasing controversy; hence his excuse for reporting a few illustrative cases that had come under his observation, hoping thereby to add what he could to harmonize the difference between the physician and the surgeon on this, the most frequent and important intra-abdominal lesion, in his opinion, of the present day. The main point at issue between the physician and the surgeon in the treatment of appendicitis depended much on a perfect diagnosis. This, too, accounted in a measure for their differences of opinion as to when the medical treatment should end and when the surgical treatment should begin. According to his experience in the management of this affection, there was only one course to pursue, namely, to remove the appendix just as soon as the diagnosis had been made. Usually he deferred the operation until the bowels had been evacuated by first administering a few small doses of calomel, followed by a saline purge.

DR. JOSEPH TABER JOHNSON looked upon appendicitis as a surgical disease, and believed it should be so treated. He deprecated the use of opium and considered it the patient's greatest enemy, in that it masks the symptoms and rendered diagnosis exceedingly diffi-

cult. If opium were not given in some cases a diagnosis could be easily made, surgical interference resorted to, and the patient's life saved.

DR. JAMES MCFADDEN GASTON spoke of the importance of making a distinction between cases that have foreign bodies in the appendix and those of a catarrhal nature leading to a general inflammatory condition around the caput coli. Until we had inflammatory conditions which led to an exudate around the caput coli, it was difficult to definitely determine the exact condition which existed in supposed appendicitis. He was becoming more and more impressed with the fact that there were cases of appendicitis that were unattended with perforation, and that these were curable without operative measures. An illustrative case was cited.

DR. F. W. MCRAE did not believe every case of appendicitis was a surgical one from the outset. A disease which showed so large a percentage of recoveries was not always an operative one. Treves and other English surgeons had shown that eighty per cent. of patients with appendicitis got well without operation. While demonstrator of anatomy he examined every appendix which came upon the dissecting-table, kept an accurate record of each case, and found that about thirty-three and one-third per cent. showed evidences of previous inflammatory trouble around the appendix. The individuals, most of them convicts, had died of other diseases.

DR. HOWARD A. KELLY favored early operation, alluded to the difficulty sometimes of distinguishing appendicitis from tubal and ovarian disease of the right side, and related a case in point. In the case of a woman with very high temperature and distended belly he opened the abdomen, evacuated a quart of pus, washed out, and found a gangrenous tube and ovary, as well as a gangrenous appendix. The patient recovered nicely from the immediate effects of the operation, but died on the thirtieth day thereafter from abscess of the liver.

DR. CHARLES P. NOBLE said the safest general rule was to operate as soon as a diagnosis of appendicitis was made. It was impossible to differentiate the patients who would recover from a primary attack from those who would die.

DR. M. C. MCGANNON, of Nashville, recalled one case of appendicitis, that of a boy, in which the temperature rose to 105° F. The patient was delirious. The abdomen being opened the appendix was found to be black but not perforated. It was easily removed, and the boy made a prompt recovery. He believed that in many cases, if the physician should wait and watch for distinct symptoms before operating, patients would die.

DR. A. J. COLEY had met with six cases of appendicitis, and made a strong argument in favor of early operative interference.

DR. A. M. CARTLEDGE said the diagnosis was the only problem that practitioners were especially concerned with, together with the proper technique in the execution of the operation. The more he operated, the more he was inclined to believe we should operate on every operable case as soon as the diagnosis had been made. Mistakes were made by waiting and watching for symptoms to manifest themselves. Very few, if any, surgeons could tell when an appendix had ruptured.

DR. GEORGE BEN JOHNSTON said that for the sake of statistics operations for appendicitis should be divided into two classes. First, those which are performed for recurrent attacks of the disease, and those which are employed for the relief of the severer varieties in which perforation has occurred, or will take place when there is pus present. If the surgeon was to operate upon recurrent cases, it was better for him

to do so between the attacks, in order that he might choose his time for operation. While there were cases of the disease that recovered without treatment, the best results were obtained by surgical interference.

DR. N. P. DANDRIDGE said that with increasing experience he was more and more favorably disposed toward early operation; at the same time cases presented themselves in which he did not advise operative measures. He believed that some of the desperately bad cases were and could be saved by operation.

DR. R. B. RHETT said he had operated twenty times for this disease. He cited some interesting cases illustrating the importance of early operation.

DR. W. D. HAGGARD, JR., called attention to the method of Gerster to prevent contamination of the peritoneal cavity in opening appendicular abscesses that are not adherent to the abdominal wall or are not walled off. It consists in introducing thick layers of iodoform gauze through the abdominal incision and packing it between the walls of the abdomen and the abscess sac itself, so that in the subsequent steps of enucleation there is no possibility of soiling the peritoneal cavity.

DR. D. FORD, of Augusta, Ga., spoke in favor of early operation, believing that if patients were not operated on, sooner or later perforation would occur, followed by general peritonitis and death.

DR. W. E. B. DAVIS thought there were few cases of appendicitis that gave rise to general peritonitis in which the surgeon was called and could do any good. Frequently the surgeon was called too late. Even though the family physician recognized the condition, it was not an easy matter to persuade the patient to be operated on within the first twenty-four hours, and unless these cases were treated surgically within twenty-four or thirty-six hours very few of them could be saved. All cases of severe attacks of the disease, in which pain was intense, if seen the first day and consent was obtained, should be operated on. In all cases in which there was a second attack, operative measures should be resorted to.

DR. GEORGE A. BAXTER spoke of obliterating appendicitis and asked the essayists to give their opinion of it in their closing remarks.

DR. BROKAW replied that obliterating appendicitis was nothing more nor less than the relapsing form of the disease, as a rule, or what had been termed "growling" appendicitis.

DR. GOGGANS said, in closing, that he could no better present his views on early operation than to say, that if he had the disease, or peritonitis supervening upon it, he should demand operation. If he was so low that he could not stand a general anæsthetic, he would take a local one, and would ask the surgeon to open his abdomen and remove the appendix.

Compound Comminuted Fracture of the Wrist.—DR. H. M. HUNTER, of Union Springs, Ala., reported an interesting case of compound comminuted fracture of the radius and ulna, near the wrist-joint. He had been unable to find a similar case on record in the literature of fractures. There were three points with regard to this case. First, that he was unaware of a similar fracture being reported; second, he had never read nor heard of the method he had described to reduce the fracture of the forearm. Third, he had never seen nor read of such perfect results as were obtained in this case, the wrist having perfect motion and there being absolutely no interference with supination and pronation.

DR. N. P. DANDRIDGE, of Cincinnati, reported a case of transperitoneal ligature of the external iliac artery for inguinal aneurism, in which he removed the aneurismal sac.

In the discussion, DR. W. E. B. DAVIS also reported a case of ligation of the common iliac for aneurism of

the external iliac, which was followed by an excellent result.

Officers Elected.—The following officers were elected: *President*, Dr. George Ben Johnston, of Richmond, Va.; *First Vice-President*, Dr. F. W. McRae, of Atlanta, Ga.; *Second Vice-President*, Dr. W. E. Parker, of New Orleans, La.; *Secretary*, Dr. W. E. B. Davis, of Birmingham, Ala.; *Treasurer*, Dr. A. M. Cartledge, of Louisville, Ky.

DR. E. S. LEWIS, of New Orleans, was elected a member of the judicial council, to supply the place of Dr. Hunter McGuire, whose term had expired.

The association then adjourned to meet in St. Louis, Mo., the second Tuesday in November, 1897.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEETING OF MEDICAL COUNCIL—THE ELECTIONS—THE DUBLIN HALL CASE—PRELIMINARY EDUCATION, ETC.—THE LATE DR. FRASER, SIR B. W. RICHARDSON—SURGEON-MAJOR FOAKER AND SURGEON-GENERAL MARKEY—OPERATION ON SIR W. MACCORMACK—ABORTION MONGERS.

LONDON, November 27, 1896.

THE General Medical Council met on Tuesday. It seems a pity that the session began while the election of the direct representatives is pending, as two of them are not candidates for re-election, and other changes are possible—in fact, generally anticipated. The subject of the election came up in the council, Dr. Glover as a candidate asking to be furnished with a list of recent registrations. We are flooded with election circulars and post cards, and in some cases ladies have been canvassing. Some vexation has been expressed at this, but if all the arts of parliamentary electioneering are to be tolerated—and this seems to be the case—why not this? With such an educated constituency, I should have liked to see the addresses of all candidates forwarded with the proxy papers, and the rest left to the journals and the good sense of the voters. But all the candidates are incurring heavy expenses, and in some cases the hat is already going round for their assistance.

The proceedings were once more opened with the president's address. I should think Sir R. Quain must be getting tired of preparing these discourses, which are of no practical use; and, as the time of the council is estimated to cost a guinea a minute, something would be saved by dispensing with them. To sketch out the course of business in this way is wasteful. The executive should furnish the *agenda*, and the council go to work in a business-like fashion.

The Dublin Apothecaries' Hall case was taken up on Wednesday and Thursday. The council refused to appoint examiners, as requested by the hall, and that body will now apply to the privy council. What course "my lords" will take remains to be seen. They have expressed a willingness to assist the corporations in obtaining new charters to enable them to exercise discipline, after the manner of Cambridge universities; but some of the bodies are by no means anxious to obtain such powers. Edinburgh University has resolved to take no action in this direction, and other "authorities" will follow the example, until the profession insists or Parliament intervenes.

It was decided to improve the preliminary examinations. This is to be done by pointing out deficiencies to certain bodies, whose examinations are recognized. At first it was proposed that the changes should come into force in 1900, but an amendment to carry them

out at once was adopted. It is a question whether this system of recommendations is a good one, and there are not wanting those who would like to see the list of recognized preliminary examinations considerably abridged.

The procedure in penal cases was discussed on a proposal of the executive committee, which was referred back to that committee for further consideration.

Death continues his severe demands on our ranks. Dr. Patrick Fraser died on November 12th, "full of days," having been born in 1805. In younger days he served as surgeon in the flagship under Admirals Sartorius and Napier. In 1845 he became physician to the London Hospital, and retained that office until 1866. During that period the Crimean war broke out, and in 1854 Dr. Fraser and the late Mr. Wordsworth offered their services to the government. The hospital authorities kept their appointments open for them. How well I remember them both at that time, and the esteem in which they were held was enhanced by their patriotism. It is now some twenty years since Dr. Fraser retired from practice altogether, and a generation has grown up to which his is a name in ancient history. Those who knew him remember his sterling character, his intelligence, kindness, and skill. You may remember his book on "Wounds of the Chest."

Sir Benjamin Ward Richardson died early on Saturday morning, after a very brief illness—so brief that, although I knew him well, I did not hear of it until Sunday morning. He was at a City meeting on Wednesday. In the evening his son, going to his consulting-room, found him on the couch in an unconscious state from an apoplectic seizure. At first some hope was entertained by the medical friends hastily summoned, but he did not regain consciousness, and on Saturday breathed his last. He leaves a widow and two sons. He took the M.D. of St. Andrews in 1854, in which year he gained the Fothergillian medal of the Medical Society of London. He had been physician to the Metropolitan Dispensary and some other institutions. He was elected F.R.C.P. in 1865, and the following year gave the *materia medica* lecture at the college. One year more and he obtained the coveted F.R.S. Other honors and distinctions fell to his lot, and in 1893 he was made a knight. Sir B. Richardson took an interest in many branches of science and medicine, as well as in numerous public questions. His physiological researches are pretty well known; some of them were outlived, so to say; others awaited revision. His work on "Coagulation of the Blood" is an example of how quickly in these times theories are superseded. But Richardson was a practical physician, as evidenced by his "Clinical Essays," his "Discourses on Practical Physic," and the ten volumes of *The Asclepiad*. He was also an enthusiastic sanitarian. You will remember his "Hygeia, a Model City," which appeared in 1875, and was much talked of by the public. Among other works in this branch were "National Health" (1889), and "Chadwick's Health of Nations" (1887). How great was his activity and how widespread his interest may be judged from his numerous contributions to various journals and societies. He was also the author of three plays, and in 1888 issued "The Son of a Star," a romance, though at that time he was engaged in the temperance campaign, with which of late years he has been so identified. That work may be dated from 1876, when he delivered the Cantor lectures of the Society of Arts, taking as his subject, "Alcohol." For some time previously he had been investigating the properties of this substance, and I suspect some of the temperance leaders heard a rumor of his results, and used influence to get him appointed lecturer and to induce him to take that opportunity of publishing his researches. Be that as it may, the lectures proved to

be a valuable support, from the scientific aspect, to the advocates of abstinence from alcoholic beverages. Later on the author threw all the force of his energies into this scale, and his loss to the temperance cause is irreparable. He has been for several years physician to the Temperance Hospital, which has taken an important place among our charities. His adaptation of the ether spray was the outcome of his researches on anæsthesia, and largely contributed to the success of the testimonial of £1,000 and a microscope, presented to him in 1868. Methylene bichloride as a general anæsthetic was another outcome of his researches. He designed the lethal chamber now in use for the painless extinction of lost and starving dogs, etc. He was also interested in an equal or greater degree in making our slaughterhouses less terrible, by adopting painless methods of killing. Cycling, too, attracted the early attention of this versatile physician, and he became an expert wheelman.

Surgeon-Major Foaker, who died on November 12th, in his eighty-sixth year, joined the army in 1838, was in the principal battles of the Crimean war, and retired in 1860.

Another distinguished army surgeon died last week, suddenly, while still on active service, and fifty-nine years old. This was Surgeon-Major-General Markey, C.B. He joined the medical staff in 1859, and had seen much service in India, Afghanistan, and Egypt.

Sir William MacCormack is better. A local empyema developed, which has been drained. The temperature fell then and the appetite returned. I am assured he is now doing well.

A criminal abortion case has excited some attention. A qualified doctor was tried for murder, with his assistant. The jury found manslaughter. The doctor was condemned to penal servitude for life; the assistant gets off with five years.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE SCHOOL OF THE SALPÊTRIÈRE—CHARCOT AND RAYMOND—RAYMOND AND CHARCOT—ITS FOUNDER AND PROPAGATOR—ITS CHIEF TO-DAY—RAYMOND'S LABORS—HIS GREAT AND VALUABLE WORK JUST PUBLISHED—JEAN CHARCOT—VIGOUROUX—ELECTROTHERAPY, ETC.

PARIS, December 14, 1896.

Two names are indelibly written in the history of the Salpêtrière; two names will shine forever over the domain of neurology—Charcot and Raymond.

The old hospice situated in a remote quarter of Paris at an angle of the Boulevard de l'Hôpital, was installed as early as the year 1653 in the buildings of a small arsenal as an asylum for poor, aged, and infirm women. The name Salpêtrière was given to it perhaps for want of a better, perhaps because until then the buildings had served for the manufacture of saltpetre. In 1684 in the centre of the hospital was constructed the workhouse or prison for lost women. It was, however, not until 1791 that patients having incurable mental affections, who had been up to that time treated at the Hôtel Dieu, were transported to the Salpêtrière. A few years later, in 1795, the workhouse or prison was abolished and given up to the infirm, the building named Saint Vincent de Paul becoming an important service in the hospital. Other buildings were added from time to time until the completion of the vast pile with its parks and gardens that one now sees. The Salpêtrière of to-day, surrounded on all sides by its high walls, the lofty dome of the church towering majestically above its numerous and immense buildings, the architecture of which belongs

to different epochs, like old Gothic cathedrals or palaces, gives one the impression of a smaller city within the great one—a city not devoted to pleasure but to the care of the aged, the infirm, the insane, and those suffering from every imaginable form and variety of nervous disease.

Already in 1862 the population of this little city of the diseased numbered five thousand souls, the total number in 1896 being about seven thousand. What a field for neurological study and clinical work—the largest and greatest in the world. It was Charcot aided by Raymond who founded the school of the Salpêtrière, properly and scientifically speaking. It is left to Raymond, in every particular the equal of his dead colleague and friend, to carry on the great work, and the title of “chef d'école,” left by his predecessor, has fallen upon him who deserved it most. Professor Raymond's Tuesday's and Friday's lessons or clinics, which he began two years ago, are frequented by hundreds of physicians and students from every quarter of the globe, who come to familiarize themselves with the diagnosis, prognosis, and treatment of diseases of the nervous system. Professor Raymond's written contributions to science have been many and valuable, the most important of which, serving as a text-book to students and works of reference to practitioners, is “Diseases of the Nervous System,” in two volumes, the first being devoted to muscular atrophies and amyotrophic diseases, the second to systematic sclerosis of the spinal cord and a study of diseases of the nervous system in Russia.

His last and greatest work has just appeared under the title “Clinic of Diseases of the Nervous System.” These are the clinical lessons that Professor Raymond has held at the Salpêtrière during the first of the two years that are now expiring since his succession to the chair of neuro-pathology. They were given in the vast auditorium, forming with the reception rooms and electrical hall, of which more anon, an entire building in the grounds of the Salpêtrière. This auditorium cannot properly be called an amphitheatre, being rather a hall or theatre, capable of seating and accommodating many hundreds. At one end is an elevated platform or stage and at the back of this is a beautiful oil painting of colossal size in a handsome gold frame, covering the whole end of the edifice, painted by Robert Fleury and representing Pinel breaking the irons from the wrists and ankles of the insane as he renders to them liberty and daylight, in conformity to his famous words: “The insane are to be treated, not punished”—an appropriate background for the great work that is going on there year after year without interruption. This picture was presented to the Salpêtrière by the government. It is here that Professor Raymond demonstrates in the brilliant and majestic style that characterizes him and lectures upon the different cases of nervous disease that are brought to him for diagnosis and treatment; sometimes there are several different types of a given pathological process presented at the same *séance*, besides many and various others, so that he finds it no easy task to get through with them all in the two hours allotted to his clinical work. Professor Raymond is a man above the medium height in stature, with a broad expansive brow and quick intellectual eye; he speaks smoothly and not too rapidly, but without a hitch; never at loss for the right word, he has the power of riveting the attention of his hearers from the beginning to the end of his lessons. He confides to others the care of taking down what he says. This has been admirably done by Drs. E. Ricklin and A. Souquer, who have done Professor Raymond and themselves much credit in compiling and editing a work that is destined to be the greatest epitome of neurology, neuro-pathology, and neuro-therapeutics of

our time. We apply the word “destined” to what already really exists, simply because this is the first series, 1894-95. Others are to follow.

The book in question is a handsome octavo, printed on thick paper with large type, from the press of Octave Doin, Paris. The colored plates are by Jean Charcot. After the first chapter, which is devoted to Professor Raymond's inaugural lesson, being really a eulogium of the departed Charcot, follow in succession three others, headed “The Work of a Man.” In these Charcot is considered as a physician, and, above all, as a neuro-pathologist, with especial reference to his study and researches on hysteria, hypnotism, and treatment by metallo-therapy, suggestion, and transport.

“The Work of an Epoch” now claims the five succeeding chapters. This epoch is divided into four periods, the first of which, beginning with Charles Bell and his works in the year 1814, sets forth the erroneous opinions of Walker, Bellingeri, and Valentin, upon the respective functions of the anterior and posterior roots of the spinal cord. He pays *en passant* a tribute to Magendie, who in 1839 discovered the recurrent sensibility of the anterior roots, and continues by referring briefly to the work of Stilling and Wagner in 1842 to 1850, until which time it was thought that the two varieties of nervous fibres, sensitive and motor, ascended the entire length of the spinal cord to unite and accord in the brain. In his recapitulation of the anatomical and physiological discoveries during the first half of this century, he dwells at some length upon the rudimentary state of nervous pathology during that period.

The end of the fourth period brings us down to the present day. This period is marked by a revolution in our conception of the fine structure of the nervous system, which we owe to the perfections in histological technique as it now exists.

Professor Raymond after demonstrating the ectodermic origin of the neuroglia, passes on to the application of new notions and ideas to nervous physiology and pathological anatomy. He says: “The procedure of Golgi furnishes us the means of studying the exterior form of nervous units and their connections. The theory of neurons is the most important result that it has furnished up to the present time.”

The procedure of Golgi he believes will shortly elucidate many anatomo-pathological questions. “Thus, the nitration of the peripheral nerves will permit us to see much more distinctly the fibres without myelin and to distinguish those fibres from empty sheaths.”

The remaining of the thirty-two sections are a record of daily work done at the Salpêtrière, embracing the study with cases of bilateral paralysis of the deltoid muscle by elongation of the two circumflex nerves—hemorrhagic compression and radical paralyzes of the brachial plexus, etc.

Considerable space is occupied by the lesions of the cauda equina, about the pathology of which comparatively little is known, being barely sketched, often omitted altogether from classical books on neurology. Two cases, both of women, are presented as different types of disease of the cauda equina. The first type begins with lancinating pains in the left leg and around the waist, hyperæsthesia of the left thigh and gluteus, cutaneous anæsthesia of the perineum, with hyperæsthesia of the internal face of the left gluteus, and of the external border of the corresponding foot: anæsthesia of the mucous membranes of the urethra, bladder, rectum, and left half of the vulva; vesico-rectal troubles; disturbed motility of the left inferior limb accompanied by atrophy of the same; stepping and exaggeration of the patellar and plantar reflexes, with a sacral left unilateral eschar, these completing the group of symptoms thus briefly summarized.

The contrast with the second clinical type is highly interesting. This begins with pains in the lower limb on the right side, cutaneous hyperæsthesia, incontinence of the sphincters, anæsthesia of the perineum, of the vulva, of the right gluteus, of the fibular region, as well as of the internal border of the right foot.

The differential diagnosis of cases of this nature must be made from dorso-lumbar rheumatic arthritis, lumbago, sciatica, and Pott's disease; also from the cerebral, spinal, neuritic, and hysterical monoplegias.

The lessons on lateral amyotrophic sclerosis and labio-glosso-laryngeal paralysis of bulbar and cerebral origins are followed by practical essays on Jacksonian epilepsy. The eminent author lays particular stress on the chapters dealing with heredity in nervous disease; heredity and predisposition dominate nervous pathology. Nervous heredity and its result, a state of degenerescence, are prime factors in the etiology of true psychoses and neuroses, such as hysteria, epilepsy, exophthalmic goitre, Huntington's chorea, tics, certain tremblings, Parkinson's disease, etc. Not the least interesting are the closing chapters on the myoclonias and ambulatory deliria with fugues and hysterical somnambulism.

As regards the therapeutic side of this comprehensive work, Professor Raymond seems to have in mind in general two principal plans of treatment—the one dealing with the symptomatic, the other with the causal indications. Surgical intervention is at times to be resorted to, for instance, in deformation of the rachis with compression fracture and certain tumors—trepanation for epilepsy, etc. In Jacksonian epilepsy he counsels revulsives, preferably *pointes de feu* (ignipuncture) on the parietal region and the bromides. He is a staunch advocate of electricity in all its forms, a treatment indicated perhaps more frequently than any other in the different forms of paralysis. This is true of the galvanic and faradic currents, static electricity being more efficacious in hysteria and neurasthenia. Injections of strychnine also find favor with him in symptomatic paralysis of the bladder and large intestine, but are administered always with extreme prudence.

Antipyrin and the subcutaneous injection of morphine are his typical mild and heroic calmatives in pain. In many cases, of course, only palliative treatment is advised. Hypnotism and suggestion are reserved for hysterical subjects.

Professor Raymond pays a well-merited compliment to American surgeons when he writes on page 112: "The works of the American surgeons, to which I made allusion a moment ago, had been worth to us documents of great value relative to traumatic neuritis." We close the book fully convinced that this is the first series of the greatest and most important work of our day on diseases of the nervous system.

No physician passing through Paris should fail to pay a visit to the Salpêtrière; if he cannot attend Raymond's clinic he can at least see the hospital, the wards, buildings, etc., with the grounds, lawns, flower beds, squares, and streets. He will certainly find there Dr. Jean Charcot, the efficient chief of clinic, who has inherited his distinguished father's amiability of temperament and will take great pleasure in showing him what is most interesting in this neurological world. He should not fail to see the electrical hall, where every modern electric appliance is used in the treatment of diseases of the nervous system. Patients are treated here several days in the week. This department is under the direct charge of Professor Vigouroux, to whom it really owes its existence. Professor Vigouroux has been for years chief of the electrical department of the Salpêtrière and his writings on electricity and the treatment of neurasthenia

by Franklinism are classical text-books. The two static machines used are Wimshurst's and by connecting the isolating benches together by means of small chains eighteen patients are treated at once. This hall is connected by a very short passageway with the waiting-rooms and Professor Raymond's clinic. Beyond, a new electrical building has been erected within the last year or two, under the direction of Dr. Huet, and provided also with a Wimshurst static machine, from which the current is given to twelve patients at once, thus making a total of twenty-eight that can receive treatment every ten or fifteen minutes. The new installation is also provided with apparatus for giving complete faradic and galvanic baths.

Nor should the visitor omit spending a half-hour in the museum of the Salpêtrière. The collection of casts of brains and the heads out of which they came will alone repay him. Especially worthy of study are the cerebral depressions. In the centre of the museum is a full-length figure in wax, representing a case of ataxic atrophy, given by Charcot and illustrating the degree of muscular atrophy attained with the ataxic dislocation of joints which characterize tabes dorsalis when the disease has lasted many years.

Another building is occupied by the pharmacy, one of the largest and best appointed in Paris; still another by the autopsy amphitheatre, and so on. But we must stop. To do full justice to the subject a large volume would be necessary: but this sketch, brief as it is, will give some idea of the great school of the Salpêtrière and of the work done by Charcot and by its chief to-day, Raymond.

THE TREATMENT OF TYPHOID FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with much interest Dr. Nammack's letter in your issue of November 28th, in reference to the Woodbridge treatment of typhoid fever. It is a very curious thing that one may read all sorts of reports upon the results of this treatment—some highly commendatory, others quite the reverse, and still others which award to the treatment certain advantages but deny the somewhat sweeping claims of Dr. Woodbridge for it. What Dr. Nammack says about the ideal treatment of the poor man afflicted with typhoid fever well expresses what many of us have long felt. An easy and simple treatment, which can be carried out without the expense for attendance and paraphernalia called for by the Brandt treatment, would be a blessing of inestimable value to suffering humanity, and one, let us hope, not unattainable. Whether a serum treatment shall be found, as Dr. Nammack seems to expect, seems quite problematical for several reasons, which need not concern us here.

What has led me to take up your valuable space with these few remarks are the enormous importance of the subject and the belief that after much deliberation I can offer some suggestions in the treatment of typhoid which will prove of undoubted value. In the present state of our knowledge, the following plan seems to be the most likely to give satisfactory results when for any reason the Brandt treatment may be inapplicable. Just as soon as the patient comes under observation and is found to have a continued fever which cannot be controlled by quinine, whether the serum-diagnosis test of Widal shall indicate typhoid or not (and I am informed that the value of this test is not as yet by any means determined), let him be put upon small frequently-repeated doses of calomel, and let these be continued until the constitutional effects of the drug have manifested themselves—to wit, the mercurial fetor in the breath, some sponginess and swelling of the gums, and the characteristic

stools. To accomplish this with one-twentieth-grain doses of calomel every one-quarter to one-half hour may take two, three, or four days, or perhaps longer, since individuals differ so markedly in susceptibility to the action of the drug. In the mean time, let elimination and depuration be increased by copious draughts of pure water. After the system has once been brought under the influence of calomel, it seems quite probable that Dr. Delafield's suggestion (made in the recent discussion of typhoid before the section on general medicine in the New York Academy of Medicine), that no mercurial will do any more good, is a valuable and timely one, and that gentle catharsis can be better maintained by Epsom salts (or by other salines or mineral waters).

I might suggest in passing that it seems probable that the shortening of the mild cases of typhoid, which Dr. Delafield noted among the thirty cases which he had treated with the Woodbridge treatment, and which he reported in the discussion just alluded to, was due to the early use of calomel in these cases. It might be safe to go a step further, and claim that these cases were mild because the use of calomel had made them so, although, if such was Dr. Delafield's opinion, he did not express it. So far as I know, no one has ever maintained that calomel will abort every case of typhoid nor will quinine control every case of malaria. Yet, from *a-priori* reasoning, it seems probable that a drug with the eliminative and antiseptic action which calomel institutes in the intestine may and in some cases does sweep out from the intestinal tract the specific micro-organism whose presence and action there is undoubtedly the cause of the group of lesions which we know as typhoid fever. The assertions of Wunderlich and other eminent Germans (Ziemssen's Encyclopædia, etc.) to this effect cannot in my opinion be justly disregarded.

Following Dr. Delafield's suggestion, I would discontinue the calomel just as soon as the system has been brought under its influence, and would maintain gentle catharsis by Epsom or other salts or mineral waters, aided by copious draughts of pure water, and would put the patient upon the chlorine-water treatment of Burney Yeo,¹ and keep him on that and on liquid diet until convalescence is well established.

In all the recent discussions of the treatment of typhoid fever which have met my eye, I cannot now recall a single allusion to the method so ably advocated by the distinguished Englishman,² who not only prefers it to the Brandt treatment but claims for it a much more favorable mortality rate.

Nor have I seen a recent paper upon this treatment except one by Dr. Reynold Wilcox,³ who reported the successful use of chlorine-water treatment in a limited number of desperate cases of typhoid, and who has recently informed me that he is still in favor of the method.

The treatment is mentioned without comment in Allbutt's "System of Medicine," and Wilson's "American Text-Book of Applied Therapeutics," 1896.

My own experience with it is limited to about a dozen patients, all of whom recovered except one hospital patient, who was moribund when the treatment was begun.

As to the Woodbridge treatment, like Dr. Nammack, I hoped for great things from it, having convinced myself, after having gone through an epidemic of sixty cases while in the army, that the preliminary use of calomel or other mercurial until the system shall be mildly mercurialized, as directed by Dr. John Harley (Reynold's "System of Medicine"), does tend to abort typhoid fever and does render its subsequent course

milder and safer than when no mercurial is used. Knowing this about the mercurial part of the treatment, I had hoped that the so-called antiseptic and eliminative treatment, which Dr. Woodbridge seeks to carry out with his guaiacol, menthol, etc., would prove equally efficacious; and that, in short, the ideal treatment had at last been found. As the matter now stands, it would seem to be our safest course to use the combination which I have above outlined. We shall thus combine valuable methods of treatment advocated by various authorities, of whom I might mention Wunderlich, Harley, Delafield, Thistle, Burney Yeo, Wilcox, Woodbridge, and a number of others.

I hope that I have not made this letter too long. I feel that Dr. Burney Yeo's chlorine-water treatment of typhoid has not received the attention, in this country at least, that its importance and, I might add, its harmlessness and the ease with which it can be administered demand.

And I hope, further, that Dr. Nammack (if he has not already tried it) will give this method a trial; and if he does I believe that he will not despair of getting hold of a treatment of typhoid which is admirably adapted to the poor man's case, as it does not require any expensive appliances nor a high degree of intelligence in the nurse.

RICHARD C. NEWTON, M.D.

MONTCLAIR, N. J., November 28, 1896.

THE INTUBATION TUBE AND ITS MODIFICATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: An article on intubation by Dr. Thomas J. Hillis, which was published in the MEDICAL RECORD of November 28th, calls for a few remarks. The only part of the article which I wish to criticise is that advocating the use of an intubation tube having an appliance designed to facilitate extraction, to the exclusion of all other considerations. This appliance, which destroys the function of the epiglottis by preventing its closure during the act of swallowing, consists of a semicircular wire which passes around and is raised a little above the posterior portion of the head of the tube; that portion of the latter corresponding to the interarytenoid notch is scooped out, leaving quite a little gutter for the entrance of food or vomited matter, which the epiglottis cannot possibly prevent because it is held up by this wire prop.

To exclude foreign material from the lower air passages the entrance thereto is doubly guarded by the epiglottis and the constrictor muscles of the larynx. Should the smallest particle of extraneous matter pass the first guard there is a violent contraction of the second which tends to arrest its further progress. Now when we place a tube in the larynx we destroy one of these guards and the whole duty of protecting this vital passage devolves upon the other, the epiglottis. During the evolution of intubation, with the single exception of devising a simple means of making the tube self-retaining, the greatest amount of experimentation was directed to overcoming the difficulty of swallowing under these circumstances. These experiments were continued long after the tubes were in every other respect as perfect as they could be made. It was soon demonstrated that no form of tube, however small the head, would permit the larynx to contract on itself as in the normal condition during the act of swallowing, and all further experiments were therefore directed to devising some means of aiding the epiglottis to perform the double work now imposed upon it. The best of the many devices tried is that now in general use, in which the shoulder of the tube is higher behind than in front, the object of

¹ See Amer. Journ. Med. Sci., June, 1894.

² Op. cit.

³ Amer. Journ. Med. Sci., September, 1895.

this arrangement being to meet the epiglottis half way, so to speak, thus utilizing to the greatest advantage its intrinsic power of contraction as well as the still greater power exerted by the base of the tongue, as the latter is drawn backward while the larynx is lifted upward and forward in the act of swallowing.

It is not claimed that liquids are thus completely excluded because the syringe-like action of deglutition forces some of them under the epiglottis, no matter how closely it may cover the mouth of the tube. But it is claimed that with rare exceptions the protection against the admission of vomited matter is absolute because there is no impediment to the escape of the contents of the stomach from the pharynx, such as exists in swallowing. A properly constructed tube in the larynx, therefore, does not contraindicate the use of emetics if called for.

Those who advocate the employment of this easy-to-get-out modification, if they think at all on the subject, must defend its use on the ground either that the epiglottis plays no part whatever in excluding food and the contents of the stomach from the air passages, and consequently that there is no objection to placing a prop under it, or that the entrance of these substances does no harm.

Every one of the numerous modifications of the intubation tubes that have from time to time appeared has been simply a greater or less degree of mutilation of the perfect instrument. No improvement has ever been made and it requires no prophetic knowledge to say that none ever will be made, except possibly in the material of which the tubes are constructed. Let those, therefore, who have inventive genius lying idle and who will not seek other fields for its investment try to discover some such material that will take the place of metal, and if they fail no one will be injured thereby. Intubation can never be made easy except by a large amount of practice, and it is consequently the operation of all others that should be confined to the hands of the few who have had or can have such practice.

A score of intubationists in this city, where they are now numbered by hundreds, could do all the intubations and do them skilfully, without much interference with other work and with very little increase in their incomes. Whatever be the motives that induce so many to bungle this operation they are certainly not mercenary, because diphtheria is essentially a disease of the poor, and, in the vast majority of cases, of the very poor, so that compensation bearing any relation to the nature of the work done is the rare exception.

J. O'DWYER, M.D.

"MOUNTAIN FEVER."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of November 7th Dr. Newton, of Montclair, N. J., is reported to have said before the New York Academy of Medicine at its meeting on October 20th, that "in the army he had seen many cases of so-called mountain fever, which autopsy proved to be typhoid with intestinal lesion." To us physicians practising in the mountainous regions of West Virginia anything in literature touching the question of mountain fevers is of great interest. We have a form of continued fever prevailing in this State epidemically all the year around. Its symptoms collectively form a picture not unlike that generally called typhoid, as seen at the bedside, which of course materially differs from that given in our text-books. In quite a number of these cases, however, the diagnosis of typhoid can be made only by exclusion and in some it seems altogether unwarrantable. It is surprising, however, to find what a great diversity of

opinion is held by local physicians as to the nature of this affection. Thus you hear a good deal about remittent fever, bilious fever, simple continued fever, mountain fever, gastric fever, and "the" fever. The absurd term "typhoid malaria" is still in common use among physicians here, and has almost become a household expression, to designate the severer forms of this type of fever with perhaps a fatal outcome, in spite of the fact that during the last war, when this term was first coined, "the mortality from typho-malarial fever was very much less than from typhoid fever" and seems to have been applied to the milder forms of enteric fever. The mortality from this fever was very great in former years but is now very small, probably not exceeding ten per cent., and no doubt due largely to the immigration of a better class of physicians along with the general development of the country. Aconite, quinine, and acetanilid have thus been replaced by care, judgment, and discretion. It thus happens that autopsies are scarce and hence the interest of Dr. Newton's remarks. I believe Dr. Newton could write some very interesting pages if he chose to tell us of his experience with this "mountain fever," from a clinical or, what would be more interesting, from a pathological point of view. Would not somebody else volunteer?

WILLIAM W. GOLDEN, M.D.,
Vice-President West Virginia Medical Society.
ELKINS, W. VA.

A COMMENT ON DR. MORRIS' PAPER ON APPENDICITIS, AS READ AT THE COUNTY MEDICAL SOCIETY, NOVEMBER 23, 1896.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Morris said: "Between trusting appendicitis cases to the surgeon or to the bacteria the decision must be a histological one. Some surgeons are more dangerous than some bacteria, and some bacteria are more dangerous than other surgeons. . . . Discussion as to the treatment—medical or surgical—in medical societies is farcical; it is a matter of individual art. . . . My statistics in the cited series of one hundred cases show a mortality of two per cent." The ergo is obvious. We all concede Dr. Morris' great skill.

Dr. Morris said: "Medical treatment will show a mortality of twenty-five per cent. in appendicitis. I should not like such a mortality in my family, although I could select families in which I would rather have it than in my own." There is an ergo here to be obvious later.

Dr. Morris discussed a series of one hundred cases operated upon by him with two per cent. mortality. It was conclusively proven that, on account of obstruction, abscesses, bands of adhesion, etc., the majority of these one hundred patients would have died under medical treatment. Where is the missing ergo?

It is here. The physicians who would have lost twenty-five per cent. of their cases of appendicitis under medical treatment managed, with great discrimination, to get this twenty-five per cent. to Dr. Morris' operating-table, thereby saving ninety-eight per cent. of the otherwise lost quarter. There can be no other explanation, considering the findings in the series of cases.

This missing ergo seems to the writer the vital point which the debaters miss, namely, how to weed out accurately for the knife this imminent twenty-five per cent. We hear of preconceived notions about operating as routine in all appendicitis cases, and about operating as routine in no appendicitis cases, and we can choose our consultant to suit our personal predi-

¹ Sternberg: "Reference Handbook of the Medical Sciences," vol. iii., p. 94.

lection; but would not the welfare of the patient be better conserved by a half-way meeting on this point between physician and surgeon?

The writer, in common doubtless with many other practitioners, has cases of appendicitis under observation which seem safe in the medical seventy-five per cent. category. He has had others which he has put in some skilful surgeon's ninety-eight per cent. Those in the seventy-five-per-cent. category have not yet met the two-per-cent. surgical risk.

EUGENE COLEMAN SAVIDGE, M.D.

66 WEST FIFTIETH STREET.

"CATARRHAL SALPINGITIS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of November 21, 1896, Dr. Vineberg, of New York, has an article upon catarrhal salpingitis, in which he reports several cases to illustrate this condition. I fail to see that he proves Case III. to be one of catarrhal salpingitis. Did the woman live because of the operation or in spite of it? I saw nothing alarming in her condition was reported. If she had received the same treatment before the operation as she did when her life was despaired of, would she not have escaped both the operation and the premature birth of her child? What benefit did she receive from the operation? Is it not a better illustration of the mania for operating than of catarrhal salpingitis?

ADELAIDE LAMBERT, M.D.

263 ORANGE STREET, NEW HAVEN, CONN.,
November 23, 1896.

A WOMAN PHYSICIAN IN TURKEY IN ASIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of October 17th, received here by me yesterday, you copy a paragraph from *The Hospital*, stating that the "sultan of Turkey has forbidden women physicians to attend upon his subjects." Dr. Grace Kimball, who has been a physician four, not fourteen years, at Van, to whom you refer, returned to America to take the post of physician in a woman's college in the East.

It is exactly three years ago to-day since I received from the Imperial Council of Medicine at Constantinople a diploma authorizing me to practise in all parts of the Turkish empire—this after presentation of my American diplomas and taking the usual "colloquium" examination required from all foreign applicants. Ever since I have travelled in many parts of the empire, never being required to show this diploma, nor even being asked for my tezkéré, or passport, by any official except upon landing at seaport cities. I have been able to render aid to every grade of the official families, and have from every class in the empire received only courtesy, appreciation, and gratitude. That I am the only woman who has the right to practise in the empire is true, but throughout this country many others without molestation are rendering valuable services in caring for the sick and suffering.

The opportunities afforded are unlimited—skin diseases among the Bedouin Arabs, malarial fever in the valley of the Jordan, leprosy in certain villages, and every variety of diseases of the eye in every place. On one tour lasting three weeks I saw twenty-three cataract patients; at a place where I remained a few days patients flocked from nineteen villages and I had nineteen strabismus operations. I remain in each place from three to seven weeks, according to the needs of the place and the number of operations to be per-

formed. I take a full supply of medical and surgical supplies and appliances with me, and two Syrian assistants share my labors.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 12, 1896:

	Cases.	Deaths.
Tuberculosis.....	99	104
Typhoid fever.....	30	13
Scarlet fever.....	134	9
Cerebro-spinal meningitis.....	1	3
Measles.....	131	4
Diphtheria.....	276	38
Small-pox.....	0	0

A Step Lower.—St. Louis is the proud possessor of two hospitals, each owned by a stock company and run for the profits in the business. People are solicited to become members by paying fifty cents a week, for which, in case of sickness, they receive hospital care. This is the lowest stage yet reached by the hospital abuse.—*Cleveland Journal*.

Ohio Doctors.—The *Columbus Medical Journal* says that, according to statistics there are 7,579 physicians in the State of Ohio, of whom 4,030 belong to the regular school, 1,199 are eclectics, 678 homeopaths, 155 physio-medics, and 757 unclassified. It is estimated that the new law regulating the practice of medicine has driven out between 1,500 and 2,000 irregular practitioners from the State of Ohio, and it is quite likely that others will find the climate entirely too warm for comfort.

Precocious Mothers.—The *American Journal of Surgery and Gynecology* notes that a girl ten years and two months of age had been delivered of a healthy child. In the *Atlanta Medical and Surgical Journal* of April, 1896, Dr. T. J. Mitchell, of Locust Grove, Ga., has an almost equally young mother, one who at the age of thirteen years was already the mother of three children. She first became a mother at the age of eleven years, three months, and twenty-three days, and gave birth to twins at the age of thirteen years, one month, and fifteen days.

The Nomenclature of the Brain shows how ideas may influence language. Our anatomical fathers believed that in the encephalon the homologues of all the parts of the body, both male and female, could be found in miniature; and if you turn to your text-book on anatomy to the description of the brain you will find arms, brachia; legs, crura; knees, corpora geniculata; breasts, corpora mammillaria; five stomachs, ventriculi, one of which was anciently called the womb, utriculus; a vulva cerebri; buttocks, nates; testicles, testes; a penis, clava; a vulgar name for the pubic hair, flocculus; a veil, velum interpositum; and a marriage bed, thalamus. With all this procreative apparatus before us, we are not surprised to find a union (fornix) and numerous offspring, quadruplets (corpora quadrigemina).—*The Language of Medicine*, by F. R. CAMPBELL, A.M., M.D. (pp. 47-48).

Crotte's New Method of Treatment in Consumption.—The French Academy of Sciences has recently appointed a committee—composed of M. Chauveau,

the physiologist; M. d'Arsonval, biologist and electrician, and Professor Bouchard—to make a thorough investigation of the alleged new cure for phthisis. Dr. Crotte's patients have been poor persons whom he has treated gratuitously, and it is said that he has greatly improved the condition of six hundred consumptives who had passed beyond the early stages of the disease. The antiseptic known as formaldehyde is inhaled in a gaseous form, and static electricity is at the same time applied to the chest. Dr. Crotte's theory is that the electricity opens the way for the germ-killing antiseptic and permits it to reach the bacilli in the cavities of lung tissue. This is not the first time that attempts have been made to apply germicides directly to the embedded bacilli of tuberculosis, but it has been said that an application of sufficient strength to kill the germs in the lungs would also kill the patient. Experiments with injections of carbolic acid have been made in this country and in Japan.

Presenility.—An infant of eight months is reported to have died in St. Louis, whose development, features, and general appearance were those of old age. The texture of the hair was coarse, like that of the adult, and hair grew upon the face.

Reading-Matter at Advertising Rates.—We regret to see in a Western exchange the names of two New York physicians of good standing attached to reading-matter in the advertisement columns. These articles were evidently written in their original form with proper intent and purpose. As they deal, however, in each instance with proprietary remedies, it has evidently seemed to the advantage of the manufacturing firms to reproduce them. They stand, however, side by side with bold laudation of nostrums, and the reflection is not creditable.

Sand Filters.—Allen Hazen (*The Sanitarian*, November) concludes: "The city of Philadelphia is now using water in a most wasteful and extravagant manner, and immediate measures should be taken to check such waste, and to reduce the consumption to a reasonable amount. It is possible to construct sand filters similar to those in use at London, Hamburg, and many other European cities in connection with the existing pumping stations, of sufficient capacity to furnish water for all reasonable requirements, for the present population, and for that which may be expected in the near future."

Laparotomy on a New-Born Infant.—Dr. Marjantschik reports the case of a full-term child, normal in every respect except for an apple-shaped tumor in the middle of the abdominal wall, extending from the ensiform process to the navel. Operation was done by Dr. Tschernow, about thirty hours after birth. The tumor was found to contain part of the liver, omentum, and intestines; these were carefully replaced, the edges of the abdominal wall freshened and then brought together, the sutures passing through all the tissues from peritoneum to skin. The infant died on the fifth day after the operation, autopsy showing the cause of death to be peritonitis and acute gastro-colitis. The writer reviews the thirty-one cases previously reported, in which seven of the patients died. He concludes that operation should be done in all cases if the child seems capable of life, and that it must be undertaken as early as possible. The method of operation must depend upon the size of the defect in the abdominal wall and the number of adhesions; but the most correct method is laparotomy.—*Centralblatt für Gynäkologie*.

When May Gonorrhœics Marry?—Dr. Lowenhardt (*Journal des Connaissances Médicales*) gives the following rules to be observed by physicians consulted

by blennorrhagics to gain medical consent to marry: As the virulence of the urethral discharge depends upon the presence of the gonococcus, the candidate should be subjected to numerous bacteriological examinations, carried out separately on the secretion of the anterior and posterior urethra. A slight secretion is not sufficient, but the urethral mucosa must be irritated in such manner as to place it in analogous conditions to those (excess in *Baccho et Venere*) which light up an indolent process. This result may be obtained by injecting a few drops of a five-per-cent. solution of silver nitrate into the urethra; if the discharge thus set up contains no gonococci, but is entirely made up of epithelial cells, marriage can be permitted. Another rather popular method of provoking a urethral discharge in order to establish the verity of a cure is to give an injection of 1 to 1000 bichloride solution, and to instruct the patient to drink a quart or more of beer. This would seem to be more heroic than circumstances would warrant. The presence of the numerous pus corpuscles necessitates renewed examinations and energetic treatment of this pseudogonorrhœa. In spite of failure to find gonococci after repeated examinations, it is better to wait until the discharge has ceased entirely, and to withhold consent to marry until there can be no peradventure of contagion. The extreme views of Noeggerath and Tait on the incurability of gonorrhœa in the male are too often and too clearly refuted by practical experience to merit serious consideration. Latent gonorrhœa, in the etymological restriction of the adjective to "lying hidden," has no existence. If the disease exists, it can always be discovered.

Specialism.—Wife: "Isn't that the celebrated dermatologist, Dr. X—, who cured you?" Husband: "No; I got his bill yesterday. He's a skin specialist."

Time of Rupturing the Amniotic Sac in Labor.—The *Atlanta Medical and Surgical Journal* gives the following rules: 1. In multiparæ, rupture when the os is fully dilated. 2. In primiparæ, delay until the soft parts are also dilated. 3. In cases of face and breech presentation, delay in rupturing the sac is best. 4. When the pelvis is small and the fœtus large, delay rupturing. 5. In premature labor, with a dead fœtus, rupture early. 6. Rupture the sac early when the membranes are unusually thick, tough, and unyielding. 7. When speedy delivery is demanded, rupture early and dilate with the fingers. 8. Rupture the sac when an excessive amount of amniotic fluid retards labor. 9. When version is necessary, and can be accomplished by bimanual manipulation, perform this operation before rupturing. 10. Remember that a dry labor is always to be deprecated; hence do not rupture at all, unless for good reasons and the case demands it.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE TREATMENT OF PUERPERAL ECLAMPSIA.¹

By J. CLIFTON EDGAR, M.D.,

ASSOCIATE PROFESSOR OF OBSTETRICS IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK; ATTENDING PHYSICIAN TO THE SOCIETY OF THE LYING-IN HOSPITAL, TO THE NEW YORK MATERNITY AND TO THE EMERGENCY HOSPITALS; LECTURER AND EXAMINER ON OBSTETRICS IN THE NEW YORK TRAINING SCHOOL FOR NURSES.

It is necessary to preface our remarks upon the preventive and curative treatment of puerperal eclampsia with the statement that the real cause of the condition in the human female is still an unknown quantity. As far as we are aware, no new light has been thrown upon the pathology and etiology of the condition.

That the pre-eclamptic condition and the subsequent eclamptic seizure are due to (1) uræmia, (2) hydræmia, (3) ammoniæmia, (4) reflex irritation, (5) microbic influences, or (6) to the influence upon the system of some toxic material, modern scientific investigation does not permit us to state. Most observers are agreed that the last mentioned approaches the true explanation, and that the condition is one of toxæmia, of auto-infection, of an accumulation in the blood of some toxic material—biliary, urinary, fætal, or all three, but just what this material is has not up to the present time been determined. It appears probable, moreover, that the condition has not one but many causes. Further, modern clinical research and study would seem to prove that the pre-eclamptic state, or what some have been pleased to term "the toxæmia of pregnancy," has certain well-marked symptoms and signs to guide us to a diagnosis of this condition, and that in the majority, if not in all instances, this state extends over a period of days, if not weeks or months.

The limits of the present paper do not permit us to enlarge further upon the clinical picture of this pre-eclamptic condition, other than to state that it resembles closely the clinical picture seen in slow or rapid poisoning by some mineral or narcotic poison, and that the condition is always accompanied by failure of the eliminative organs to do their duty, notably on the part of the kidneys. If these premises are correct, then of the two treatments of eclampsia, the preventive and the curative, the former is by far the most important, especially so when we come to find that in the majority, if not in all instances, the eclamptic seizure is a preventable accident.

(a) **The Preventive Treatment.**—What symptom or sign, or what combination of symptoms or signs, have we then, that will enable us to recognize this pre-eclamptic state, in order that we may be warned in time to prevent the subsequent eclamptic convulsions?

The symptoms of the state preceding an eclamptic attack include a rapid pulse, accompanied usually by high arterial tension, loss of appetite, gastric and intestinal disturbances, headache, lassitude mental and physical, a gradual or rapid diminution of all the excretions, both liquid and solid—in a word, what one

would expect to observe from the introduction or retention in the blood of some toxic material.

Aside from the direct examination of the blood itself, the condition of the urinary secretion offers us the most convenient physical sign or clinical index of this pre-eclamptic state. The amount of urine passed in twenty-four hours is not always a reliable guide of kidney failure. Albuminuria, as is well known, may be absent before, during, and even after an eclamptic seizure. The amount of urea excreted is a far better guide, as has been shown by Bouchard, of Paris, in the non-pregnant condition, and recently by Dr. E. P. Davis, of Philadelphia, in pregnancy; for the latter found that when urea fell to 1.5 per cent., stimulation of the excreting processes resulted in distinctly favorable results, in all cases in which toxic symptoms were previously present. It is not to be inferred from this that urea causes the convulsions, for large quantities of urea may be injected into rabbits without producing toxic symptoms. Indeed, Bouchard found that bile had nine times the toxic power of urea. It is generally accepted that the diminution in the amount of the urea excreted indicates kidney inadequacy, but it is not always a reliable guide. There are other substances in the urine with as great or greater poisonous qualities. Urea may be found in sufficient quantity and an eclamptic attack occur. Bouchard determined the toxicity of the urine by injections of the same into the circulation of rabbits. His experiments show that normal healthy urine is toxic in the proportion of a certain unit per kilo by weight of the rabbit. In kidney insufficiency, when some poison or poisons are retained in the circulation, the toxic properties of the urine diminish, and it requires more of the urine to the kilo by weight of the rabbit to produce toxic symptoms in the animal. This gives us a delicate test for determining kidney inadequacy in doubtful cases. Bouchard's experiments further show that in renal insufficiency the poisons retained in the patient's blood arise from:

1. Food, especially nitrogenous food, as muscle, and food containing the salts of potassium.
2. Bile.
3. Putrefaction in the intestines, and absorption of its products.
4. Toxic materials constantly being produced by the metabolism of all the cells of the body.

To this last we add the metabolism of the fætal tissues, as this greatly increases the toxic material in the mother's blood, for, clinically, we are familiar with the fact that when the fætus dies *in utero*, or is delivered in the case of a living child, the eclamptic seizures usually cease.

Again, Winckel's observation that in twin and triplet pregnancies there is a greater predisposition to eclampsia has been verified by others. Moreover, the tendency to eclampsia becomes greater proportionately with the advance of gestation and the consequent increase of fætal metabolism.

Further, we know that the maternal mortality diminishes progressively from the ante-partum to the post-partum states; namely, that it is greatest when eclampsia sets in during pregnancy, is less during labor, and lowest of all when the attack occurs for the first time

¹ Read before the New York Academy of Medicine, at a special meeting, November 27, 1896.

after the birth of the child. Thus, the mortality during eight years at the Boston Lying-in Hospital, as has been shown by Green,¹ was: Ante-partum eclampsia, maternal mortality, 46 per cent.; foetal mortality, 69 per cent. Intra-partum eclampsia, maternal mortality, 25 per cent.; foetal mortality, 25 per cent. Post-partum eclampsia, maternal mortality, 7 per cent.

Our present knowledge of the causation of puerperal eclampsia, meagre though it be, furnishes us, if not with the key to the successful preventive treatment of the condition, still with a working hypothesis, namely, the early recognition of the pre-eclamptic state. To accomplish this, something more than a perfunctory monthly or bimonthly examination of the urine for the presence of albumin is called for, since non-albuminuric eclampsia occurs in from nine to sixteen per cent. of cases, and it would appear to be quite as fatal, if not more so than an eclampsia accompanied by albuminuria. Something more is demanded than the late recognition of renal insufficiency, as it shows itself in a marked diminution in the quantity of urine, specific gravity of the same, and amount of urea excreted.

When we shall accustom ourselves to watch our cases of pregnancy, not only for the physical signs of pronounced renal inadequacy as an index of an approaching eclamptic attack, but also for the general symptoms of the overcharging of the blood with toxic material—as high arterial tension, headache, gastric disturbances, physical and mental lassitude, and further for failure of the bowels, liver, skin, and lungs properly to perform their functions, and intelligently treat the same, then, and then only shall we have done our whole duty by our patient, and done all in our power to correct the pre-eclamptic condition and avert an impending eclampsia.

We would formulate our line of treatment of this pre-eclamptic state somewhat in the following manner:

1. Reduce the amount of nitrogenous food to a minimum.
2. Limit the production and absorption of toxic materials in the intestines and tissues of the body, and assist in their elimination by improving the action of (1) the bowels, (2) the kidneys, (3) the liver, (4) the skin, and (5) the lungs.
3. If necessary, remove the source of foetal metabolism and of peripheral irritation in the uterus by the emptying of that organ.

Our first indication, the reduction of the amount of nitrogenous food to a minimum, can best be fulfilled in an exclusive milk diet, to which, as the symptoms subside or disappear, can be added fish and white meats. We have found it not only safer, but less trying to the patient, to commence with an absolute milk diet, than to compromise and afterward be compelled to cut off all but the milk. For our second indication—that of elimination—we must first secure an abundant supply of pure air and water. This may be assisted by moderate exercise or light calisthenics or massage, in certain instances. For the bowels we advocate daily doses of colocynth and aloes at bedtime, followed by a saline in the morning. For the liver an occasional dose of calomel and soda at bedtime, followed in the morning by one of the stronger sulphur waters, as Rubinat, Villacabras, or Birmenstorf. Increased diuresis is secured by maximum doses of glonoïn. The action of the skin is encouraged by enclosing the body in wool or flannel underclothing, by massage, by the warm bath, hot bath, hot pack, or hot-air bath, according to the urgency of the case.

We are accustomed in instances of eliminative insufficiency to give at bedtime twice weekly, or more

frequently if necessary, a tablet composed of calomel, digitalis, and squill, each one grain, and muriate of pilocarpine, one-twentieth of a grain. This is followed in the morning by a full dose of Villacabras water. We have found a decided diaphoretic-diuretic action follow the administration of such a combination, with the additional prompt action upon the liver and intestines as well. So of our five eliminative processes four are stimulated to more energetic action by its use.

Because jaborandi has been practically abandoned as a diaphoretic in the presence of an eclamptic attack, we know of no good reason contraindicating its use in this, the pre-eclamptic state, in the absence of pronounced cardiac disease, and we advocate its use for its diaphoretic and diuretic actions.

Finally, when exercise cannot be taken and an abundant supply of fresh air is wanting, oxygen inhalations will prove of service. Some preparation of iron will also be called for, as the tincture of the chloride, or Basham's mixture.

This, then, is the general hygienic and medicinal treatment of the pre-eclamptic state. No hard and fast rule can be laid down. Every case must be treated on its merits. In one a restricted diet and mild stimulation of the renal and intestinal functions is sufficient, and the patient may be allowed to be about and even exercise in the open air, her skin being protected from sudden changes by being incased in wool or flannel. Other more pronounced cases of eliminative insufficiency must be kept absolutely quiet in bed upon an exclusive milk diet, and the stimulation of all the eliminative organs must be resorted to, to remove the symptoms of impending eclampsia.

But it must be kept ever before us that the hygienic and medicinal treatment is only of secondary importance to the milk diet, and that the latter is the foundation of the preventive treatment of puerperal eclampsia. Given a case in which, in spite of an exclusive milk diet and the vigorous stimulation of the five excretory outlets already mentioned, the symptoms and signs of the pre-eclamptic condition continue or at any time become urgent, the indication is to induce artificially abortion or premature labor.

We cannot understand the position of those authorities (notably of the British school of midwifery) who advise against inducing labor in the presence of urgent symptoms of the pre-eclamptic state.

The arguments that by the methods usually in vogue induced labor increases reflex excitability and precipitates convulsions; that by the same methods, because of the time necessary to remove the barrier of the cervix, the patient's fate is sealed before the delivery is effected; and, moreover, that the onset of labor increases the danger to the patient, are good ones and must demand our attention.

In answer, we would state that our methods of terminating the pregnancy need not increase reflex excitability, and if perchance they do, the excitability is readily controlled for the time necessary to accomplish our ends: that the time necessary is, in most cases, very short; and, finally, that to-day the onset of labor and the termination of pregnancy may be practically brought about at one and the same time, and we have no prolonged or tedious labor to react unfavorably upon the patient.

The objection raised by Byers at the last (second) International Congress of Obstetrics and Gynecology, held at Geneva, in September, 1896, that induced labor, because of the necessary manipulation, increases the risk of sepsis, will not deter us from performing the operation when we know we are surgically clean.

Charles, of the Liège Maternity, reported, at the last International Congress of Obstetrics and Gynecology, in favor of induced labor, when treatment fails or the symptoms become urgent in the pre-eclamptic

¹Green: "Puerperal Eclampsia. Experience of the Boston Lying-in Hospital in the Last Eight Years," *American Journal of Obstetrics*, 1893, xxviii, 18-44.

state. His statistical table shows that every mother recovered and seventy-five per cent. of the children were saved.

We believe in a rapid manual dilatation of the os in these cases, but only after the cervical canal is in a condition favorable for its safe performance. Moreover, we would insist upon a complete dilatation of the os before delivery is undertaken.

(b) **The Curative Treatment.**—In the presence of an eclamptic attack we face a desperate condition. The latest statistics from various parts of the world still place the maternal mortality at from twenty-five to thirty-five per cent. As long as the pathology of eclampsia remains obscure there can be no rational curative treatment of the condition. Our experience does not permit of our recommending any single treatment. Many subjects recover, no matter what the treatment, many die in spite of treatment, and others do well without any treatment at all. No single treatment can be recommended; each case must be managed according to the indications present. Our experience has taught us that not a single but a combined treatment promises best for saving the lives of mother and child in the event of an eclamptic seizure. We would offer for this combined treatment three indications, as follows:

I. Control the convulsions.

II. Empty the uterus under deep anæsthesia, by some method that is rapid and that will cause as little injury to the patient as possible.

III. Eliminate the poison or poisons which we presume cause the convulsions.

Although we have named these indications in the order of their importance, still we often carry them all out at one and the same time. In another class of cases we fulfil the first and third, and wait for a suitable moment to carry out the second. The third indication—elimination—should really go hand in hand with the first two and be put into action at one and the same time with them.

(I.) *Control the convulsions.* There is to-day a wide range of opinion regarding the relative value of the various medicinal means employed to control eclamptic convulsions. That eclamptic attacks must be controlled, that the danger to mother and child is in direct proportion to the number of convulsions occurring before the emptying of the uterus, most observers are agreed. The four medicinal means most certain and safe as antieclampsics are chloroform, morphine (hypodermatically), veratrum viride, and chloral hydrate, the latter alone or combined with sodium bromide. It would appear from the Transactions of the last International Congress of Obstetrics and Gynecology that of these drugs morphine is most frequently relied upon.

We cannot altogether subscribe to the teachings of the Rotunda Hospital, that morphine and chloral when given in eclampsia "act just like the poison which causes the eclampsia and increase the tendency to death;" still we believe we are too prone to resort to the purely symptomatic treatment with narcotics and anæsthetics, forgetting the more important eliminative treatment. At the Rotunda chloroform is now given only when operative interference is required. For the convulsions at this hospital morphine would seem to have given much better results than chloroform for years past. Our preference is for chloroform, veratrum viride, and chloral, in the order named. Until three years ago we used morphine freely in eclampsia, but since have abandoned its use almost entirely, as we believe it prolongs the post-eclamptic stupor and increases the tendency to death during coma by interfering with the eliminative processes.

Second only to chloroform in value is veratrum viride. Provided the pulse be strong as well as rapid,

it is the most certain means at our command for temporarily and even permanently controlling the convulsions. When the pulse is weak we rely upon morphine hypodermatically, chloroform by inhalation, and chloral by rectum, with stimulation if necessary. As a temporary measure in ante-partum and intra-partum and even as a curative means in post-partum eclampsia, veratrum viride will, we believe, accomplish all that has been claimed for it.

(1) Veratrum viride reduces the pulse rate, and convulsions are practically unknown with a pulse rate of 60 or under; (2) it reduces the temperature; (3) it relaxes and renders more yielding the rigidity of the cervical rings; (4) it causes prompt diaphoresis and (5) diuresis, so that it aids not only in the fulfilment of our first indication, the control of the convulsions, but in the third, the elimination of an unknown poison as well. Our practice has been to rely upon chloroform, veratrum viride, and morphine or chloral as temporary measures, and the prompt emptying of the uterus permanently to control the convulsions.

(II.) *Empty the uterus under deep anæsthesia by some method that is rapid and that will cause as little injury to the woman as possible.*

Those who follow the teachings of Charpentier, of France, and Winckel, of Germany, namely, that the uterus in eclampsia should be left alone, except after full dilatation of the os, as the irritation of inducing labor or artificially dilating a cervix precipitates convulsive attacks, will, we believe, see many cases lost that could be by prompt and intelligent measures be saved. It would appear from careful observation that the danger is practically over in some ninety per cent. of cases the moment the uterus is emptied, if accomplished early in the attack. Not that by this means the convulsions always cease, but they become less dangerous, and the case becomes one of post-partum eclampsia, in which the mortality, as we have stated, is only seven per cent.

Although one can scarcely find an authority to-day, as shown by the reports of the last international congress, who absolutely rejects local interference in the presence of ante-partum or intra-partum eclampsia, still authorities differ widely as to the extent to which such interference shall be carried out. Charpentier, in 1892, as the result of an exhaustive analysis of four hundred and fifty-four cases of eclampsia, and again in the present year (1896) as the result of further observation, practically arrives at the same conclusions, namely:

1. That labor should be waited for and terminated naturally whenever possible.

2. That induced labor should be reserved for exceptional cases in which medical treatment has entirely failed.

3. That interference should be delayed until the cervix is dilated or dilatable, so as to avoid danger to the mother; that in eclampsia Cæsarean section, manual dilatation of the cervix, and especially deep incisions of the cervix are absolutely unjustifiable.

Charpentier, in this statistical analysis of the different methods of treating eclampsia and of the method known as Dührssen's deep incisions of the cervix, arraigns the latter in very forcible language, characterizing the operation as brutal and unjustifiable. He places himself in "resolute opposition to forced labor, . . . and even to induced labor, which he reserves for exceptional cases where medical treatment fails." He rejects absolutely forced labor by deep incisions of the cervix. From his analysis of the 454 cases, which included all known methods of treatment of eclampsia, he has constructed the following table: Mortality from spontaneous labor, 13.93 per cent.; from artificial labor, 29.13 per cent.; from Cæsarean section, 36.26 per cent.; from forced labor, 40.75 per

cent. The infant mortality in the 454 cases was 16.4, or 36.12 per cent. Charpentier concludes that the best treatment in eclampsia is to wait until labor begins, and let it alone unless absolutely necessary to interfere. In the mean time he administers chloroform and bleeds if the patient be robust.

On the other hand, it would appear from the literature of the last five years and from the reports of the last international congress (Geneva, September, 1896) that the weight of medical opinion is in favor of emptying the uterus in as short a time as possible in instances of eclampsia, whether the attack occurs before or during labor, although there is a wide range of opinion as to the means to be employed. In the second stage of labor, after dilatation has been secured, all authorities are agreed that the immediate emptying of the uterus is indicated and is to be performed promptly; the indication under such circumstances is readily carried out without additional danger to mother or child. In pregnancy and the first stage of labor the undilated cervix is the barrier to immediate delivery, and it is here that obstetricians differ so widely as to the best method of procedure. An expectant or palliative treatment means almost certain loss of the child, and something like one-third of the mothers are lost. On the other hand, the child is saved and the mother is practically safe, as far as the eclampsia is concerned, if the uterus is immediately emptied by appropriate surgical means.

During pregnancy and the early part of labor four procedures are offered for rapidly emptying the uterus, viz.:

1. Cæsarean section.
2. Mechanical dilatation of the cervix (various methods).
3. Deep incisions which at once completely remove the barrier of the cervix.
4. Combined mechanical dilatation and deep cervical incision.

The first method, Cæsarean section, for the relief of eclampsia still carries with it a high mortality (36.26 per cent. according to Charpentier's figures); moreover, there are many objections to its employment, as the uterine atony and hemorrhage, the irritation of the uterine and abdominal scars, and of the curative peritonitis about the uterine sutures, all of which are to be avoided as exciting causes of subsequent eclamptic seizures.

The second method, the mechanical dilatation of

FIG. 1.—Cervix in Latter Part of Gestation or at Beginning of Labor. Vaginal and supravaginal portions of cervix unchanged. *v.*, Cuff of vagina; *ex.os.*, external os and infravaginal portion of the cervix; *c.v.j.*, cervico-vaginal junction; *s.v.c.*, supravaginal portion of cervix; *in.os.*, internal os; *l.u.s.*, lower uterine segment.

the cervix and the immediate extraction of the fœtus, appears to be the popular method of the day. Properly performed the method is safe and efficient. Before dilatation is well advanced, however, from forty minutes to an hour and a half is necessary safely to

carry it out, and certain conditions of the cervix, even in this time, refuse to yield to manual dilatation or result in lacerations into the lower uterine segment. The third method of delivery, by deep cervical incision, offers us a surgical means for emptying the uterus

FIG. 2.—Lower Uterine Segment During Labor. *v.*, Cuff of vagina; *ex.os.*, external os, infravaginal portion of cervix has disappeared; *c.v.j.*, cervico-vaginal junction; *s.v.c.*, supravaginal cervix, small portion only remaining; *in.os.*, internal os; *l.u.s.*, lower uterine segment.

in from five to ten minutes, provided the supravaginal portion of the cervix has disappeared or is made to disappear by appropriate means. The fourth or combined method is a combination of the second and third methods, and is applicable to cases in which the supravaginal portion of the cervix is still present and rapid emptying of the uterus is demanded. Here mechanical dilatation of the os until the internal os has been caused to disappear is made use of, and the dilatation then in an instant completed by the incisions. The third method and its modification, the fourth, are comparatively new, and we have few statistics as to the results of the operation. We believe a rapid manual dilatation of the os and subsequent extraction of the fœtus will fulfil the indications in most cases, but unless this can be intelligently carried out, with a due appreciation of the mechanism of dilatation, especially in primiparæ, a purely expectant treatment will give better results. Unfortunately puerperal eclampsia is four times more frequent in primiparæ than in multiparæ, although, on the other hand, the mortality is greater in the latter.

The cervix uteri is composed of constricting and dilating muscle, and, while it is true that the first convulsions usually induce labor, still the resulting asphyxia exerts a marked constricting action upon the body of the uterus and cervix, which is especially marked at the internal ring of the os. Therefore, any method of rapid manual dilatation of the os that is undertaken before the internal os has been made, partially at least, to disappear is attended with great danger of uterine rupture (Figs. 1, 2). This is especially true in primiparæ, in whom the supravaginal portion of the cervix obtains late in pregnancy and even up to the beginning of labor (Fig. 1). We believe a warning should be sounded against the careless undertaking of rapid manual dilations of the os, particularly in eclampsia. Uterine rupture and death have, we know, been the outcome. Moreover, undue shock has resulted from the dragging of a fœtus through an imperfectly dilated os, to say nothing of the loss of the child.

In placenta prævia the hemorrhage and the resulting anæmia of the lower uterine segment and cervix render these parts more readily dilatable. In eclampsia the reverse obtains, as we have already hinted. Hence it is that in eclampsia in instances in which the internal ring of the os has been drawn up into the body of the uterus (Figs. 2, 3), and the external ring

remains rigid and tense, particularly in primipara, and there is urgent need of rapidly terminating the labor, we prefer four clean incisions extending from the edge of the os to the utero-vaginal junction, in

FIG. 3.—Lower Uterine Segment During Labor. Os uteri in progress of dilatation. Supravaginal and intravaginal portions of the cervix have disappeared. Os admits one finger. *v.*, Cuff of vagina; *ex.os.*, external os; *u.v.j.*, utero-vaginal junction; *l.u.s.*, lower uterine segment.

order to save the patient from the greater dangers of rapid manual dilatation.

In the second place, we believe a warning is not out of place against the premature extraction of the fœtus before full dilatation has been secured and the external ring of the os paralyzed. Premature extraction, under such circumstances, we know has resulted in many unnecessary and dangerous lacerations of the lower uterine segment, and an increase of the mortality for the child and mother.

(III.) *Elimination of the poison or poisons which we presume cause the convulsions.*

For the elimination of the toxic materials from the blood and tissues we have nothing new to offer. We believe it essential, however, to rely not upon one but upon all the eliminative organs of the body, and, moreover, that the fulfilment of this third indication in the treatment of eclampsia should go hand in hand with the first two already mentioned. To this end we secure catharsis as early and as promptly as possible by the administration of croton oil, compound jalap powder, or calomel, followed by salines and high enemas of sulphate of magnesium. In the coma or post-eclamptic stupor of the condition, we have relied mainly upon the repeated administration of concentrated solutions of sulphate of magnesium or Villacabras water, by means of a long rectal tube high up in the descending colon. The hypodermatic administration of magnesium sulphate we have found too slow and uncertain to be of any use. Diuresis we obtain by dry or wet cups over the kidneys, followed by hot fomentations. The value of glonoin as a diuretic and antieclamptic, the latter by reducing the arterial tension, we believe, cannot be overestimated. Second only in value to glonoin we consider veratrum viride. We give it at this time for the same reasons and looking for the same results as when we administer it in the pre-eclamptic condition. Diaphoresis we encourage by means of the hot-air bath or the hot pack, our preference being for the former. Pilocarpine as a diaphoretic in the presence of an eclamptic attack we utterly reject, because of the danger of œdema of the lungs and glottis which it may produce. We have seen these conditions follow promptly upon its administration. The drawing off of large quantities of toxic liquids in the form of blood or serum, by means of venesection, catharsis, diaphoresis, diuresis, followed by the replacement of the same, by intravenous, stomachic, rectal, or hypoder-

matic means, causing a washing or disintoxication of the blood and tissues, as it were, has thus far proved of doubtful value. In instances of collapse, however, with the small compressible pulse, the introduction into the blood of a normal saline solution is of the same value here as in collapse under other circumstances. As a general stimulant, to assist in the elimination from the lungs and to prolong life in the post-eclamptic stupor or coma, we have found the free administration of oxygen of the greatest value. Further, alcohol will often be needed as a stimulant during and after an eclamptic attack, and strychnine in the post-partum state and in the face of threatened collapse—although for physiological reasons it would seem to be contraindicated—has served us well.

Finally, although no one has been or is a firmer believer than the writer in the efficacy of a prompt removal of fetal metabolism and of irritation for not only the control but the cure of the eclamptic condition, still we beg to enter a protest, first against the careless use of the term *accouchement forcé* as applied to the rapid, scientific, and intelligent emptying of the uterus; and, secondly, to the easy confidence with which this *accouchement forcé* has been recommended as the best if not the only means at our command for the control of eclamptic seizures, without attaching sufficient importance to the condition of the cervical barrier. By *accouchement forcé*, we understand to-day three operations, namely, (1) the complete instrumental or manual dilatation of the cervical canal, followed by (2) either combined or direct version, or the application of the forceps, and (3) the immediate extraction of the child.

The *accouchement forcé* of the older writers upon obstetrics was often quite another and more serious operation, for the condition of the cervical canal was frequently lost sight of, and it too frequently meant (1) the plunging of the hand or the application of the forceps through a cervical canal imperfectly dilated,

FIG. 4.—Bimanual Dilatation of the Parturient Os. Os two-thirds dilated. Entire effacement of the internal os. Compare Fig. 3. From a photograph.)

and (2) the immediate extraction of the fœtus through this constricted os. That the latter definition of the term still obtains, seems proven by the frequency of accidents in the extraction of the fœtus that are con-

stantly being brought to our notice. Our maternity hospitals are repeatedly in receipt of ambulance or emergency cases due to the neglect on the part of the operator to fulfil the first condition of the operation, namely, complete dilatation. Within the past few days, while preparing this very portion of the paper, the writer was summoned by telephone to remove from the uterine cavity a foetal head decapitated by traction upon the trunk, in the presence of an imperfectly dilated os. The retained head resulted in post-partum hemorrhage, and the additional shock of its subsequent extraction. It is no uncommon event for emergency cases to be brought to our hospitals with a podalic version or extraction partially completed because of the operations being attempted in the presence of a partially dilated os (Figs. 4, 5); moreover, for uterine rupture to occur, due to the same cause.

In Fig. 5 we have represented the outcome of a premature extraction through an imperfectly dilated os. With such a complication—a rigid, imperfectly dilated external os, grasping the foetus tightly under

FIG. 5.—Dangers of a Rapid Breech Extraction through an Imperfectly Dilated Os. External os not fully dilated or paralyzed. Traction on the legs results in extension of the head and both arms.

the armpits—the loosening of the arms, the dragging of these, and subsequently the head through the os will take considerable time, and not only forfeit the child's life but subject the lower uterine segment to dangerous if not fatal rupture. Our plea in these cases is not alone for complete dilatation or disappearance of the external ring, as seen in Fig. 6, but further, for a paralysis of the ring as we see it performed in Fig. 7, so that the dangers of the extraction, whether by forceps or version, may be reduced to a minimum for both mother and child.

The limits of the present paper forbid our entering upon the arguments for or against any particular variety of rapid manual or instrumental dilatation of the parturient os, further than to state that our preference is for a rapid bimanual method, as shown in the illustrations, since we have given this method an abundant trial over a period of several years, and it has proved most satisfactory.

The bimanual method is to be preferred to other digital and instrumental methods, because (1) the membranes are preserved throughout the operation or until full dilatation is obtained: (2) there is no interference with the original presentation and position;

(3) the sense of touch of the operator's fingers is unimpaired; (4) there is no constriction of the operator's hands; (5) the amount of force exerted upon the

FIG. 6.—Lower Uterine Segment at Completion of First Stage of Labor. Os uteri completely dilated. *v.*, Cuff of vagina; *ex. os.*, border of external os, scarcely perceptible; *u. v. j.*, utero-vaginal junction.

external ring can be better estimated, and hence there is less likelihood of lacerations occurring; (6) in placenta prævia there is less preliminary separation of the placenta by this method than by any other; (7) by no method with which we are acquainted, can not only complete dilatation but complete paralysis of the parturient os be so quickly and safely obtained (Figs. 4, 7).

Again, we beg leave to protest against the undertaking of a rapid manual dilatation of the os (namely, the entire dilatation completed within an hour) before the cervix has become, at least slightly, relaxed by uterine action and is already somewhat yielding. A rigid cervix, in the condition as we see it in Fig. 1, should, we believe, receive a preliminary treatment, a cervical dilator of gauze or hydrostatic bag, that will set up some uterine action and render the rings of the os yielding enough to make a rapid dilatation a safe

FIG. 7.—Bimanual Dilatation of the Parturient Os. The os is fully dilated and is being stretched and paralyzed, to prevent subsequent accidents to the after-coming head during the extraction of the fetus. Compare Fig. 6. (From a photograph.)

operation. In the presence of even a minimum amount of uterine action, or with a softening, yielding, and relaxing os, although the anatomical conditions may

obtain as in Fig. 1, we may still undertake the rapid manual dilatation and produce complete paralysis of the cervix within an hour, as seen in Fig. 7. Far better a purely expectant treatment, as regards emptying the uterus, than the attempt rapidly to overcome a rigid os by manual methods, the supravaginal portion of the cervix being present. We have known complete uterine rupture to result from such an undertaking, the maternal intestines prolapsing between the fingers of the operator. Fortunately for the eclamptic woman, the frequency of the attack increases proportionately with the progress of gestation, and, we may add, with the increase of fetal metabolism. Hence, the attack is more frequent in the latter part of pregnancy and in labor, when we can more readily and safely apply our surgical principle of treatment, namely, an early and rapid evacuation of the uterus.

Unfortunately, the attack is four times more frequent in primiparæ than in multiparæ, and in the former the presence of the supravaginal portion of the cervix late in pregnancy and of an unyielding and unrelaxed os compel us to make use of preliminary and temporizing means before we can safely perform a rapid dilatation of the os and subsequent extraction of the fetus. It is in such cases, and at such a critical time, when we are waiting for the measures preparatory to a rapid dilatation and emptying of the uterus to act, and to give us at least a yielding and relaxed cervical canal, if not a partial disappearance of the internal os, that we have found *veratrum viride* most valuable and life-saving, by reason of the various actions of the drug already mentioned.

50 EAST THIRTY-FOURTH STREET, NEW YORK,
November 27, 1896.

THE TREATMENT OF DIPHTHERIA: AN INQUIRY INTO MODERN METHODS EMPLOYED AT BERLIN IN THE SUMMER OF 1896.¹

By LOUIS FISCHER, M.D.,

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN POLIKLINIC, TO THE MESSIAH HOME FOR CHILDREN, TO THE WEST SIDE GERMAN DISPENSARY, ETC.

It was my good fortune to have the opportunity of carefully observing the treatment of diphtheria at Berlin last summer, through the courtesy of Professor Baginsky. Indeed, I was rather anxious to see what changes, if any, had been made since orrhoterapy was generally introduced, and to compare the results with what I saw in the summer of 1894. To one inexperienced with the brilliant results of antitoxin treatment, it would have been a surprise to see the majority of patients when they were admitted to the diphtheria pavilion, and then to note the changes in these patients in the following two or three days. For what on one day would ordinarily be considered a very malignant case and one in which a grave prognosis could be given, would frequently be so transformed by the treatment pursued that the day following one would almost be willing to guarantee a good prognosis.

Professor Baginsky pointed with great pride to this pavilion, and showed me mild cases and convalescent cases. Among the number I saw two cases in which tracheotomy had been performed for urgent laryngeal dyspnoea after an ineffectual intubation. His rule had been, after a proper clinical diagnosis aided by a bacteriological culture had been made, to remove the patient from the quarantine to the diphtheria pavilion, and inject about one thousand, or at times fifteen hundred or even two thou-

sand units of antitoxin. If a concentrated antitoxin of five or ten cubic centimetres contained this number, he preferred it rather than to inject larger quantities of the remedy. If stenosis existed, the patient was quickly intubated, the American (O'Dwyer) method being used; if, however, stenosis persisted and no great relief was afforded in a given time, then and then only was tracheotomy performed; so the cases which I saw were of the worst type.

Whoever has had a large experience in the treatment of mild diphtheria in children will agree with me that a certain class of patients will recover if iron is used locally or internally, bichloride internally, or Loeffler's solution locally; or, in some instances, even with gargling with a strong salt-water solution. In these children, however, we have a strong constitution and the disease is distinctly localized, and with them any form of treatment will succeed, be it hot poultices or ice externally. We frequently have a small patch of pseudo-membrane on a tonsil or in the pharynx, in which a bacteriological examination will show Klebs-Loeffler bacilli, and the disease disappears in two or three days—I might say by itself, or really without any special treatment. Frequently there is hardly any fever, no swelling of the submaxillary glands—nothing save pain on swallowing, and possibly the child may complain of being tired. In my experience these children recover with any form of mild local antiseptic treatment, if we pay great care to hygienic and dietetic treatment, using possibly nasal irrigation and isolation. Indeed, this latter is about the only thing that needs careful attention, for just because these children feel comparatively comfortable their parents neglect them and permit them to roam about, and then we have a great source of mischief, dissemination of the Klebs-Loeffler bacilli and resulting infection.

I wish, however, to take up your time this evening with the consideration of malignant diphtheria. There are three possibly fatal forms, viz.:

1. Laryngeal diphtheria.
2. Nasal diphtheria.

3. Septic diphtheria, which results from prolonged absorption of toxic elements, generated in either the laryngeal, nasal, or even tonsillar type of the disease. Any form of diphtheria can in time develop septic symptoms, so that in this type we are really called upon to deal with a diphtheritic septicaemia rather than with an ordinary form of diphtheria.

Diphtheritic Croup.—Baginsky maintains that laryngeal croup is always a secondary lesion, and is the result of the extension of the diphtheritic process from the nose, velum palatinum, and tonsils.

Viewing it from a practical standpoint, we are summoned, let us say, to a case of urgent dyspnoea, in which laryngeal stenosis due to diphtheritic deposits exists. The voice is hoarse, accompanied by a ringing cough and prolonged inspiration and expiration; the respiration is becoming slower and slower; the auxiliary muscles of respiration are brought into play, and the thorax appears to be considerably enlarged. Still, it is impossible to give the lungs enough air. The intercostal spaces, the jugulum, and scrobiculus cordis at the lower portion of the sternum are deeply drawn in with each respiratory act. The accessory muscles of respiration brought into play are in the neck and thorax—the scaleni, omohyoid, pectoralis, serrati, and sterno-cleido-mastoid muscles. The child appears livid and cyanotic, and is usually covered with a cold, clammy perspiration. If a piece of membrane is coughed out, there may be a temporary relief of these urgent symptoms, but it rarely lasts more than a few hours. Then the symptoms usually reappear, and are more severe than before. Unless mechanical relief—i.e., intubation—is rapidly af-

¹ Read before the section on pediatrics of the New York Academy of Medicine, December 10, 1896.

forded, carbonic-acid poisoning will set in, and our patient will die of asphyxia.

Nasal Diphtheria.—Diphtheritic rhinitis is frequently ushered in by a simple catarrhal rhinitis, in which there is an excess of mucus or muco-purulent secretion. The secretion is of a yellowish or grayish color, and can be removed by syringing the nose or with a small forceps. At times bleeding follows this method: the mucous membrane of the nose appears of a deep reddish hue and is intensely congested. If we examine the membrane we find that it appears under the microscope to be made up of fibrin, in which round cells are embedded, and the bacteriological culture rarely fails to give either Klebs-Loeffler bacilli or streptococci, or both together. At times diphtheritic rhinitis occurs secondarily to the pharyngeal process, and as a result of the extension of this inflammatory condition through the choana: narium or the posterior nares.

The symptoms of occlusion of the nasal passages by these exudations, be they pseudo-membranous or otherwise, the excoriations at the entrance to the air passages (*alæ nasi*), the stinking breath (*fætor ex ore*), the snoring and open-mouth breathing—all point to interference with natural breathing and obstruction in the nasal passages.

It is, therefore, a good plan, knowing as we do that almost all cases of membranous rhinitis contain Klebs-Loeffler bacilli and that they are infectious, to isolate. This would be especially called for in a given case of rhinitis in a family in which a case of diphtheria had already existed, and wherein we might have reason to believe that the simple rhinitis was the result of a new infection and the first symptom of a diphtheritic process. The constitutional symptoms of all forms of diphtheria are alike. The patient has fever, appears somnolent, usually has enlarged submaxillary glands, manifests anorexia, appears intensely anæmic, at times has excessive perspiration, and shows general evidence of a severe illness; if old enough, children complain of intense headaches.

It is not the purpose of this paper to inquire into the physiological effects of antitoxin, or into the manner in which it produces its effects, nor do I care to tire you with the results of its effect on the blood in particular; but I desire to remind you that, knowing as we do that antitoxin has no direct effect on the Klebs-Loeffler bacilli, the bacilli can be demonstrated days after an injection of antitoxin has been given, at the site of infection or where the diphtheria was first seen. This point must not be lost sight of in the treatment, and particularly it must be borne in mind in the question of isolation.

Toxins.—The classification of toxins by Sidney Martin is worth repeating. Martin states that there are two kinds of toxins: 1, that produced in the diphtheritic membrane; 2, that produced in the tissues of the body. The poison of the membrane causes the local as well as the constitutional symptoms of diphtheria, and here antitoxin is most effectual, for it has a specific effect and can control the clinical manifestations which are peculiar to the toxin of diphtheria. If large quantities of this so-called membrane toxin are allowed to enter the system through neglected or delayed treatment, these toxins transform the albuminoid bodies of the tissues and cause tissue poisons or tissue toxins. Martin finds that these tissue toxins can be classified into: 1, those that belong to digested proteids; 2, those that are not proteid substances. The first is an albumose: the second is an organic acid. Albumoses have a specific action on the human organism; when present in small quantity they produce fever, and if allowed to act for any length of time on the human organism they produce paralysis. In very large quantity they produce great exhaustion,

and also fatty degeneration of the heart and kidneys. It is in these cases that antitoxin at times fails, owing to the presence of poisons other than those peculiar to the membrane toxins, and which are by-products produced by degenerative changes in the tissues. That the so-called mixed infections, Klebs-Loeffler bacilli and streptococcus cases, cannot all be cured by injecting antitoxin and antistreptococcic serum, has been repeatedly shown. Monti believes that we shall have to produce artificial mixed infections in animals, infections which shall combine the toxins of Klebs-Loeffler bacilli and of streptococci, and thus probably yield a modified serum.

Emmerich gave the name of immune proteids to the hypothetic bodies formed from body albumin, or, rather, from transformed cells in the human organism, during the transformation or action which follows when specific antitoxin is introduced and reaches the human Antikörper or antibodies of the blood.

If the body becomes gradually habituated to alcohol, no antialcoholin is formed: if to morphine, then when morphine is introduced, no antimorphinin is formed; and still a certain toleration of these poisons is and can be produced by virtue of the living cells, so that heroic or otherwise toxic doses can be taken without killing the individual.

Serum Statistics.—In the fifth annual report of the Emperor and Empress Frederick Children's Hospital, from January 1, 1895, to January 1, 1896, we find among the detailed reports that the greatest success of the year comes from the diphtheria wards since the introduction of the serum treatment. The number of new cases admitted was 538, as against 583 in the preceding year—probably because serum treatment was more extensively used in private practice by physicians. Mortality from diphtheria, first year, 36.56 per cent.; second year, 35.57 per cent.; third year, 41.78 per cent. Average, 37.63 per cent.

In 1894, the first year antitoxin was used, the mortality fell to 27.8 per cent., including cases wherein other forms of treatment were used; in cases wherein serum treatment alone was used, the mortality sank to 16.6 per cent. In 1895 the mortality fell to 11.2 per cent. The number of diphtheria cases examined in the polyclinic was 574, of which 516 were admitted to the diphtheria pavilion; 460 children were treated with immunizing doses of antitoxin, of whom 18 contracted diphtheria rather late, and of a very mild type. Not one single death occurred among the latter.

Prof. C. Fraenkel, in a paper read before the German Hygienic Society at Kiel on September 11, 1896, gave the following statistics: From 1875 until 1886, in all twelve years, there were 529,901 deaths from diphtheria in Prussia, or about 45,000 yearly, or 165 to every 100,000 souls. In 1892 there were 55,746, which is 118 to every 100,000 souls. In 1893 there were 75,322, which is 158 to every 100,000 souls. In 1892 there were 320 deaths in every 100,000 cases of intestinal disorder, 259 deaths from tuberculosis, and next follows diphtheria; but, if we exclude the nursing period or the first year of infancy, and also the years from fifteen to sixty, in which most deaths occur from tuberculosis, then we find that diphtheria causes 98 per cent. of the deaths from all causes beginning with the second and ending with the fifteenth year.

According to a report in the *Wiener medizinische Wochenschrift*, 2,039, September 19, 1896, 1,103 patients were injected, of whom 970 were cured, 133 died, or 12.5 per cent. In 68 cases death occurred during the first twenty-four hours; deducting these, there were 1,035 cases, with 68 deaths, or 5.3 per cent. mortality. The same journal reports that all children treated without serum died, whereas all treated with serum—16 in all—recovered. Of these 16, 3 had laryngeal diphtheria.

The *Wiener klinische Wochenschrift*, 1896, No. 13, reports a series of 229 cases treated by Blumenfeld, with 20 deaths—a mortality of 8.7 per cent.; 60 cases were of the severest character, with laryngeal involvement. During the same period, 48 cases treated without antitoxin gave 11 deaths, or 23 per cent.

Dr. Ladanyi¹ says: "Diphtheria exists continuously with us in Europe since 1870. It is never extinct; now and then only mild forms are seen, and at the same time the most malignant," so that he believes we can exclude the "genus epidemicus."

We must consider what formerly existed when the disease was treated without serum. Under former methods of treatment the course of a mild case of diphtheria without complications showed at the end of the first week, usually at the beginning of the second week, a fall in the temperature and the throat cleared—this in treatment without serum.

If we inject serum, what follows?

In from twenty-four to thirty-six hours, sometimes twenty-four to forty-eight hours later, we have a distinct line of demarcation; rarely do we see a second formation of pseudo-membrane; the temperature falls. The disease is virtually arrested in from twenty-four to forty-eight hours.

The septic cases, those in which, in spite of antitoxin injection, anuria and other nephritic symptoms appear, were known long before antitoxin was discovered, and might be the result of the severer activity of the toxins in the system—affecting already weakened organs. So, for example, feeble children—who prior to infection were anæmic, or tuberculous, or scrofulous, or rachitic, with previous organic disease, or those infected during a convalescence from measles or other disease—are more prone to develop laryngeal stenosis, gangrene, etc., than children previously healthy. We must throw aside all theoretical, statistical, and bacteriological ideas, and be guided wholly by empiric experience and observation. The serum causes, *de facto*, a beneficial influence on the diphtheritic process, and modifies it to the benefit of the patient; and this and this only is a factor which can explain the lower mortality.

The cause of the decreased number of cases can and should be looked for in the number of prophylactic injections given to those probably exposed to diphtheria, and the consequent smothering of the sparks of the disease and resulting immunity.

Virneisel City Hospital at Coblenz² reports 158 cases of diphtheria. Of 150 of these treated with antitoxin, 131 were cured—87.3 per cent.—and 19 died—12.7 per cent. The mortality was zero for those injected on the first day, 31.6 per cent. for those injected on the third day, 68.4 per cent. for those injected after the third day of illness. Six of these patients were moribund at the time of treatment.

Kossel reports in Paris, during 1886, 1,524 deaths from diphtheria. In 1895, 411 deaths, one-third of the former death rate.

Lenharts³ had 137 cases; mortality, 12.4 per cent., and 3 relapses.

König and Mexter⁴ injected an infant, five days old, with 150 units. The child recovered without any unpleasant after-effects.

St. Joseph's Children's Hospital in Vienna:⁵ 138 males, 129 females, in all 267, treated for diphtheria and croup. Discharged cured, 188; improved, 2; died, 61; mortality, 22.84 per cent. Deducting 19 children brought in in a moribund condition, a mortality of 15.73 per cent. would result. Seventy-four

cases required tracheotomy or intubation, some secondary tracheotomy. Of these 74 subjects, 35 were discharged cured and 39 died. The year previous to the serum therapy, the mortality was 50.5 per cent. The mortality in 1895 was, therefore, 27.7 per cent. less than in 1894.

Kinder-Abtheilung des Spitäles der allgemeinen Poliklinik in Wien:¹ In all 108 cases were injected—73 fibrinous, 25 phlegmonous, 10 gangrenous; 27 patients died; 4 moribund were not injected; mortality, 25 per cent.

Paser,² City Hospital of Ulleveld by Christiania, from January till November, 1895, had 392 cases of diphtheria. Bacillus cultures were obtained in each. In 140 mild cases not injected there were no deaths: 212 very malignant cases injected gave a mortality of 21, or 9.9 per cent. Before the serum period, in 883 cases coming under treatment on the first and second day, the mortality was 153, or 17.3 per cent.; in 713 cases admitted from the fourth to the seventh day of illness, 224, or 30 per cent.; in 418 cases admitted from the fifth to the sixth day of illness, 128, or 30 per cent. Sixty-nine patients had stenosis of the larynx; of these 41 were operated upon. In 40 intubations or tracheotomies secondarily there died 10 per cent. Before serum therapy the mortality in operated cases was 78.4 per cent. The epidemic during the serum period was a serious one.

Professor Monti gives a series of 72 cases. Of these 29 had laryngeal symptoms, with 6 deaths, or 8 per cent.³ He gives large doses, or from 2,000 to 5,000 antitoxin units.

Vadova⁴ reports 240 cases of prophylactic injections resulting very favorably.

Abba⁵ reports a series of cases, with a mortality of 4 per cent.; cured, 96 per cent.

Dr. Ramelle uses injections of serum per rectum, having cleansed the parts previously. My own experience is decidedly against the use of antitoxin per rectum, for in each case it produced no effect whatsoever.

Ewing James, in an article on "Leucocytosis in Serum Therapy," states that one-half hour after an injection of serum the white corpuscles increase quite rapidly in number. Those increased are chiefly mononuclear cells. Polynuclear cells stain easily with gentian violet after serum injection. If, however, this latter reaction of staining does not occur, then the prognosis is very bad.

In our country John S. Billings⁶ has also studied this leucocytosis, and found the condition to be similar to that seen in scarlet fever and pneumonia, the increase noted by his investigation being in the polynuclear forms.

The literature of favorable antitoxin reports is so overwhelmingly large, that I hope to be pardoned if I do not quote all. In our country Louis Fischer, H. Biggs, A. Campbell White, Paul Gibier, and, later, A. Caille, and Edwin Rosenthal, of Philadelphia, are worthy of notice. A. Seibert and F. Schwyzer⁷ report a series of experiments to prove the toxicity or non-toxicity of antitoxin. The authors found, 1st, that antitoxin was innocuous; 2d, that carbolic acid contained therein as a preservative was non-toxic; and 3d, that there was great danger of injecting air.

Adamkiewics⁸ experimented on guinea-pigs with carbolic acid, air, etc. His conclusions are that air can be injected into a vein and taken up by the veins

if injected slowly, and that it will be eliminated without having done harm. Thus, 10 c.c. produced no ill effects when injected slowly, whereas 2 c.c. injected forcibly and at one operation proved instantly fatal. He believes the virulence increases with the force used.

In our country great credit is certainly due Dr. Biggs for his activity in generalizing the antitoxin treatment after it was introduced. While I have used large quantities of Schering's serum, and while I am willing to stand by every word that I have published in regard to its efficacy, I have recently used domestic antitoxin and was pleased with its effects.

The American Pediatric Society's collective report for 1896 contains 3,384 cases, of which 1,256 were laryngeal, or 37.5 per cent. Operations were done in 565 cases, as follows: intubation in 533 cases, with a mortality of 25.9 per cent.; secondary tracheotomy in 9 cases, with 7 deaths; tracheotomy alone in 32 cases, with 12 deaths, or a mortality of 37.4 per cent.

Rosenthal, of Philadelphia, is quoted with 18 operations and 16 recoveries.

Booker, of Baltimore, had 17 operations and 17 recoveries.

O'Dwyer says: "In my last 100 cases, 70 without serum, the mortality was 73 per cent.; in my last 30, with serum, the mortality was 33.3 per cent."

The report of the American Pediatric Society is certainly incomplete, for I sent a record of fifty cases, most if not all of which were seen in consultation in this city with some very eminent gentlemen, and these have been omitted. In a paper read by me before the German Society of this city in April, 1895,¹ my mortality in a series of 225 cases injected was stated as equivalent to 15½ per cent. Since that time 100 carefully recorded cases, mostly in private practice, still give me a mortality of 7 per cent. These, however, were septic and moribund cases.

The report of the London *Lancet* special commission, published July 18, 1896, is worth reading.

A large number of specimens of antitoxin, from Schering's laboratory, from Behring's, and from Burroughs & Wellcome's in England, also some from French laboratories, were tested to determine the real merits of the various brands, and the German specimens were found the best of all.

As there are various forms of diphtheria so must there be different methods of treating them, and we accordingly have, first, a treatment for mild forms, in which I believe no antitoxin is required, and in which the disease is localized and there is no apparent general systemic infection. In such cases we can confine ourselves to local treatment.

Local Treatment of Mild Forms.—We know that tearing off pseudo-membrane is always followed by bad results; so also is cauterization of necrotic membranes, whether by acids, by Paquelin cautery, or otherwise, and that these heroic measures are usually rewarded by a spreading of the disease, *i.e.*, an increase in the pseudo-membranes. Baginsky warns against this method of treatment: so also have Jacobi and many other authorities. Loeffler, however, recommends that his mixture of alcohol (60), toluol (36), and liquor ferri sesquichloridi (4) be applied locally at the site of infection. After going into all manner of local applications, Baginsky returns to sublimate, which he still uses for local antiseptics and cleansing. For the cleansing of the nose and throat, Professor Baginsky uses a lukewarm table-salt solution (0.5 to 1 per cent.). This is to be used with care, owing to the risk of entering the Eustachian tube and producing disagreeable otitis media. The only precaution I take is not to exert too great hydrostatic pressure during irrigation: I usually tilt the tip

of the syringe toward the centre of the nose. It is in this class of cases that bichloride of mercury in one-half-per-cent. solution, applied hourly on cotton, can be used to advantage; or tincture of chloride of iron may be applied on cotton hourly, besides stimulating the body with tonics, fresh air, and concentrated food. Should, however, any complications arise, then the disease must be treated on general principles. Great stress should be laid on the necessity for immediate burning in the fire of all swabs used.

Serum Treatment of Malignant Forms.—The moment we see that we are dealing with a general infection, with fever, enlarged cervical glands—in fact, that the whole system participates, then no time should be lost. Antitoxin should be at once injected. Children up to two years of age, with pseudo-membranes in the pharynx, who have not yet assumed a necrotic tendency and who do not show laryngeal stenosis, should receive 500 antitoxin units; but if any laryngeal stenosis exists, or if necrosis in the pharynx exists, then from 1,000 to 4,000 units must be injected at once. In children in whom the disease has already existed a long time, and in whom there are enlarged lymphatic glands, hoarseness, and laryngeal stenosis, 2,000 antitoxin units should be injected at the commencement of the treatment and the result carefully noted. If no improvement is visible in twenty-four hours, it is wise to follow the first injection by a second one, of either 1,000 or 2,000 units. In older children it is wise, in very malignant cases, to commence treatment by injecting 3,000 antitoxin units. The symptoms of improvement which should guide us as to the necessity of repeating the injection of antitoxin are a rapid decline of the fever, throwing off of the false membrane, or an apparent loosening of this otherwise firmly adherent pseudo-membrane, with general constitutional improvement and limitation of the pseudo-membranous patches.

Baginsky states that although he has seen urticaria, erythema, and at times inflammation of joints following injection, the patients all improved in time. Albuminuria, heart lesions, and nephritis he does not consider the results of antitoxin injections when they occur during orrhoterapy, for he says these complications existed long before antitoxin was known.

Besides the injections of antitoxin, active local treatment is required, and Baginsky believes an ice collar should be applied and small pills of ice or ice cream taken internally whenever possible, *i.e.*, if the child is old enough. The internal medication consists chiefly of cinchona and iron, or the ethereal tincture of iron, in conjunction with a strengthening diet. As a local application the following may be used with a brush every hour or two:

R Ammonie sulfo-ichthyolic.	.	.	.	10.0
Hydrag. bichl. corros.	.	.	.	0.1
Aque. dest.	.	.	.	100.0

For infiltrated cervical glands, mercurial inunctions or an ichthyol-lanoline salve, 10 to 20 per cent., several times a day, are of decided advantage in some cases.

Treatment of Septic Forms.—Having given the required amount of antitoxin, which in some cases is as much as 3,000 or 4,000 antitoxin units at the first injection,¹ we must attend to local treatment as given above and watch for cardiac adynamia, which manifests itself by feeble pulse, muffled heart sounds, and

¹ In diphtheritic laryngeal stenosis, when septic symptoms exist and when a large quantity of antitoxin is required, it is advisable to inject as small a quantity as possible, highly concentrated. For this purpose potent and extrapotent antitoxin have recently been made, each cubic centimetre containing 300 and 400 antitoxin units respectively, so that 5 c.c. would be in the last instance equal to 2,000 a. u. and 10 c.c. would be equal to 4,000 a. u.

arrhythmic cardiac action. If we are called upon to treat this condition, then tincture of strophanthus, one drop for each year of age, may be given three times a day or oftener; digitalis, Squibb's fluid extract, cautiously used in one-drop doses, is advantageous. It should be remembered, however, that the use of digitalis must not be prolonged, for it disturbs the stomach, and also that its action is cumulative. It is in this condition that wine, champagne, or whiskey is so urgently called for, and as much as half a pint of whiskey may be given daily, preferably by giving milk and whiskey; or eggs and wine or eggs and brandy may be used instead. We must also think of the value of caffeine, camphor by hypodermic injection, nitroglycerin, and mustard baths when indicated.

Oxygen is a most valuable adjunct in this condition, especially so if dyspnea due to a complicating pneumonia exists, and even when no pneumonia existed I have seen great benefit following its use. Such valuable remedies should not be entrusted to inexperienced parents or to persons not familiar with their use, and therefore it is always wise to have a trained nurse in charge of these cases. Whether we give oxygen by the mouth or the nose is immaterial, providing we give it; I certainly prefer to have it administered through the nose than to have a struggling child bite and break the glass mouthpiece through a parent's ignorance in forcing the glass tube between its teeth, as recently I saw done while entering a room in a case in which I was called in consultation.

Method of Using Antitoxin.—As illustrating my method of using the antitoxin, permit me to cite the following cases:

Samuel Roberts, two years and nine months old, 193 Myrtle Avenue, Brooklyn, was seen by Dr. Bienenstock at 2:30 A.M., September 1st. The child had a croupy cough, and the throat showed yellowish deposits on the pharynx and tonsils, so that the clinical diagnosis of diphtheria and laryngeal croup was made. The child was placed on caffeine and benzoate of sodium, which seemed to reduce the temperature, but at 8 A.M. the stenosis of the larynx was so increased that I was called in consultation. I saw the child on the morning of September 2d, and met Dr. O'Connell, of Brooklyn, besides Dr. Bienenstock. After consultation we decided that the main point was to give mechanical relief for the stenosis, and I intubated about noon. Besides putting an ice collar around the child's neck and leaving the mouth alone, we agreed to use rectal feeding. No antitoxin was given at this first consultation. We left the tube *in situ* for about six days. The temperature having gone down to almost normal and the child being in a fair condition, the stenosis having entirely disappeared, we decided to extubate. I extubated on September 6th, at 9:30 A.M., waited a short time, and found no audible stenosis. We still ordered cold to the neck and continued the expectant plan of treatment. When I got to New York, about an hour later, I was summoned as urgently as possible to reintubate. Meanwhile, Dr. S. P. Truax, of Brooklyn, had been called, besides also the attending physician, Dr. Bienenstock, and the child received a little warm sweet oil in its mouth to relieve the collapsed condition. At 1 P.M. I reintubated, when the stenosis at once disappeared and the child's condition again improved. It was then that on talking over the treatment with the attending physician I decided to use antitoxin. I injected 5 c.c. of Aronson's double antitoxin, of the strength of 1,000 units, in a careful aseptic manner in the interscapular region. Besides rectal feeding, using concentrated meat and egg emulsion plus some stimulation of brandy, we decided to leave the mouth alone. It was the rule to order a saline enema of the ordinary warm salt solution to cleanse the rectum of any accumulated

fecal matter prior to each nutrient enema. On September 14th I extubated; the temperature remained normal, and on September 20th the attending physician informed me that the child had been taken into the park, that the voice had returned, that there had been very little emaciation, and that the urine was normal. The patient was discharged as cured.

A child, M—, about five years of age, was seen by me in consultation with Dr. Martin Goldberger, of this city, on Tuesday, October 13th. I found that the child, according to the attending physician, had been ill two or three days. When he first saw the case he diagnosed diphtheria and, recognizing it to be malignant, gave an injection of 1,000 units of antitoxin. The child did not improve enough to satisfy the doctor, and he found on careful examination that he was dealing with a septic type of the disease. Large membranes filled the alae nasi; the temperature was 102.4° F.; pulse, 110; respiration rapid; general appearance good. The child was a mouth-breather, evidently from the presence of adenoids. A very distressing labored breathing with dyspnea was noticeable, and to all appearances the child was suffocating. On holding the nose tightly shut with my fingers, the breathing by mouth appeared easier, and it was evident that the noise during respiration was due to the obstruction of the current of air by pseudo-membranes in the nose and naso-pharynx. The examination of the throat revealed enormous hypertrophied tonsils. There were loss of appetite, slight constipation, no vomiting, some thirst, and intense headache. On considering all points in this case, besides the somnolent condition, I decided to inject a large quantity of antitoxin and gave 2,000 units of Aronson's. The temperature at my first visit was 102.4° F., and gradually crept up to 105° F. on the second day. The temperature was always taken in the rectum. Both Dr. Goldberger and myself suspected pneumonia, but a careful physical examination of both lungs proved negative. Remembering, however, the possibility of a pneumonia centralis, we cautiously used stimulants, ordered the expectant plan of treatment, and gave oxygen. In this case it required from thirty-six to forty-eight hours for the temperature to fall, and then it fell by lysis, *i.e.*, gradually. The swelling of the submaxillary glands was not very marked. The mechanical treatment of forcing a permanganate-of-potassium douche, 1 to 1,000, through the nose was rewarded by bringing away large masses of tenacious membrane, and it was ordered several times a day. In this child the constant drowsiness and sleeping, the large pseudo-membranes in the pharynx and tonsils, and rhinitis, besides no food being taken, made the prognosis very grave. The treatment was followed up by careful stimulation and nutrition. The patient was discharged cured five or six days after my first visit. The urine was examined several times and showed nothing abnormal, save the usual manifestations of slight albuminuria, which subsided without further treatment. A little earache developed about ten days after the treatment was first commenced, which we attributed to possible entrance of fluid from the nose through the Eustachian tube during the mechanical irrigation. Dr. Goldberger informed me that the child had completely recovered and was again out of doors.

In a paper read before the Medical Society of Pennsylvania, May 21, 1896, Edwin Rosenthal, of Philadelphia, gave a series of interesting reports of reduced period of intubation consequent upon the serum treatment of laryngeal diphtheria. His conclusions are: 1. The duration of intubation varies. Some cases were extubated after one-half hour; others after forty-eight hours; but his average was one hundred and twenty hours. European observers—Bokai, Von Ranke, Heubner, and American observers—

O'Dwyer, Fischer, Rosenthal, all agree as to the considerable saving in the length of time the tube is required now with the use of serum, as compared with the time that was formerly required. 2. The operation of tracheotomy is avoided, and intubation, when used in conjunction with antitoxin, may be considered to effect a cure even in long-continued cases (five days and over). The use of serum has placed intubation on a definite basis by: (a) lowering the mortality; (b) shortening the period of intubation; (c) avoiding the major operation of tracheotomy.

Dr. Jacobi, speaking of antitoxin, says: "Nor is there a practitioner but has at present the right or rather the duty to give it a place among his most reliable remedies. If present experience is confirmed by many more similar facts, it will be entitled to be claimed as a specific, though it have not the power to cure every case of diphtheria, any more than quinine cures every case of malaria, or mercury of syphilis. Paralysis is no less frequent in antitoxin cases than it was formerly; it may be that many cases which survive with antitoxin and develop paralysis would not have lived to become paralyzed under a less satisfactory treatment. At all events, there are but few left who maltreat both the child and the throat by the former cruel methods of local applications and cauterization." He quotes Baginsky, Fischer, and others.

Dr. A. Campbell White, while physician at the Willard Parker Hospital, made some very interesting experiments, in which he tried to find the most useful antiseptic to be used in local irrigation, and speaks highly of the salt-water solution. He says: "We have found no antiseptic solution which has so materially shortened the duration of the diphtheritic membrane or the necessary period of isolation of the patient." His interesting report is contained in the New York health department bulletin No. 1. This I can fully endorse, as a result of careful personal observation.

After-Treatment. By this I mean that following antitoxin the matters to be especially considered are: 1. Supporting diet. 2. Careful cardiac tonics. 3. Stimulants only when called for. 4. Nasal irrigation. 5. Local antiseptics, rarely called for. 6. Attention to bowels and urine. 7. Treatment of complications as required. 8. Strictest attention to hygienic measures, insuring fresh air, bathing when required, absolute cleanliness as to clothes and linen. 9. Immediate disinfection, or, preferably, the total destruction by burning or steaming of everything used in contact with the patient, especially swabs, etc. 10. Isolation until all bacilli have disappeared, blood-serum culture to determine this point. 11. If it is a laryngeal case, then my plan is to feed per rectum whenever possible, especially when nurses are handy, by means of peptonized foods, such as milk and eggs, avoiding stimulants per rectum.

I regard strychnine as a most valuable adjunct in the cardiac feebleness, and I believe it will increase the muscular tone of the heart better than any other drug.

Feeding in Diphtheria.—I make quite a distinction in feeding with and feeding without intubation. My success is greatest and my complications are fewest when I have those children that are intubated fed per rectum and per rectum only. The so-called Schluck-pneumonia is in most instances really only a mechanical pneumonia, due to fluids entering the trachea and alveoli through the tube while *in situ* during intubation, and the question of leaving the tube in the larynx is to-day not to be considered as formerly or in the pre-antitoxin days. I rarely find it necessary to leave the tube in the larynx more than from three to five days, and during this time we can safely use the rectum for absorption. It is important to remember that the rectum merely absorbs and does not digest. Hence we must peptonize foods. On the other hand,

if we are not dealing with an intubated case, we can safely feed per mouth. I use concentrated foods, some of which are beef, veal, and chicken broths, chicken jelly, clam or oyster soup, expressed beef-steak juice, yolk of egg with milk and brandy or whiskey if indicated. I feed every two or three hours, using small quantities, one, two, or three ounces at a time.

Nasal feeding: In obstinate children we frequently have great difficulty in feeding per mouth, and rather than exhaust a child by using force, and knowing that we must sustain life, it is frequently advisable to feed through the nose in the following manner: Lay the child flat on its back, and have the nurse hold its arms and head; pass a small rubber catheter well lubricated (I use glycerin for this purpose) into the nose, and by pushing it we can easily enter the pharynx, œsophagus, and stomach. I attach a glass funnel to a piece of rubber tubing, such as we ordinarily use for lavage, and, having entered the stomach, allow the peptonized milk, which has previously been prepared and put into the funnel, slowly to enter the stomach. Nasal feeding I have used only when the rectum showed irritation from rectal feeding, giving symptoms of tenesmus, etc., and when I wished to give the parts rest. It is distinctly understood that I do not advise nasal feeding in nasal diphtheria.

If a cathartic is called for, I give either calomel or, if the child is old enough, a few tablespoonfuls of liquor of citrate of magnesium or a few spoonfuls of Villacabras water. Locally, ice-cold cloths or an ice collar are exceedingly valuable. I do not use sprays or gargles of any kind, as a thorough nasal irrigation suffices to gargle the vault of the pharynx.

While describing medicinal treatment and orrhotomy, it is, I believe, proper to mention mechanical treatment; but this is most urgently called for in laryngeal stenosis, and it is hardly in the province of this paper to give the details of intubation, the uses of which are so well understood by most of us.

187 SECOND AVENUE.

NOTES ON APPENDICITIS.¹

BY ROBERT T. MORRIS, M.D.,
NEW YORK.

Frequency of Occurrence of Appendicitis.—In order to make an estimate of the number of appendicitis cases that develop annually in the United States, I wrote to several general practitioners who are in the habit of diagnosing appendicitis, and asked them to report upon the new cases that had come to them in one year, between the dates of July 1, 1895, and July 1, 1896. Eight physicians have answered my query, and the average number of cases for each one during that period was four. In order to make an estimate of the number of appendicitis patients who die under medical treatment, I analyzed the findings in one hundred consecutive operative cases of my own, and found that the death rate in that particular series would have been about twenty-eight per cent. eventually, but not necessarily in the first or second or tenth attack. The estimate was based upon these findings:

100 Consecutive Operative Appendicitis Cases.	Estimated Deaths under Medical Treatment.
7 cases of tuberculosis and cancer.....	5
1 case of strangulation of bowel by appendix adhesion band.....	1
38 abscess cases.....	15
8 cases with hard incarcerated concretions.....	2
12 cases of occluding stricture dams.....	5
34 cases in common interval stages or in acute stages before advent of pus.....	0

¹ A paper read at the meeting of the New York County Medical Society, November 23, 1896.

This estimate, I presume, is low enough to please the most conservative.

Incidentally, it may be interesting to know that the surgical death rate in this series of one hundred cases was two per cent. A fair criticism will be made that only the worst cases get to the surgeon. To this I answer that the list contains practically all of the cases of any sort of severity that occurred in the practice of some physicians of my acquaintance, and consequently an average medical death rate of twenty-five per cent. would be low enough, remembering always that this refers to eventual death rate, and not to the rate in first, second, or tenth attacks.

According to Polk's "Medical and Surgical Reporter of the United States for 1896," there are rather more than 103,000 physicians in this country. Instead of allowing four new cases of appendicitis annually for each one, let us put the number at two, which gives 206,000 new cases of appendicitis annually in the practice of physicians in the United States. Twenty-five per cent. death rate for causes given in my stated analysis would show 51,500 deaths from appendicitis annually, at an estimate which is probably too low. It is my plan to obtain statistics from a much larger number of physicians, but it is necessary for me to know personally that the physicians to whom application is made are in the habit of recognizing the cases. For instance, one physician of my acquaintance who has a deservedly large practice because of his fine general qualifications, is reported to say that he has never seen a case of appendicitis. I have operated upon two cases of appendicitis which had been under his treatment in previous attacks, and I know of two other cases that terminated fatally under his treatment, which had been diagnosed as appendicitis by other physicians. He is certainly not one of the men from whom I can obtain statistics, although he is the sort of man whom the best class of people depend upon for trustworthy information in regard to the subject. With a stubbornness which has won for him success in overcoming obstacles in life, he maintains that appendicitis is a fad, and his cases of that disease do not appear as such in the vital statistics reports.

Etiology.—Appendicitis begins at an infection atrium. The infection atrium is produced in the mucosa or in the serosa of the appendix. An infection atrium is apparently produced in the mucosa of the appendix by traumatism inflicted by the right psoas muscle commonly, by traumatism inflicted by a concretion frequently, by traumatism inflicted by entozoa occasionally.

An infection atrium is also produced in the mucosa of the appendix by bacterial inflammation of any sort which injures the protecting epithelial layer.

An infection atrium is produced in the serosa of the appendix when destructive inflammation extends from the serosa of some neighboring structure to the serosa of the appendix.

When an infection atrium has allowed the entrance of bacteria or toxins or both into the tissues of the appendix, the results are in character similar to the results of similar invasion of the colon, but they are different in degree. The reasons why they are different in degree are not more than two or three, but these are of determining importance.

First reason: The narrow outer tube of the appendix will not allow the lymphoid layer and the connective tissues of the inner tube to swell quickly and freely, and the inner tube is therefore subjected to compression anæmia within the confining outer tube. Compression anæmia so disables the compressed tissues that they readily fall a prey to bacteria.

Second reason: The blood supply of the appendix is principally from a solitary terminal artery. Branches of this artery are occluded by infective in-

flammation. Bacteria attack tissues which are deprived of their blood supply when arterial branches of the solitary appendix artery are occluded by endarteritis.

The two reasons above given do not apply to the colon, and that explains why the colon so often escapes the common destructive inflammation to which the appendix is subjected.

In appendicitis it is not necessary to have "anything in the appendix" excepting bacteria, for that is all that we have in the bowel in cholera infantum. The biggest thing that ever gets into the bowel is the colon bacillus, when that bacillus is favored by conditions for its development at the expense of structures which cannot defend themselves. The reasons why the appendix is a target for the colon bacillus are the ones that I have given. We see why it cannot defend itself as the colon does.

The principal reason why appendicitis occurs less frequently in women than in men seems to have been explained by Robinson, of Chicago, who has shown that the appendix in women much more frequently hangs over into the pelvis, out of the way of psoas traumatism.

Diagnosis.—The diagnosis of appendicitis is made principally by expert palpation, and secondarily from the testimony of the subjective symptoms and vital signs. The most important thing to bear in mind in this connection is the fact that the temperature of the patient is a matter of no consequence as giving any clue to the condition of the appendix.

Palpation.—Some physicians say that they cannot palpate a normal appendix; other physicians fear that no one can do it. Gynecologists, who are in the habit of palpating ureters and Fallopian tubes, find it an easy matter to palpate normal appendices after they have adopted a correct method of procedure. Some surgeons palpate most of their interval appendices in the presence of an audience, and state their findings before operating. It is all a question of acquired skill and method.

In attempting to palpate the appendix in an acute progressive case, we have to deal with a board belly so rigid that deep palpation is difficult and dangerous; but when board belly makes palpation difficult palpation is unnecessary, because we already have testimony enough. Board belly is the principal differential sign between acute appendicitis and salpingitis.

Pathology.—When a physician is uncertain whether he shall turn an appendicitis case over to the surgeon or over to the bacteria, he must be informed upon the relative dangers from the two entities, and the question is decided upon the known pathology of appendicitis and the known qualifications of the surgeons in any locality. The physician cannot avoid making a study of these two real factors in the problem, because it is absolutely a question of life or death for some of his patients—perhaps for a member of his own family.

The pathology of appendicitis which I offered to the profession at Washington in 1893 has been pretty generally accepted, or corroborated since that time, in this country and in Europe. It is all contained in my book upon the subject, so I shall this evening simply give object lessons in the known pathology, by passing about a series of type specimens illustrating the various stages of appendicitis, from early infection to rhexis and complete gangrene, and from early infection to complete connective-tissue replacement of all structures of the appendix excepting its peritoneum—an ending reached by the largest proportion of all appendicitis cases after passing through the dangers of acute infection. There is no occasion for the display of any speculative philosophy or any personal feeling in discussions upon the subject of appendi-

eritis. It is all a question of knowing the pathology or not knowing it.

Catarrhal Appendicitis.—There is no specimen of catarrhal appendicitis in the group, because I have not as yet operated upon any case in that stage. There is no doubt that catarrh of the mucosa occurs in the incipency of infective appendicitis, and it must occur simultaneously with catarrh of the colon and cæcum; but apparently it causes no symptoms which would lead me to make a diagnosis of appendicitis. When we have symptoms of appendicitis sufficient to lead me to advise operation, the case has passed beyond the catarrhal stage. If any one can make up his mind that it is right to operate in the catarrhal stage in any given case, and if he will present me with the specimen, I shall be very thankful for it, as such a specimen is very much needed for the completion of my series. The diagnosis of catarrhal appendicitis is constantly being made by physicians who have not obtained a series of specimens. Those of us who are in the habit of getting the specimens find that the cases diagnosticated at the bedside as catarrhal appendicitis are cases with big or little concretions, cases with walled-in sloughs and perforations, cases with big or little ragged ulcerations of the inner tube, cases with stricture dams and empyema and tuberculosis. These are the things that we find when we really look to see what is the matter with the appendix.

The term "catarrhal appendicitis" is a narcotic term, which dances before the eyes of consultants and pleases them. We must use persistent effort to eradicate it from the consulting-room. It is almost as vicious a narcotic term as "malaria" in post-partum infection cases, and both terms leave a black train of deaths in their wake. They are more deadly in their effects than the narcotic word "exhaustion," which is made to take the place of the painful word "septicæmia" in descriptions of fatal cases following operation. The word "exhaustion" painlessly shifts the responsibility from the live surgeon to the dead patient, and does little damage excepting to morals.

Medical Treatment.—The cases of acute infective appendicitis with big or little concretions, with walled-in sloughs and perforations, with big or little ragged ulcerations, with stricture dams closing off mucous cavities, may all subside one or many times under various kinds of medical treatment. The ice pack and catharsis are effective with some physicians. Morphine treatment and locking the bowels are effective with other physicians. Patients often die under any form of medical treatment in the first attack, or in the second attack, or in the tenth attack. Patients who do not die under any sort of medical treatment often lose much valuable time in bed. No one can foretell which patient will recover, which one will spend much or little time in bed, which one will die. That is always determined afterward. When we lose a bright boy whose case did not present "symptoms calling for an operation," we say: "There! that was a case for operation!" The diagnosis of the nature of any case of appendicitis is made afterward. The reason why no one can foretell the outcome in any case of appendicitis is because the abdominal wall is opaque.

Surgical Treatment.—The surgical death rate of two per cent. in the series of one hundred consecutive cases quoted this evening, could evidently have been avoided if the two cases could have had operation at a time which I would have chosen: but circumstances prevented, and so these two men were buried. If circumstances had prevented all of the one hundred cases from having operation, about twenty-eight of the patients would have been buried for reasons perfectly clear and evident, as shown by the findings at operation.

Immediate Operation.—In view of the fact that no one can describe the appearance of an infected appendix until he has looked at it, in view of the fact that each hour of progress in an advancing case allows wider infection of structures, in view of the fact that each subsequent attack leaves the patient a little farther away from safe and easy operation—I long ago stated the rule that we should isolate an infected appendix as soon as an accurate diagnosis could be made, provided that the case was in skilled hands and that the case was otherwise within surgical limitations. I was promptly misquoted. Opponents who were not quite familiar with the significance of the word "rule," made it appear that I was not wise enough to bend to justifiable exceptions. If a patient has diabetes or a dilated heart or sclerotic arteries, I see to it that a consultation is called, and I listen well to the opinions of physicians if they possess the judicial temperament and if they really know something about genuine surgery. I was widely misquoted on the subject of removal of "slightly infected or normal appendices." This began as good-natured banter on the part of friends, and ended as malignant quotation by men who found that they could make use of it. The idea of removing normal appendices I have always opposed in speaking and in writing. The reason for my opposition is because a perforating wound of the bowel is made by removing a normal appendix. The danger is small in skilled hands, and yet it is enough to forbid us from subjecting a patient to that risk until acute infective appendicitis makes the matter one of comparative dangers for the patient. Any one who has been led into believing that I have at any time advocated any other idea, is not familiar with the plane on which my surgical work is conducted. As to "slightly infected appendices," they are not sent to me. I have no patients of my own. There is no need for discussing the question.

The Nearest Surgeon.—Some physicians who have lately come to believe in the rule that cases of true infective appendicitis should have the infected appendix isolated, say that they send their cases to the nearest surgeon. The nearest doctor, or the nearest lawyer, or the nearest broker, or the nearest engineer are all lotteries. Some surgeons not previously famous have become famous through their results in appendicitis work. Other surgeons who had deservedly acquired a fine reputation, have suddenly sent it to smash on appendicitis cases, and some of them have told me that they were discouraged and that they did not want to operate upon another case. The nearest surgeon, then, is not sure to make surgical treatment any safer than medical treatment in appendicitis. Ambitious and successful surgeons from the smaller towns have sometimes gone to some great city to see a celebrated general surgeon do appendicitis work, and have returned to their homes with methods which blasted their reputations and stopped all operating for appendicitis in their vicinity. On the other hand, a Hartford surgeon, at the last meeting of the American Medical Association, reported on a series of one hundred consecutive appendicitis operations of his own, showing a mortality rate of two per cent.

Mistakes in Diagnosis.—Surgeons of proper experience do not make mistakes in diagnosticating appendicitis more often than they make mistakes in diagnosticating fractured bones.

The Short Incision.—In order to avoid scar marring and to reduce the liability to post-operative ventral hernia, I gradually shortened the length of the abdominal incision to one and one-half inches for most of the cases without abscess. This idea, carelessly repeated by surgeons who would not willingly do me a harm, was made to assume different forms. Some said that it was a hard-and-fast rule. Others

thought that the method was to be applied in pus cases. Others thought that I wished to have beginners do that sort of work. The rule is this: Every surgeon should work through as small an incision as he can use safely and well for the patient's best interests. If the surgeon feels that he needs an incision ten inches long, by all means let him use that incision. The blunt-dissection or "gridiron" method of entering the abdominal cavity, I feared would require too large an incision; but that was a preconceived notion. Dr. McBurney, in his admirable contribution to the subject in Dennis' "Surgery," says that in proper cases the incision through the deeper layers of the abdominal wall need not be more than two inches in length; and since reading that opinion I have employed the blunt-dissection method in nearly all of my interval cases with adhesions, making the incision one and one-half inches long through all structures of the abdominal wall.

Abscess Cases.—In cases of appendicitis with abscess, I have made it a rule to break up adhesions in a search for multiple abscesses and for the infected appendix, exposing the free peritoneal cavity without hesitation. Our resources to-day allow us to do that very safely indeed, but one must not attempt it unless he has confidence in his resources. Arguments pro and con before the medical societies are farcical. It is all a matter of individual art. Certain details of treatment in abscess cases have passed out of the realm of individual art and belong to science. I will refer briefly to two points.

Gauze Packing.—When we accidentally leave a gauze sponge in a patient's abdominal cavity and close the incision, the patient is likely to develop ileus. When we put gauze packing into a patient's abdominal cavity, leave one end protruding, and term it a drainage device, this patient is also likely to develop ileus, because as a layman he does not know the fine distinction in nomenclature between "accident" and "drainage device."

Iodoform Gauze.—When an operator has employed iodoform gauze in the abdominal cavity, he sometimes asks me to see the case a day or two later, and a conversation something like this follows: "I wanted to have you see the case, because the patient does not seem to be doing well. His temperature is only a little elevated, his tongue is pretty clean, but his pulse is altogether too rapid and he seems to wander a little in mind. The case was not a bad one at all, but the patient is not doing well." In reply I say: "Take out your iodoform gauze instantly. Remove iodoform from the wound with sterilized oil. Examine the urine for free iodine." A few days later we again meet. The doctor says: "By George! you were right about that iodoform poisoning, and I remember now that I lost a boy with similar symptoms a year ago. But why does Dr. X—not lose cases from iodoform poisoning? I learned the method from him."

In fighting for reform against some of our earlier errors in appendicitis work—late operation, counter-incisions, large incisions, inaccurate suturing, gauze packing, incomplete work, ligation of the appendix like an artery—I seemed to be working against the consensus of opinion in surgical circles; but now that the contest is about over, many surgeons inform me that they were working along the same lines, but so quietly that their popularity was not endangered.

I have not allowed any consideration for popularity, any influence of friends, or any attacks of antagonists to interfere with my work. I saw patients dying, and patients developing post-operative ventral hernias, and patients subjected to two or three operations—and that was stimulation enough to carry on reform work. The atmosphere has been pretty thick with smoke at times, and at one meeting of the surgical section of

the Academy of Medicine the section got itself into the curious predicament of putting the stamp of disapproval upon methods which had given the best statistics at that time. One of the most eminent surgeons, whom we would all like to revere, so far forgot his dignity as to call into question the integrity of my statistics, instead of leaving that sort of thing to a class of men who could do it without injury to the academy. The spirit of scientific investigation was not abroad that night, and the meeting was dominated by quite ordinary motives. The profession at large understood.

Medical Statistics.—At the present time we are much in need of medical statistics of appendicitis. None have been given to us in a scientific way. There have been a number of reports of treatment of series of single attacks, some very favorable and some very unfavorable. What we need is a report upon one hundred consecutive cases of appendicitis treated medically for a period of two years, with full notes on recurrent attacks, loss-of-time rate, interval palpation findings, interval complications, deaths, and post-mortem findings. The time that I have set is very short, but enough things happen to the average appendicitis case in two years to make an instructive report. The statistics must come from men who make the diagnoses accurately, and who make skilful palpation of appendices in the intervals between attacks. Physicians who take the patient's statement of the case without making careful painstaking examination, must not place their cases in the report, because there is a marked tendency on the part of patients who fear operation to say to their physicians that they feel perfectly well whenever a twinge of pain attracts their attention to the seat of the old trouble. The statistics for such a series as I propose cannot be collected in the cities where skilled surgical services are at hand, because we already know that the medical death rate from such unavoidable factors as concretions, stricture dams closing off mucous cavities, abscess, and tuberculosis, is so much larger than the surgical death rate that the medical treatment of one hundred cases carried to a finish would be experimentation of the most heartless kind. The statistics must be collected by some association of physicians who are so situated that one hundred of their appendicitis patients cannot have the benefits of the difference in a surgical death rate of two per cent. and a medical death rate of twenty-five per cent.

Vaginal Secretions.—Krönig, in about two hundred examinations, found that the vagina in pregnant women, aside from the gonococcus and the thrush fungus, contained no pathogenic micro-organisms. The streptococcus was not found in a single case. Moreover, Krönig found after inoculating the vagina with pure cultures of streptococcus, staphylococcus, and bacillus pyocyaneus that none of these micro-organisms could be discovered after eleven to twenty hours. Krönig attributes the germicidal powers of the vagina, which were demonstrated by these observations, to the outward flow of the vaginal secretions, and not to any special microbe having its normal habitat in the vagina. According to this observer, acid, neutral, and alkaline secretions all have germicidal power. Further, Krönig found that if an hour after the infection of the vagina an antiseptic douche of lysol were administered, not only were the infecting micro-organisms not destroyed by the douche, but also that it took the vaginal secretions from nineteen to thirty-six hours to destroy microbes that without the douche would disappear in eleven to twenty hours.—*Deutsche medicinische Wochenschrift*, October 24, 1894, p. 819.

Progress of Medical Science.

Successful Graft of the Spinal Cord of a Rabbit in the Median Nerve of a Man.—Robson (*British Medical Journal*, October 31, 1896, p. 1,312) has reported the case of a gardener, twenty-nine years of age, who sustained a deep incision on the lower and inner part of the right upper arm, with division of the brachial artery, by falling on a scythe. The artery was ligated and the two ends of a divided nerve sutured. The wound healed slowly by granulation, but finally closed, leaving the muscles of the wrist and hand supplied by the ulnar and median nerves paralyzed, while those supplied by the musculo-spiral retained their motility. Sensibility was lost in the same distribution and also in that of the internal cutaneous nerve. An operation was undertaken, an incision being made along the line of the cicatrix and prolonged some distance upward and downward, and supplemented by a transverse incision about an inch above the elbow. The lower end of the upper segment of the ulnar nerve, which was bulbous, was connected by fibrous tissue with the upper end of the lower segment. A small nerve was found at the upper part of the wound, which proved to be the internal cutaneous. The lower end of the same nerve was found subsequently and united to the upper with a catgut suture. After considerable search the bulbous lower end of the upper segment of the median nerve was discovered at about the middle of the upper arm, concealed by the belly of the biceps; and the upper end of the lower segment, expanded and sending ramifications into the cicatrix, was found subsequently just above the bend of the elbow. The fibrous tissue between the ends of the ulnar nerve was excised and the two healthy portions were united by grafting strands of the sciatic nerve of a rabbit so as to fill up the gap and establish continuity. It was not possible to bring the divided ends of the median nerve closer together than two and a half inches. In the absence of more suitable tissue the spinal cord of a rabbit just killed was used as a graft to connect the ends of the median nerve, the inserted cord lying loose and quite free from tension when finally placed in position. Fine catgut sutures were used throughout. The edges of the wound were brought together, the usual dressings applied, and the arm was fixed upon a rectangular splint. Union took place by first intention, with a total absence of fever and pain. Eleven days after the operation the patient could feel the scratch of a pin on the flexor aspect of the first phalanx of the thumb, as well as at the root of the index finger. He could tell when the hairs on the back of the first phalanges of the ring and little fingers were touched, but could not feel the scratch of a pin in that situation. Seven days later sensation had returned over the whole of the palmar surface of the thumb and the proximate phalanx of the index finger. After a further interval of sixteen days sensation seemed to be creeping slowly along the first finger and to be present over the whole of the palmar area supplied by the median nerve and extending down as far as the web of the fingers and a short distance along the middle finger. The muscles presented evidences of gradual development and the general nutrition of the hand improved. Slight power of grasp and some power of flexion of the wrist returned, with slight power of adduction of the thumb and flexion of the fingers. Sensation was present all over the thumb and index finger and in the second finger up to the first phalanx on the palmar aspect, also in the third finger, though less distinct. In the course of several weeks more sharp shooting pains began to be felt in the distribution of the ulnar nerve and the flexors of the fore-

arm began to react to galvanism. Improvement thus continued, when the patient was lost to observation, and then was not seen again until after the lapse of six years. The man had continued the use of galvanism for a time and did not resume his work until more than a year after his accident. During the subsequent five years he had not missed a day's employment, attending to all of his duties, from wheeling a well-laden barrow to using a scythe. On examination the right arm was found scarcely smaller than the left and power had returned to all of the muscles except the abductor of the thumb. Sensibility also had been restored and the electric reactions were normal except in the muscle named.

The Diagnostic and Prognostic Value of Angina in Variola.—Dr. Chassy (*L'Indépendance Médicale*, October 7, 1896, p. 328) says that angina in variola always manifests itself at the same time as the cutaneous eruption (ordinarily at the end of the third day). It is often evident before the cutaneous eruption. Like it, the elements pass through the same phases, macules, papules, vesicles, and pustules. Peri-amygdaloid and submaxillary œdema are frequently observed in the confluent forms. It is a benign œdema, which may be confounded with parotiditis. Angina of variola presents little gravity if uncomplicated. It does not leave cicatrices after healing. Its coincident appearance with cutaneous eruption is an element of differential diagnosis that is highly important. Slight hemorrhage, at an early stage, in the papules of the palatine vault (resembling tobacco seeds), announces the early, hemorrhagic, deadly form. The presence of streptococcus pyogenes appears to be an aggravating element in prognosis. Angina of variola is of great importance from a hygienic standpoint. It assures an early diagnosis, even in varioloid and in concealed forms. It proclaims and controls the intermittent outbreaks following in the course of the contagious disease. The treatment should be antiseptic—gargles and naso-pharyngeal washes with lukewarm boric-acid solution.

Infantile Scorbutus.—Dr. A. L. Vernhes (*L'Indépendance Médicale*, October 7, 1896) writes as follows: This malady, studied by many authors, results from the influence of insufficient nourishment or of over-feeding. It is often complicated with rickets, and its principal symptoms consist in hemorrhagic manifestations, which give it a marked analogy to scorbutus. Of the true nature of this disease but little is known; it is, however, generally attributed to defective nutrition followed by inanition. It often follows gastrointestinal affections or infectious diseases, such as scarlatina, whooping-cough, etc. This leads us to suppose that infection plays a rôle as the occasional cause of this affection.

Remarks on the Topography of Zona.—Dr. Dongradi (*L'Indépendance Médicale*, October 7, 1896) writes that most cases of zona called primary or essential have a spinal origin. The disagreement which exists as to the topography of the eruption and the distribution of cutaneous nerves; the concordance of the topography of this eruption with that of sensitive troubles of medullary origin; the possible coexistence of spinal anaesthesia with the eruptions; the character of the pains, which are vague and diffuse; the habitual absence of neuralgic points; the existence, sometimes verified, of symmetrical pains and of spinal hyperaesthesia; some instances of motor troubles associated with the zona—constitute the arguments in favor of the medullary theory. The infectious theory of Landouzy is easily reconcilable with the spinal origin of zona.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 26, 1896.

THE SURGICAL TREATMENT OF GASTRIC PERFORATION AND HEMORRHAGE.

THE most certain, withal the most radical, method of preventing the disastrous consequences always likely to follow perforation of or hemorrhage from the stomach or intestines consists in direct exposure of the seat of lesion and suture of the opening or ligature of the bleeding vessel. It goes without saying that such measures may not always be necessary, but the decision in the individual case must depend upon the conditions present and the special indications to be met. Whenever doubt exists as to the course of action to be pursued, the principle will be a safe one to follow that the risks and dangers of operative interference are in general less than those of expectancy. The validity of this proposition has been amply demonstrated throughout the whole range of modern surgery. As illustrations we need but point out the control of intracranial hemorrhage by trephining and the application of a ligature to the bleeding vessel or the packing of the wound; the excision of the vermiform appendix in the event of suppurative, ulcerative, or perforative appendicitis; the performance of celiotomy for the relief of perforation or the control of hemorrhage in case of typhoid fever or gastric ulceration.

The difficulties under the several conditions named are always considerable, often apparently insurmountable and sometimes really so, but the results in every way justify the surgical procedure. In the event of perforation of the stomach, operation may be undertaken at once and should not be interfered with by any ordinary counterindication. Single or occasional hemorrhage in a case of gastric ulceration may be left to the usual therapeutic measures, but persistent, frequently repeated, or copious hæmatemesis, sufficient to portend a fatal issue, may be looked upon as an indication for abdominal section and exploration, together with such additional procedures as the conditions present in the given case may seem to justify.

A not inconsiderable number of operations have already been performed in cases of gastric ulceration, as a rule on account of the occurrence of perforation, but in at least one for the control of hemorrhage. In a very fair proportion the results were entirely successful. One of the earliest of the successful cases

has been reported by Barling.¹ Following symptoms of peritonitis due to perforation of an ulcer of the stomach, a swelling appeared in the left hypochondrium, which proved to be an abscess behind the stomach. Upon evacuation of this accumulation and the provision of drainage recovery ensued. Two other cases previously operated on by Barling terminated fatally. In one the site of perforation could not be discovered at the operation, although a perforating ulcer of the stomach was found after death. In the second case an ulcer was found and sutured, but after death a second area of ulceration, almost perforated, was found in a different situation. A successful result has also been reported by Gilford,² who excised the margins of a perforated gastric ulcer and approximated the edges with sutures. Atherton³ has reported one case in which death followed the evacuation through a small incision in the epigastrium of about two quarts of sour greenish fluid from the peritoneal cavity and the introduction of a drainage tube; and a second case in which recovery followed exposure of the perforation after celiotomy and suture of the margins. An exceedingly interesting group of cases of perforation of the stomach consequent upon ulceration was reported at a meeting of the Clinical Society of London⁴ during last year. Dunn reported one case in which suture of the perforation was followed by recovery, and a second in which perforation was not found at the operation, while a large area of gastric ulceration was found after death. Silcock related a case in which a perforation was successfully sutured, but death took place in consequence of septicæmia due to a purulent accumulation about the stomach, liver, and spleen. In a second case, in which a perforation was found in the midst of adhesions between the stomach and the liver, recovery followed the introduction of a drainage tube and closure of the wound. Lees reported one case in which the contents of a subphrenic abscess were evacuated through a trocar and several days later fatal hemorrhage took place; a second case, which terminated fatally, although operation was done within forty hours after rupture and the perforation was closed by suture; and a third case in which one perforation was sutured and death resulted from perforation of a second ulcer. Cheyne reported a case in which the perforation was found limited by adhesions; the wound was left open for a week, but two days later the patient died, and on post-mortem examination a large abscess was found above and behind the stomach. White related a case terminating fatally, in which operation failed to disclose the existence of ulceration and there was little evidence of peritonitis. In a second case temporary relief was afforded by washing out the stomach, but death occurred suddenly and post-mortem examination disclosed the presence of perforating gastric ulcer firmly adherent to the under surface of the liver. Bradford reported two cases, one of which was successfully operated upon, the other terminating fatally

some time after the evacuation of a considerable amount of fluid from the peritoneal cavity. Finally, in a case of gastric ulceration attended with copious hæmatemesis, Küster¹ performed cœliotomy for the purpose of controlling the hemorrhage and preventing secondary contraction. After exposure of the ulcer in the stomach the thermo-cautery was applied. The patient recovered satisfactorily from the operation and gained in weight and strength, and the hemorrhage did not recur. In the most recent contribution to the literature of this important subject, Hirsch² reports a case in which, although hæmatemesis was frequent and copious, ulceration of the stomach could not be found on surgical exploration; and a second case in which, on account of the profound degree of anæmia present and in view of the previous experience, an operation was not undertaken. Death ensuing in the latter, post-mortem examination disclosed the presence of a small ulcer on the anterior wall of the stomach near the pylorus, with the erosion of a large vessel. In view, therefore, of all of the circumstances, and guided by the experience that has already been gained, the conclusion seems justified that operative interference is indicated in cases of gastric ulceration when, notwithstanding regulation of the diet and enforcement of rest, hæmatemesis occurs with such frequency and in such a degree as to endanger life.

THE CLOSE OF VOLUME FIFTY.

THE completion of the fiftieth volume of the *MEDICAL RECORD*, in the present issue, is in some respects a matter for congratulation in connection with the fact that during all the period covered from its first publication until the present it has been under the same editorial management. Through all the continuous labors of the past thirty years the lives of editor and publisher have been spared to make this statement possible. When passing retrospection is thus invited, it is some comfort to believe the efforts to make this publication what it now is have not been altogether vain.

Probably no medical journal started under more unfortunate prognostications than did the *MEDICAL RECORD*. The leading medical men in this city at that time, while they cordially endorsed the project, were almost unanimous in their predictions that no medical journal could succeed, pecuniarily or otherwise, as none had yet done so, and that ultimate failure, much as it might be regretted, was a foregone conclusion. Still, by the very few who thought otherwise it was determined to take the chances of reversing the well-established rule. At this distance of time it is perhaps reasonably safe to conclude that the victory rightly belongs to such as can do and dare. It may not be uninteresting in this connection to say that the original policy of the journal has been consistently carried out in every particular. It has been a rare privilege, granted to few if any, to have worked so long and so continuously in one direction, and to have watched the encouraging progress of the journal during all these

years, as shown by its growth from the smallest beginnings to the present realization of the most extravagant expectations. In this consummation what changes have taken place! How many theories have risen and fallen, how many advocates of them are heard no more, how many, alas! who started in the early career of the *MEDICAL RECORD* have passed away! Comparatively few are now living who can rejoice with us in having placed the first volume on their shelf and in adding one to another until a jubilee number has been reached. To such as may recollect those earlier times we tender the kindly greeting which passes between old tried friends; to the new ones, many and unseen, we still strive to be close and true. Fifty volumes done—the *MEDICAL RECORD* landmark for a fresh start—with greetings of even better times to come and more work to do.

BODY SNATCHING.

How frequently one is led to reflect upon the similarity of events as they occur and are chronicled in the journals of the two English-speaking countries separated by the Atlantic. Coincidentally one reads of the disappearance of a body from the New York Morgue and of the wrong body being taken by mistake from the Queen's Hospital in London. The body of an unknown woman who has died in one of our hospitals is identified by a man as that of his mother-in-law; the insurance money is collected and spent in a funeral, while the real mother-in-law, in actual life, is engaged in the arduous duties of laundry work. Almost upon the same day an undertaker rushes into the dead-house of an English institution and carries away and buries one body, when he should have been in less haste and secured the one in which the friends were more interested.

It is a fact well known to many physicians that certain undertakers are affected with precipitation. Some of them have it in a severe form. It was only the other day that a well-known surgeon had the following disagreeable experience: Death had occurred in a most rare and scientifically interesting form. Permission to perform an autopsy had been granted. Upon reaching the house with one or two invited confrères, the surgeon found that an undertaker had removed the body, the friends thinking the physician had ordered it. Going to the undertaker's establishment, the gentlemen were surprised to find the object of their search embalmed and on the ice, the process having destroyed all possibility of scientific research in the case. Six hours had elapsed from the time of death.

Let us suppose these gentlemen had paid their last visit, not to dissect the patient in the interests of science, but to determine whether the patient were in a state of real death or pseudo-death, what chance would the undertaker have left them or the patient?

Friends, and especially physicians, are to blame for the worse than barbarous manner in which the dead and supposed dead are hurried away by undertakers to beds of ice which preclude any possibility of revival from states of suspended animation. William

² Berliner klinische Wochenschrift, September 21, 1896, p. 847.

Tebb and Edward Vollum have just written a work on "Premature Burial and How It may be Prevented." We do not know what arguments these authors advance, but the subject has received attention often enough in times past to make us ashamed of the manner in which in most civilized countries patients are treated just after they are thought to have expired.

A CRUEL DECEIT.

WE have of late derived much pleasure from the contemplation of sundry portraits of robust and handsome healers with which, in contrast to their word pictures of loathsome disease, some of our esteemed contemporaries adorn their pages. We see in one the round and rosy features of Sir Dyce Duckworth; in another the intellectual but somewhat austere countenance of Mr. Jonathan Hutchinson meets our admiring gaze; while a host of lesser lights, our own and Europe's, twinkle out and illumine this firmament of western journalism. We are grateful for this exhibition of manly beauty, but with the gratitude which is a lively anticipation of favors yet to come we make bold to ask that these portraits be correctly labelled. In one of our most esteemed of contemporaries there was recently a charming picture, labelled "Osler on Angina Pectoris;" but it was neither. It was pretty, but it resembled Dr. Osler no more than it did angina. We are glad that our old friend can claim neither one. And now we are in a most distressing state of incertitude, for we are sure of the identity of hardly one of these collected portraits which made up our gallery. We may perhaps have been engraving upon our heart the features of some unhung train robber, deluded by an unprincipled editor into the belief that they were those of Virchow, of Kitasato, or of N. Senn. The thought is intolerable, and until we have the assurance that the label editor has had a change of heart or really knows the celebrities of medicine, our portrait gallery shall be closed to our visitors.

X-RAYS AND SIGHTLESS EYES.

IN our editorial columns of a previous issue we deprecate the idea of holding out to the blind any strong hope of their being made to see by the x-rays. We have always had the greatest confidence in Mr. Edison's wondrous powers and magic-like achievements, but in the present case we did not feel that he was justified in calling forth hopes which could, in most instances at least, if not in all, result only in disappointment. In a recent number of the *Electrical Review*, Nikola Tesla found little ground for any claims of making the blind see. The rays have not been demonstrated to be transverse vibrations, and at best refraction would be necessary to project a sufficiently small image upon the retina. As it now is, only a shadow of a very small object can be so projected.

Dr. Thomas More Madden, of Dublin, has recently had conferred upon him the honorary degree of master of obstetrics by the Royal University of Ireland.

News of the Week.

Board of Education and Sanitary School Inspectors.—An appropriation of \$47,500 has been granted the board of education to pay medical inspectors for each school district of this city. The health board will appoint one hundred and fifty physicians at \$30 per month for the ten school months of the year. This is a move in the right direction, since most children's diseases of an infectious nature are largely spread through school intercourse. It is to be hoped that careful examination of the scalp will form part of the inspectors' duties and that the spread of favus, ringworm, and pediculosis will thus be materially lessened.

Epidemics in Various Places.—Small-pox is reported to be raging with exceptional severity in the principal sea towns of Japan. At Kobe two hundred cases and several deaths have been reported. Yokohama has declared a quarantine against Kobe, and the board of health of San Francisco has declared both Yokohama and Kobe infected and has established quarantine against all Japanese ports. Colon, on the Isthmus of Panama, is now declared to be free from small-pox, which has been epidemic there for some time. Yellow fever is reported to be slightly less at Havana and other Cuban ports, although the disease is constantly supplied with new material to work upon in the persons of the raw Spanish recruits. In Port au Prince, Hayti, the yellow-fever epidemic shows no signs of abatement. Dr. Terres is reported as saying that the present epidemic is the worst outbreak he has ever seen during his long residence on the island. Every unprotected foreigner who has landed at Port au Prince during the past six weeks has been stricken with the disease. The reports from Bombay concerning the plague are disquieting. The official statistics show that, up to the middle of December, there had been 1,551 cases known to the authorities, and 1,094 deaths. All who can get away are fleeing in terror from the city. Calcutta has become alarmed and recently appointed a sanitary board to make a survey of the city. The report of this board is far from reassuring. It says that the city area is terribly overcrowded, several wards having a population of more than one hundred thousand per square mile, one of them rising to nearly one hundred and forty-five thousand. Houses which should accommodate fifty persons only, if ordinary precautions regarding health were observed, contain five times that number, while the *bastis*, which are collections of mud huts, are densely packed. The environment of filth in which the residents of these huts live is described in terms which make it plain that if the plague or typhus fever should obtain a footing it would be almost impossible to stamp it out. In houses, too, which are outside these *bastis*, insanitary conditions exist which invite outbreaks of epidemic disease. The government has warned the municipal authorities of their neglect of duty and urged upon them the necessity of sanitary reforms in view of the imminent danger of an invasion by the plague.

Fined for Grave Robbery.—Two Dartmouth medical students were recently arrested for grave robbery. They pleaded guilty to the charge, and were heavily fined.

Diphtheria has been prevailing in epidemic form in several places in Northern New York. In Ogdensburg, out of seventy-three cases treated with antitoxin only two resulted fatally.

Bellevue Hospital Medical College.—Dr. T. M. Rotch, of Boston, lectured before the students of Bellevue Hospital Medical College, by invitation, December 15th. The subject of the lecture was differential diagnosis in the eruptive diseases of children, with especial reference to scarlet fever and its complications. The lecture was illustrated with colored lantern slides.

Too Much Study.—Charles Winlander, twenty-six years of age, a student at the Bellevue Medical College, committed suicide on December 14th. He was formerly a student at the Rush Medical College of Chicago and came to New York from Mount Carmel, Ill., some months ago to pursue his medical studies, bringing with him his wife, to whom he had been married but eight months. It is said that too close application to his studies affected his brain. He had complained of severe headaches for some time.

M. Roux Decorated by the German Emperor.—Emperor William has conferred a decoration on M. Roux, for his discoveries in relation to the antitoxin of diphtheria, and, contrary to the precedent in the matter of German decorations, M. Roux has accepted the honor. It was said last year that the German emperor had sounded Pasteur as to his acceptance of the German Order of Merit, and that he refused to accept the honor, declaring that he could never forget 1870.

Against Street Music.—The Brooklyn board of aldermen recently adopted by a vote of eighteen to six a resolution prohibiting the operations of itinerant bands in that city and restricting the use of hand organs to certain hours. A similar resolution passed about two years ago was vetoed by the then mayor, who apparently approved of street noises.

Objections to Canadian Nurses.—The question was raised some time ago as to whether the Canadian trained nurses who come to this country to work in hospitals do so in violation of the law. At that time it was held that they could not be interfered with, as they were semiprofessional persons. Now the secretary of the treasury has ruled that these nurses can be deported, and it is said that the new ruling will be carried out at once, and five Canadian nurses employed in a sanatorium in this State are to be deported accordingly.

The Practical School of Medical Specialties is the title of a post-graduate school recently opened in Madrid. The specialties there taught are obstetrics, gynecology, pædiatrics, surgery, nervous diseases, ophthalmology, otology, rhinology, laryngology and diseases of the liver.

A Subscription to pay the heavy expense (about £1,000) incurred by Dr. Cullingworth in defending the suit brought against him by Miss Beatty, has been begun in England. Considerably more than half the needed amount, namely 561 guineas, has already been subscribed.

Tribulations of Russian Students.—The police of Moscow recently arrested forty of the students at the university, in whose rooms they found a number of letters and papers alleged to be of a treasonable nature.

The Post-Graduate Hospital.—The twelfth annual report of this institution shows that 1,895 house patients were treated during the last year. Of these 729 were babies, and 1,166 children and adults; 20,084 patients were treated in the dispensary, to which more than 75,000 visits were made. Seventy-five thousand visits, if paid for at an average of only twenty-five cents each, would bring in \$18,750 to be distributed among the struggling young physicians of this city. The directors make an appeal for funds to establish free beds in the hospital, and they state that at this moment there are not half enough free beds for the worthy poor in the hospitals of the city of New York.

Faith-Cure Fanatics Struggling with Diphtheria.—An epidemic of diphtheria is prevailing in Hopeton, Oklahoma, and it is reported that the faith-cure people, who compose the majority of the community, persist, in spite of quarantine orders, in holding public meetings at the houses where the disease exists, and physicians sent out by the authorities have been compelled to use force in order to examine the sick. In one instance a twelve-year-old boy was carried through the worst stage by a physician and volunteer nurse and was apparently on his way to recovery, but when the physician left to attend others the father refused to give the medicines or follow any of the instructions, and the boy died, the family and friends sitting around and praying, but doing nothing to relieve his suffering. Six or eight others have been allowed to die in the same way.

Making the Punishment Fit the Crime.—A Montreal school teacher recently discovered some tobacco which had been brought in by one of the boys, and by way of punishment he made an infusion of it and administered it to several of the scholars. The school commissioners very justly reprimanded the fool, who may consider himself lucky that none of the boys was fatally poisoned by him.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending December 19, 1896. December 14th.—Surgeon L. B. Baldwin detached from the *Newark* and ordered to the *Puritan*. Passed Assistant Surgeon S. G. Evans detached from the *Pinta* on reporting of his relief and ordered to the naval hospital, New York. Passed Assistant Surgeon G. Rothganger detached from the *Patterson*, December 25th, and ordered to the *Pinta*, per steamer of December 29th.

The Death Rate of Johannesburg, South Africa, is thirty-two per thousand.

The Body of Sir Benjamin Ward Richardson was, in accordance with his express wish, cremated at Woking.

Stealing Drugs from Doctors.—In the inquest in a case of suicide by cocaine of a woman in London, it was learned that she had stolen the drug, to the amount of fifty grains, from a drawer in the house of her medical attendant.

The Rinderpest.—It is reported that Dr. Edington, the official bacteriologist of Cape Town, has discovered the bacillus of the rinderpest, thus anticipating Koch, who is on the way to the Cape to study the disease.

The Moscow Medical Congress.—The following is a revised list of the officers of the Twelfth International Medical Congress, to be held in Moscow on August 19 to 26, 1897: The president of the committee of organization will be Prof. N. W. Sklifassowski; the vice-president of the committee of organization will be Prof. J. F. Klein (president of the executive committee); and the secretary-general will be Prof. W. K. Roth.

Montreal and Moscow.—The *Medical Press* does not look for a large attendance of English physicians at Moscow. Speaking of the proposal to amend the by-laws of the British Medical Association so that Americans may take part in the meeting next summer, it says that "it is stated that to amend the by-law for the forthcoming meeting at Montreal would lay the association open to the charge of attempting to promote a *r union* rival to that of the international medical congress at Moscow. But we cannot think that this can rightly be deemed to be the case. The congress at Moscow is not likely to suffer from anything which may transpire at Montreal, and chiefly for the reason that the two meetings will be patronized by practitioners drawn from entirely different parts of the world."

A Lunatic on Lunacy.—A curious occurrence took place recently in Professor Krafft-Ebing's clinic, where a patient, at his own request, was allowed by the professor to deliver a lecture in his place, in order to demonstrate the peculiarity of his mental state. The patient is a highly-educated man, of exceptional intellectual endowments, but for many years he has been the subject of so-called "circular" insanity. The recurrence of the disease prevents his pursuing for any length of time any occupation in which his natural abilities and acquired accomplishments would in happier circumstances have enabled him to gain distinction. In the maniacal phase of his illness he shows an astonishing wealth of ideas, and with his manifold knowledge and his readiness of expression (he has lately been a writer) becomes witty and even brilliant in his language. Thus, in the lecture he delivered, on the mental condition of the maniac in periodical attacks of madness, he puzzled his auditory by the brilliant and exact form of his speech, and on

a lay person or a junior student might even have made the impression that his statements were correct and his conclusions logically drawn, though, in fact, they were all nonsense. He spoke for nearly an hour, holding the attention of his audience the whole time. His look and bearing, which are those of a scholar, helped to keep up the illusion.—*British Medical Journal*.

The Bubonic Plague is spreading rapidly in Bombay. On December 8th there were thirty-nine deaths from the disease, and fifty-five new cases were discovered and reported.

The Medical Department of the British Army is reported by its director-general to be short sixty men. If England became involved in a serious war, the combatant officers would soon come to a realizing sense of their dependence upon the medical staff.

The Persecution of Dr. Cullingworth.—The nurse Beatty, who recently lost the suit which she brought against Dr. Cullingworth because he removed both of her ovaries, has just served notice of motion for a new trial of the case.

A Quick Diagnosis.—At a surgical clinic a few days ago, before a class in the Harvard Medical School, a patient was shown who had a wound on the thigh caused by the bite of a rat. The instructor, having asked the class for a diagnosis of the case, one of the students replied promptly, "Rodent ulcer."—*British Medical and Surgical Journal*.

Schnapps and Beer.—By a decision of the Hessian court, it is considered much better to eat bread than to drink schnapps before consuming large quantities of beer. A restaurant keeper had applied for a liquor license, on the ground that the health of his customers necessitated a good drink before starting in on their daily consumption of beer. After examining experts, the court said bread would do.

Ethicomania.—The Melbourne correspondent of the *Medical Press*, after describing one of the many broils of Dr. Leith Napier, the hired man from London in charge of one department of the Adelaide Hospital, adds: "The danger of meddling with such matters was, I need hardly remind you, pointedly illustrated in the recent report of the meeting at Carlisle, and it is at least curious that the gentleman whose case cost the British Medical Association £1,300 was the founder of an ethical society, and in that capacity he figured as an expert in removing or in discovering moles in people's eyes. This is precisely our experience here. Those who are the loudest in preaching the duty of ethics are just the men whose names you will find constantly occurring in the newspapers under all sorts of pretexts. It is the old business in the pantomime—'Here we are again!' The question then presents itself: Are medical journals the proper media in which such matters should be dealt with? Is it the legitimate function of a medical journalist to hunt up infractions of what we are assured are ethical rules? It is devoutly to be wished that the experience gained in this wretched Adelaide strike will serve as an antitoxin in the permanent cure of this ethicomania."

Afraid of Growing Old.—A man in Batavia, N. Y., recently committed suicide on his ninety-seventh birthday.

Dr. M. O. Terry, of Utica, has been appointed surgeon-general on the staff of Governor Black. Dr. Terry is a member of the homœopathic school. He held the same position on the staff of Governor Morton.

Influenza has reappeared in London. The cases are of the usual type, with sudden onset, grave prostration, and high fever, with specially marked gastric disturbance.

A Legacy of a Body Refused.—Dr. Caroline B. Winslow, who died recently in Washington, left a will bequeathing her body to Howard University to be dissected by women medical students in the interest of science. After that she desired that her skeleton be mounted and presented to the Minor Normal School of the district. The university declined to accept the body, and it was cremated.

Dr. William A. Macy, medical superintendent at the Manhattan State Hospital, has been appointed superintendent of the Willard State Hospital, to take the place made vacant by the transfer of Superintendent Mabon to be superintendent of the St. Lawrence State Hospital. The vacancy in the Manhattan State Hospital occasioned by Dr. Macy's promotion will be filled from the civil-service eligible list of candidates for hospital superintendent.

A Wasteful Measure.—A statute was passed last year, requiring the city of New York to furnish a suit of clothes to each insane patient sent by it to the State hospitals. Mr. Croft, commissioner of charities, has requested the board of estimate and apportionment to prepare an amendment to this statute, which shall permit the city to use the clothes more than once. He made an investigation in the Manhattan State Hospital on Ward's Island, to find out what became of the clothes furnished to the patients by the city, and found that the clothes were worn by the insane only during their passage from the city to the island, and that they accumulated so fast that it was necessary to burn great quantities of them every month. He said that the clothes cost the city \$16,000 last year, and \$25,000 would be necessary for the same purpose this year.

Unauthorized Use of a Physician's Name.—A drug company of this city recently distributed a pamphlet in England, containing laudatory testimonials of one of its preparations. One of these testimonials purported to be from Dr. W. B. Ransom, of Nottingham. As the gentleman mentioned had written no such testimonial, he brought suit against the company to restrain it from this unauthorized use of his name. The suit has been settled in Dr. Ransom's favor, and the offending company has published an apology, saying: "Although we received the testimonial in question on a post card purporting to come from Dr. Ransom, we now find that the same was not sent by him or by his authority, and that he has never used the

said drug or given any testimonial concerning it. We therefore publish this statement, and desire to express our sincere regret to Dr. Ransom for having misguidedly made use of his name in this connection and for the inconvenience and annoyance caused him thereby, and we have submitted to an injunction restraining us from further publishing or making use of Dr. Ransom's name in connection with this remedy."

The Northern Medical Association of Philadelphia celebrated on December 5th the fiftieth anniversary of its organization, by a dinner held at the Hotel Walton, which was attended by some fifty participants.

Water Filtration for Philadelphia.—The city councils of Philadelphia have passed a loan bill for \$3,000,000 for the construction of a filtration plant or of filtration plants in connection with the several pumping-stations embraced in the water supply of the city.

Dinner to Mr. Potter.—On December 8th a dinner was tendered Mr. William Potter, the recently elected president of the board of trustees by the Alumni Association of Jefferson Medical College. Dr. A. K. Minich presided and responses were made by Mr. Potter, ex-Justice S. Gustine Thompson, Dr. S. Weir Mitchell, and others.

Sir Benjamin Ward Richardson was one of the most remarkable men in the profession. Though never one of its leaders in the ordinary sense, he was to a large section of the public its most prominent representative. By his brethren he was held in considerable respect in spite of certain intellectual perversities, or rather eccentricities, which prevented his taking the rank in which his originality of mind and the quality of his earlier work would otherwise have placed him. His discoveries would have brought fame and fortune to half-a-dozen "eminent physicians," yet Richardson himself could hardly be called an eminent physician. In the same way his writings were in many ways excellent, and served a useful purpose in diffusing a knowledge of the laws of health among the people; yet, particularly in his later years, they were pervaded by an element of "crankiness" which greatly detracted from their value. Richardson was intended by nature for a philosopher; owing to some flaw in the material or some botching in the workmanship, he turned out a faddist—though a faddist of genius. In his later years he was left behind in the onward rush of scientific progress; and his crying in the wilderness where he was left was not always edifying. A striking illustration of the way in which he allowed his enthusiasm to mislead his judgment is afforded by the circumstances of his own death. It is but a few months since he told an interviewer that no man who obeyed the laws of health ought to die under the age of a hundred. Yet he himself, after a life devoted to the worship of hygiene, has just been laid in the grave before he had reached the more ancient limit of three score and ten. He was a good man and wanted only some trifling readjustment in the disposition of his brain cells to have been a great one.—*The Practitioner*, December, 1896.

Bug in the Ear.—A daily-newspaper report tells of a wonderful "operation" for the removal of a bug in the ear, with complete restoration of hearing. Dr. Burnett in a recent article (*Practitioner*) upon foreign bodies in the ear says much damage may be done by groping after foreign substances, especially when there is none present. No one but a specialist, he thinks, should ever attempt instrumental extraction. If a living insect has entered the ear, a few drops of sweet oil will smother it and it may then be syringed out with warm water. Syringing will also usually remove objects introduced by children. No hurry is demanded. Delay is better than rough handling. Death has occurred from unskilful endeavors. If larvæ of flies are present, as sometimes happens in the tropics, a drop or two of chloroform or ether will destroy them.

Neuro-Psychic Medicine.—*La Médecine Moderne* announces that Dr. Tsikonki, professor of psychiatry in the University of Kieff, will publish a new review, devoted to "neuro-psychic medicine." This will be the fifth journal in the Russian language which confines itself to nervous and mental affections.

Pathological Society of Philadelphia.—At a stated meeting of the Pathological Society of Philadelphia, on December 10th, Dr. T. J. Kalteyer presented a horseshoe kidney with its suprarenal body occupying the right side, and the left suprarenal in its normal situation. He also exhibited a long attenuated cæcum of infantile type, from the body of a woman, seventy-four years old; the appendix also was unusually long. Dr. F. A. Packard presented a specimen of aneurism of the aorta, which had eroded one of the dorsal vertebræ and had ruptured into the left pleural cavity. The patient had been free from symptoms of this condition, and was walking about when he fell and soon died. Dr. Packard showed also a bicuspid pulmonary valve and an abnormally lobulated liver, together with the intestines and mesenteric glands from a case of typhoid fever. Dr. S. Solis-Cohen exhibited multiple abscesses of the liver and ulceration of the colon from a case of dysentery; and also a perforating tuberculous ulcer of the small intestine. Dr. J. P. Arnold exhibited contracted kidneys from a young man free from arterial changes. The morbid condition, in the absence of other appreciable cause, was attributed to a fundamental tendency to interstitial fibrous deposit or a congenital hyperplastic condition. Dr. H. W. Cattell demonstrated a simple, speedy, and efficacious method of preparing frozen sections by means of a spray of methyl and ethyl chlorides. Dr. Joseph Sailer presented a brain exhibiting numerous sclerotic areas, from a case of epilepsy and idiocy with sarcoma of the kidney. The formations in the brain were supposed to be neoplastic and probably sarcomatous, though they may have been merely hyperplastic and indurated. Dr. Alfred Stengel presented two diminutive stomachs from cases of pernicious anæmia, and referred to a third stomach, in size intermediate between these two, from a case in which pernicious anæmia was not present. He exhibited also diffuse and almost universal spindle-cell sarcoma of the thyroid gland; primary sarcoma of

the gall bladder, with extension to the liver; carcinoma of the rectum in a case terminating fatally from purulent peritonitis; malignant endocarditis, with a myocardial abscess; appendicitis with perityphlitis.

Philadelphia Hospital.—At a meeting of the bureau of charities and correction on December 8th, the entire medical staff of the Philadelphia Hospital was re-elected. Dr. John B. Shober was elected to fill the vacancy in the obstetric department caused by the resignation of Dr. R. P. Hamill.

Ehrlich's Test for Typhoid Fever.—Dr. Charles L. Greene writes that he has received several inquiries as to where the solutions for making Ehrlich's test in typhoid fever may be obtained. In answer to them he would say that any competent pharmacist can put up the solutions after the formulæ given.

Emergency Ration for the Army.—The war department, after several years' experimenting, has established an emergency ration for troops operating for short periods under circumstances which require them to depend upon supplies carried upon their persons. It will consist of bacon, 10 ounces; hard bread, 16 ounces; pea meal, 4 ounces, or an equivalent in approved material for making soup; coffee, roasted and ground, 2 ounces; or tea, 0.5 ounce; saccharin, 4 grains; salt, 0.64 ounce; pepper, 0.04 ounce; tobacco, 0.5 ounce. The secretary of war directs that this emergency ration be resorted to only on occasions arising in active operations, when the use of the regularly established ration may be impracticable; that although its nutritive qualities permit its use on half allowance, it will not be so used except in cases of overruling necessity, and never for a longer period than ten days, and that not more than five days' emergency rations be carried on the person at one time.

Philadelphia County Medical Society.—At a stated meeting of the Philadelphia County Medical Society, on December 9th, Dr. Edward Martin described the ambulant treatment of fractures of the legs by means of plaster casts extending from just below the knee to below the sole of the foot, and exhibited the method of application, together with a number of patients who had been thus treated. Dr. Martin has employed this method of treatment in about thirty cases thus far, and, while the results cannot be said to be better, they have been no worse than those secured by other methods. The especial advantage of the treatment is that the patient is permitted to be up and about for the greater part of the time that firm union is taking place at the site of fracture. Dr. Thomas J. Mays read a paper entitled "The Local Application of Cold in Acute Pneumonia (Final Collective Report)." His statistics included nearly three hundred cases, with a mortality of less than four per cent. The cold may be applied in various ways—by means of ice bags, of ice through towels or flannel, of snow, of cloths wrung out of ice water, etc. It was thought that the cold had not only a favorable influence upon the fever and the temperature, but also a directly beneficial effect upon the morbid process in the chest.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL COUNCIL—VOTING—PLUMPING—WRITING TO THE TIMES—DEPUTATION TO THE GOVERNMENT—MR. ANDERSON—ILLNESS OF MR. MILLER—DOES CANCER EVER DISAPPEAR?—URIC-ACID DIATHESIS—MR. BANCROFT'S READING—DR. CULLINGWORTH'S COSTS.

LONDON, December 4, 1896.

VOTING for the medical council has been going on all the week and no papers will be received after to-morrow. It is generally considered strange that the council should have met a few days before the election. Some say that this was because no change could possibly affect its decisions. On some points this is true; but when, as has happened, a majority of one or two has occurred, this explanation fails. Some go so far as to assert that the time was chosen expressly to prevent the influence of the profession from penetrating the council chamber.

The result of the election will not be declared for some time.

The council prolonged its session over the Monday and Tuesday of this week, and was called upon to consider an electioneering card of one set of candidates. This was signed by Prof. Victor Horsley, and stated that "plumping is not permitted," the object evidently being to induce electors to vote for the three candidates of whose committee he is chairman. Mr. Rivington, who is running alone, called the attention of the council to this erroneous statement. There are three vacancies and the electors may vote for one or two or three candidates. If he initial only one name it is counted as one vote for that candidate, and so far favors him over any other two. This is plumping. Mr. Horsley says it is only one form of plumping and that another is what he aimed at, viz., recording three votes for one candidate. Even if this interpretation be admitted, his logic is sadly at fault; for it amounts to saying one form is inadmissible, therefore all forms are. The council declined to intervene and left the candidates to settle their several proceedings. Mr. Horsley wrote to *The Times* a defence of his use of the word, but was of course promptly answered. I do not think the appeal to *The Times* will commend this move to his professional brethren, and every one I have spoken to on the subject disapproves the proceeding and disagrees with his interpretation of the word plumping. I regret the introduction of electioneering tactics into this appeal to the profession to choose representatives.

The council resolved to ask the president of the local government board to receive a deputation on the subject of the irregular registration of deaths, which is too prevalent and constitutes a public danger. There was a full debate on Monday on the multiplicity of examinations and the subject must again demand attention, having been referred back to the examination committee.

The question of assisting Mr. Anderson in defending his rights came up, but the council did not see its way to devote any of its funds to this purpose. Penal cases and dental business received considerable attention.

On Tuesday, the last day of the meeting, Mr. Miller, the clerk, was seized with paralysis, and arrangements were made to give him leave of absence and to provide for the work of counting the voting-papers and completing the election. The retiring members were complimented on their services.

Does cancer sometimes disappear, and if so under

what conditions? The question is not perhaps undeserving of consideration. On Friday, the 27th ult., Mr. Pearce Gould showed at the Clinical Society meeting a woman, aged forty-three years, who was admitted to the cancer ward of the Middlesex Hospital in January, 1892, for a painful lump in the left mamma. There was a history of a blow several years previously. In 1888 she noticed a lump, which grew till 1890, when the amputation had been performed. In 1892 a lump in the left axilla was removed. In February, 1894, lumps in the scar of the first operation appeared and also one above the right breast. All were removed, but in December small lumps came round the scar, and difficulty of breathing was felt. In March, 1896, there were great dyspnoea and cough with expectoration, which once or twice was tinged with blood. Death was daily expected. There were a number of hard tubercles near the scar, just such as are seen in secondary recurrences in the skin, and masses of enlarged glands in the left axilla and over the clavicle. There was a large growth, apparently bony, an inch below the left trochanter, and further deposits. She was thought to be in the last stage of malignant disease. Nevertheless in June the lumps, except one tiny nodule, had all gone and the dyspnoea had disappeared, as well as the growth on the femur. The history of this case is just that of mammary scirrhus up to the unexpected change for the better. This history was confirmed by Dr. Collins, and microscopists had reported specimens to be typical. Mr. Bowlby said he had no doubt the case was cancer which had spontaneously disappeared, and mentioned a case he had seen which is now apparently undergoing the same process, having subsided to the extent of nine-tenths. Mr. Golding Bird reported a case of sarcoma of the testicle operated on three years ago with recurrence but subsequent subsidence, the patient being now quite well. Mr. Makins said he had met with more than one case of sarcomatous growths which had spontaneously disappeared.

Uric acid has long held its place as one of the most troublesome substances to both patients and doctors. No one has of late studied it more diligently than Dr. Haig. He has written and said so much upon it that some have spoken of his "craze" about it. A friend of mine once said he would never come to an end of his suggestions, was in fact interminable and therefore insupportable. If you suppose that Dr. Haig finds the uric-acid diathesis at every turn, you are greatly mistaken. At the Medical Society meeting last week he denied that any such diathesis exists. The excess of this acid which often exists in our bodies is introduced with the food. He cannot deny that some is normally present and this amount he puts at one to thirty-three of urea, which will not produce symptoms, but as soon as that proportion is exceeded we may expect them. The regulation of the diet should be the natural treatment, but the exclusion of everything that may increase the formation of the noxious acid requires a more rigid restriction than is easily tolerated. Then even under the most careful effort symptoms which Dr. Haig would certainly attribute to uric acid are apt to appear, suggesting to me that, if his views can be substantiated, some modification of normal metamorphosis may produce in excess that which is always present to some extent. In the discussion on Dr. Haig's paper Dr. Fortescue Fox recalled the fact that children always have a large amount of the acid, even on the plainest diet, and held that we should distinguish between acid dependent on diet and that due to a tendency to excessive formation. Dr. Vaughan Harley enlarged this argument by the statement that while all children pass more than adults in proportion to body weight, the amount decreases as the age increases. He asked if any evidence could be produced

that a healthy old man passed more than a young one. He referred also to leucocythæmia, in which the amount is quadrupled; also to malignant liver disease, in which excess is an important indication. Dr. Ewart held by the prevalent view that acid is formed in the body, the quantity not being constant for all persons, and in the gouty there being excess. Dr. Freyer asked how, on this hypothesis, we could explain the prevalence of stone, etc., in India and among the tribes living on pulses. These and some other difficulties in the way of his hypothesis will no doubt occupy Dr. Haig's attention.

The cancer ward of the Middlesex Hospital has benefited to the extent of £300 from Mr. Bancroft's reading of a "Christmas Carol" on behalf of this charity.

A subscription has been started to reimburse Dr. Cullingworth the heavy costs incurred in his defence against the action of the nurse, which the jury declared ought never to have been brought. Nevertheless, I hear he is threatened with further litigation. The appearance of Sir S. Wells in the action is generally regretted. I would suggest that he might hand his fees to the defence fund.

OUR CANADIAN LETTER.

(From our Regular Correspondent.)

THE FEMALE BICYCLISTS IN CANADA—DEATHS OF PHYSICIANS FROM SEPTICÆMIA—BRITISH MEDICAL ASSOCIATION MEETING—MEDICAL SCHOOLS.

CANADIAN readers of the MEDICAL RECORD (and they are many) were somewhat amazed to notice in a recent issue an editorial on "Immorality in Canada." The startling statement had been made in an advertising venture, which, to the disgust of every one, presumes to style itself a medical journal, that cycling, instead of adding to the health and the beauty and the charm of women in Canada, was indulged in as "a means of gratifying unholy and bestial desire." The MEDICAL RECORD did well to say that it hesitated to believe such a report. Probably the slanderous article would not have been read by half a dozen had not attention been thus directed to the calumny on Canadian women. The source from which the slander emanated would deter any Canadian journal from noticing it. The conclusion arrived at by the MEDICAL RECORD that our women are "victims of a contemptible slander" is correct. Canada has reason to be proud of her robust daughters, and to them cycling has proved a healthful and benign exercise. To Canadians it is both a surprise and a shock that any one would publish such an infamous libel as that to which the MEDICAL RECORD has justly called attention.

Another well-known Canadian practitioner died recently in Toronto from septicæmia contracted in the discharge of duty. Two weeks before his death Dr. R. J. Hastings, in endeavoring to assist a nurse to administer medicine to a sick child, had his finger bitten. For four days no notice was taken of the injury, but on the fifth symptoms of blood poisoning were apparent. While every method was resorted to to avert a fatal termination, all efforts proved unavailing. Three well-known members of the profession in Canada have lost their lives within a year from some such slight injury afterward terminating in septicæmia. Dr. Hastings was a much-respected, faithful, and energetic worker, and his untimely death under such peculiarly sad circumstances is more than generally regretted. Death has also removed two other widely known Canadian medical men lately, in the persons of Dr. Ridley, of Hamillow, Dr. D. Bergin, M.P., of Cornwall, and the Hon. Dr. Ferguson, of Niagara.

Already considerable interest is taken in the forthcoming meeting of the British Medical Association at Montreal. The profession in that city is now well organized, and while it is intended that the meeting of the association shall not be regarded as a local event, but rather as a welcome from the members of the medical profession throughout the whole dominion, the success of the gathering will in some important particulars depend upon the energy and zeal of the medical men in Montreal. No one doubts their willingness and ability, and consequently none doubts the success of the meeting. The executive committee which has been appointed embraces the presidents of the Dominion and Provincial medical associations, and the attendance is likely to be the largest in the history of medical gatherings in Canada. The members of the British Medical Association who shall cross the Atlantic, many of them for the first time, will receive a cordial welcome from the whole Canadian profession. The executive will experience some delicacy in urging medical men from the United States to attend the meeting, as such an appeal might be misconstrued by those desirous of promoting the success of the International Medical Congress at Moscow. There is positively no desire to promote a rival international meeting. The British Medical Association meeting is an annual event, and, it having been decided that the next one shall be held in Canada, there should be no suggestion of any intention to detract from the greater meeting at Moscow. Unfortunately, so Canadians consider, none but British subjects can gain membership in the association, but, as at every meeting there is always a number of guests present, the leading American authorities in the different departments of medicine will doubtless be invited to be present at Montreal. Many Canadian members will regard the forthcoming meeting as an excellent opportunity for reciprocating in some measure the kind and courteous treatment they have always received when they have had the privilege of being present at any of the great medical gatherings in the United States. The date of the meeting will be the last week in August.

The attendance of students at the different Canadian medical colleges indicates that the five years' course is not likely to prevent many from entering the medical profession in Canada. In addition to attending college for five years, six months in each year, it is now imperative that each student shall take one summer session. In some quarters there is a feeling that four sessions of eight months would be productive of better results, but is it most unlikely that any change will be made, now that both colleges and students have adapted themselves to the change. The matriculation examination which must be passed by every one before commencing the college course in medicine has gradually been made more exacting, until the present standard renders a complete liberal education necessary for every matriculant.

The large towns in Canada are gradually recognizing the necessity of having hospitals, and the number of such institutions which have been erected in the smaller towns during recent years is a pleasing evidence of the appreciation of the public, and a recognition of the fact that in a properly equipped hospital at home fully as good results may be obtained as by resorting to the larger cities. There is also pleasing evidence that in Canada there is a growing recognition that money expended in equipping these institutions with every facility for asepticism and antisepticism in the practice of medicine and surgery is likely to yield results beyond computation by the ordinary rules of every-day commerce.

The Best Work done by physicians is never paid for and can never be paid for.

ABDOMINAL SECTION STATISTICS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD for December 12, 1896, Dr. Savidge compares certain hospital statistics of abdominal-section cases, and then quotes some statistics of Péan, Jacobs, and of mine, giving in the context the idea that such statistics mean selected cases and refusal of operation in desperate cases. This idea must be corrected in its reference to my appendicitis statistics. I have operated upon every recognized case of acute appendicitis that has come into my hands, with one exception. That was a case with advanced complicating disease of the heart and arteries, which I saw in consultation with Dr. Judson C. Smith last year. Dr. Smith thought that the patient could not bear the anæsthetic and I accepted his judgment. Some of my patients were pulseless and moribund. In some cases pus ran over both sides of the table when the abdomen was opened. Some patients had general septic or suppurative peritonitis. Sometimes I found patients dead when we arrived at their homes. The only cases that I have refused to operate upon were mild acute cases, in which there was doubt about the diagnosis, or mild chronic cases, in which it did not seem wise to operate at just the time when the cases were examined. My series of one hundred consecutive unselected appendicitis operations with a mortality rate of two per cent., quoted by Dr. Savidge, was published for the single purpose of establishing the importance of certain principles in treatment. The character of the cases making up the list can be determined by any one who will step into a library and ask for the second edition of my book on the subject. I do not know how many cases of appendicitis I have operated upon. Their histories are all recorded in full in a special book at my office, and any responsible member of the profession is at liberty to come in and count them if he wants to. It is not a matter of interest to me, this score of numbers, but the principles involved in the treatment are of consequence. Dr. M. M. Johnson, of Hartford, at the last meeting of the American Medical Association reported on a similar series of one hundred consecutive appendicitis operations of his own with a mortality rate of two per cent. The principles which he employed are ones which would give a very small death rate in unselected cases.

ROBERT T. MORRIS, M.D.

49 WEST THIRTY-NINTH STREET, NEW YORK,
December 12, 1896.

HYPNOTISM, AND WHAT IT SIGNIFIES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Probably if you selected ten men to-day from your acquaintance, choosing only those who were a little better read, a little better educated than the rest, and asked these ten severally pointblank what the word hypnotism meant, they would answer without the slightest hesitation: "A certain sleep state of the individual, caused by, or induced by, suggestion from within or from without, in which state the individual is unconscious of his actions and becomes an automaton." They might add, if they had ever taken the trouble to peruse modern English literature upon the subject, that hypnotism tended to weaken the will of the subject, and, if persisted in, would indubitably result in insanity or crime.

It is perfectly amazing that such an impression of a simple, natural, and universally applied therapeutic agent should have become so firmly established in men's minds, and be so difficult to uproot. But argument is of no avail against popular prejudice, and the people will probably continue for another century to regard the word "hypnotism" with dislike, if not with

horror. It is unfortunately true that for one person who will take the trouble to investigate the phenomena of effect, there are fifty who do not trace the effect back to the cause at all, but are content with an assumption of fact as a basic truth. Within the past three months, however, it has become very clear to me that physicians in the West are not only willing but anxious thoroughly to sift the question for or against the employment of hypnotic suggestion as an honorable ally in therapeutics, and from the tenor of a recent article which appeared in these pages upon the subject of mental therapeutics I gather that the tendency in the East also is to investigate. It has always struck me as very curious, in looking over works upon this science written by medical men, that they invariably make mention of the fact, either in their prefaces or elsewhere, that they are pleased to note the change of attitude on the part of the profession toward this science of hypnotism: that whereas forty years ago it was publicly ridiculed and denounced, to-day physicians everywhere recognize it as a valuable auxiliary in medicine. This is all very pleasant and gratifying, but I doubt if hypnotism has won its way to the toleration, much less to the favor, of the profession. I believe the chief obstacle to its popularity is the erroneous impression which is abroad in the land that a person is not hypnotized unless he is either sound asleep or in a somnambulistic condition. James Braid performed all his experiments upon somnambulists. Dr. Charcot knew only three stages of hypnosis, and produced them only in active somnambulists. Dr. Esdaile, the English surgeon, induced a state of coma in his Hindoo patients which carried with it a complete anæsthesia, and may be classed as one of the profound stages. The "professor" who gives public entertainments works his vulgar effects by means of subjects in the somnambulistic condition, and the whole trend of thought upon this science is to exalt the more profound stage of hypnosis as something to be aimed at, and entirely to neglect the greater value of the lighter stages. I am not alone in thinking that the exhibitions of hypnotism as presented by the public professor should be put a stop to, but as an evil only needs a little legal severity to insure its popularity, I would suggest that a better way to attain the end desired would be to remove the element of mystery at present surrounding the subject, and show the people that there was really nothing very extraordinary in the performances which so delighted them. Once remove the general belief that these subjects are compelled to do certain foolish feats against their will, and the entertainment would lose its flavor and the "professor" his patronage. The general public does not read books upon hypnotism, but it does go to see the "professor," and from him it gets the idea that hypnotism is a power, a force, which few can exercise, and which converts an entirely wide-awake individual into an irresponsible somnambulist. Most physicians (not all, by any means) know now that no one can be hypnotized against his will, but very few would admit the truth of the contention that a state of light hypnosis is of greater therapeutic advantage in the relief of nervous ailments and functional derangements than the condition of somnambulism: in other words, that it is better for the patient to be merely passive and drowsy, because the fact that he does not upon suggestion go into a condition of somnambulism, in which sense delusions are instantly accepted, shows that he is not of such an imaginative nature as the one who does, and also shows that when he thoroughly understands the significance of his treatment he will be less likely to relapse, because less likely to yield to the adverse suggestions of others, or to his own doubting auto-suggestion. This fact has been well illustrated at the Chicago School of Psychology. Active som-

nambulists are of two classes—the very weak and the very strong. The latter are rare, indeed, but you will occasionally find a man who has such perfect command of himself that he can permit himself to accept sense delusions as real in a self-induced state of hypnosis. The great mass of mankind, however, is not somnambulistic, but if put in a state of light sleep, or in a drowsy restfulness, most men could be greatly benefited by suggestive treatment. So simple a thing is this hypnotic influence that the mother who rocks the cradle of her baby at night hypnotizes the child. She suggests sleep, and her monotonous singing has the same effect as the monotonous suggestions of the operator that “the eyelids are getting heavy,” a “feeling of sleep is coming over you,” etc. But at this point most operators stop; and if they cannot induce sleep in a patient, with evidences of catalepsy to follow, they give up. As a matter of fact, hypnosis is merely a state of exalted receptivity of the brain, due to close attention to one thing for a certain length of time, and does not depend upon sleep for its existence, but may be accompanied by sleep. Hence the foolishness of giving up suggestive treatment merely because the patient does not slumber will be very apparent. It is enough for the physician's purpose if his patient keeps his eyes shut for ten or fifteen minutes, and listens attentively to the suggestions given him. The cure of any complaint is due to the force gathered from the repetition of such suggestions upon the patient's mind. If not to-day, then to-morrow; if not to-morrow, then the next day. Persist in the treatment, remembering that the gradual cure in which you have the assistance of the patient's reason and auto-suggestion is the permanent cure.

SIDNEY FLOWER.

CHICAGO, December 12, 1896.

ANGINA PECTORIS (STENOCARDIA).

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: May I ask you to correct some errors and omissions in the report upon my paper on the above subject, on page 866, of December 12th. I am made to say: “Even microscopically we could not always recognize changes in the heart at post-mortem.” I said: “Macroscopically we failed even at the post-mortem, and only the microscopic investigation, in many cases, furnished evidence of change in the coronary arteries.”

Under the heading of “treatment,” I am made to say: “The potent factors were to unload the congestion of the liver and spleen by calomel and salines, and strengthen the heart by saline baths and exercises, etc.” I tried to call attention to the fact that the blind use of peripheral dilator drugs, such as nitroglycerin, nitrites, etc., did little good so long as the internal viscera remained congested and could fill up the peripheral vessels immediately the above drugs had ceased to act. It seemed to me like a game of the well-known story “Box and Cox” between the loaded viscera and the loaded peripheral vessels.

The proper treatment is to unload the congestion of the internal viscera by calomel and salines, and then to resort to the peripheral dilator drugs, such as nitroglycerin, etc. Immediately your congestion is relieved internally and peripherally, you maintain the equilibrium by using cardiac stimulants, sparteine, strophanthus, digitalis, etc., and general tonics.

Now with the aid of the saline baths and exercises after the Schott method, we can secure results which act to relieve the superficial or peripheral congestion, coincidentally directly stimulate the heart muscle, and improve the entire tissue metamorphosis. It was to the sequence of the treatment that I attached the greatest importance.

H. NEWTON HEINEMAN, M.D.

IS IT POSSIBLE?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will some one of your many readers inform me through the MEDICAL RECORD's columns whether impregnation within twenty-four hours of childbirth is a possibility? A fellow-practitioner has just related to me an instance in which a German woman married to an Italian bore a second child eight months after the first, or two living children, at what seemed to be full term, within a period of seventeen months. Upon investigating the occurrence, my informant was led to believe from statements made that impregnation had taken place upon the very night of the first delivery. There is an old proverb believed in France—if nowhere else—that *l'Allemand italianisé est le diable incarné*. If the report as above detailed is true, then a new proverb should be made to fit the Italian Germanized by hymeneal bonds. The latter portion of the proverb can stand as it is.

I. N. VESTIGATOR.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 12, 1896:

	Cases.	Deaths.
Tuberculosis.....	119	99
Typhoid fever.....	17	3
Scarlet fever.....	152	7
Cerebro-spinal meningitis.....	2	3
Measles.....	151	6
Diphtheria.....	282	33
Small-pox.....	0	0

Patent-Medicine Making.—Exclusive of those connected with the advertising department, a numerous branch, and the stockholders in such of the concerns as are incorporated, ten thousand men are engaged in the patent-medicine manufactories of the United States, receiving collectively more than \$4,000,000 a year in salaries and wages. There are eight hundred and fifty such manufactories, ranging in importance from those which flood the American and the foreign market with proprietary medicines, as they are technically called, down to the small laboratories or botanist shops, in which some particular herb or root is, in a grudging and primitive manner, supplied to such persons as may have heard of its efficacy. The partiality of Americans for patent medicines is well known, and doctors—who don't usually agree—agree in declaring that the true reason of the extensive use of such medicines in the United States is to be found in the fact that dyspepsia is a general ailment, and that persons suffering from dyspepsia are prone to believe that they have some other ailment. Thus they become patent-medicine patrons under conditions that recall the memorable remark of Col. Mulberry Sellers, the sanguine speculator, who, in describing the benefits of the “Oriental Eye Water,” the sale of which he believed would enrich him, declared that the more of it people used, the more of it they would need, and hence the sale once started would constantly increase. Many of the patent medicines sold, if not, indeed, a majority of them, do not come under this description, for they are merely compounds, in pleasant form and in palatable shape, of drugs and medicines in constant use by physicians, and found efficacious in what is called general practice. Though it didn't use to, New

York City now stands at the head of the cities of the United States in the manufacture of patent medicines, with eighty-five factories, giving employment to one thousand persons at aggregate wages in excess of \$700,000 a year. Philadelphia comes second, St. Louis third, New Haven fourth, and Lowell fifth. In proportion to its population Lowell is the American city which is most deeply interested in patent-medicine manufacture. After Lowell comes Chicago, a poor sixth. It is a somewhat peculiar circumstance that though enormous quantities of patent medicines are sold in the South, and the ingredients for their manufacture come very largely from that section, few patent medicines are made in the South, though New Orleans and Atlanta do a little in this line. The city of Baltimore seemed likely a few years ago to attain prominence in the manufacture of patent medicine, but recently it has fallen back on the list, while the city of Boston has been pushing steadily ahead. Providence is another New England city which is largely represented in the manufacture of patent medicines. In New York State two other cities so represented are Buffalo and Rochester. In the West, outside of Chicago, St. Louis, and Cincinnati, the city which does the largest business in patent medicines is Grand Rapids, Mich., and Peoria does a little in this line, but not very much. The exportation of American patent medicine is increasing, but the manufacturers continue nevertheless to appeal, with the greatest confidence, to the home market.—*The Sun*.

More than One-Third of the people of this country live in cities and more than half the doctors are there too.

Himself to Blame.—If the Paris physician finds himself with a decreased patronage he has only himself to blame for constantly advocating hygienic measures, supporting Pasteur laboratories, and the like.

"The Sanitarian" gives the following mortality figures:

Deaths Caused by	1885-1889.	1890-1895.
Small-pox.....	1,271	655
Scarlet-fever.....	1,225	946
Measles.....	6,671	5,192
Diphtheria.....	8,383	7,588
Typhoid fever.....	5,903	3,493

Surgical Cleanliness and Surgical Handicraft.—We know that nowadays our practice is based on sound principles. If care and cleanliness be exercised, no region of the body can be violated by the surgeon's knife; no limit can be placed to the possibilities of eradicating or ameliorating disease. The prevention of death is the aim of our science; and it is the glory of modern surgery that it has advanced in this direction beyond the dreams of even the most sanguine prophets of a past generation. We know that no wound made deliberately in healthy tissues ought to suppurate. If it does so, the defect lies in the surgeon's hands—literally and not figuratively; and at his door must be laid the graver charge of surgical disaster. "Godliness is next to cleanliness"—in other words, the most important factor in surgical success, when dealing with the life or limb of your patients, is—cleanliness. Syme long ago expressed a grave truth in forcible language when he observed that "a probe in the hands of a careless surgeon was as dangerous as a loaded pistol in the paw of a monkey;" and we might say conversely that the paw of a monkey would be a source of less danger in a wound than the dirty hands and instruments we unfortunately still sometimes see employed. The surgeon who neglects knowingly the precautions imposed by scientific investigation as regards cleanliness is as blameworthy as the fool who smokes a cigar in a powder magazine. No

sophistry or special pleading can free him from blame if the appalling catastrophe of death is the result of his ignorant carelessness or culpable neglect of essential principles. Therefore, above all things, let your hands be clean. It will be part of our effort here to so instill into your minds the principles of wound treatment that fatal results will be, humanly speaking, impossible; and to endeavor that the gospel of surgical cleanliness will become before you leave these walls an ingrained part of your being—an instinct that time can neither impair nor destroy. "Cleanliness is Godliness;" and, to put it on no higher basis, for your own sakes remember that, according to Scripture, "Godliness is great gain."—DR. R. GLASGOW PATTERSON, *The Dublin Journal of Medical Science*, November, 1896, p. 435.

Herpes Gestationis.—Drs. Fournier and Cannet (*La Médecine Moderne*, March 14, 1896) presented a patient, aged thirty years, affected with herpes. She was attacked in the course of an eighth pregnancy. The eruption showed itself in the second month of pregnancy, being, as is usual, polymorphous. Of the seven previous pregnancies, the first four progressed without cutaneous manifestations. In the course of the fifth, sixth, and seventh pregnancies the affection showed itself with variable intensity. Actual observation shows the fourth relapse of this disease.

Apples.—A Brooklyn physician translates the following from a German writer: "The apple is such a common fruit that few persons are familiar with its remarkably efficacious medicinal properties. Everybody ought to know that the very best thing he can do is to eat apples just before going to bed. The apple is excellent brain food, because it has more phosphoric acid, in an easily digestible shape, than any other fruit known. It excites the action of the liver, promotes sound and healthy sleep, and thoroughly disinfects the mouth. It also agglutinates the surplus acids of the stomach, helps the kidney secretions, and prevents calculus growth, while it obviates indigestion and is one of the best preventives of diseases of the throat. Next to lemon and orange, it is also the best antidote for the thirst and craving of persons addicted to the alcohol and opium habit."

Irregularity in Delivery Due to Short Umbilical Cord.—Dr. Guido Bell (*Indiana Medical Journal*, November, 1896) gives the following *résumé*: A short umbilical cord may be the cause of delayed or of hastened labor during any stage of birth, but delayed labor is more frequent in the second stage, and hastened labor often at the beginning. The symptoms of brevity are: 1. Secondary or dragging pains. 2. Localized tenderness of the womb. 3. An elastically retreating head.

Spermatorrhœa is a frequent symptom in neurasthenia. Most frequently it depends upon a peculiar hereditary irritability of the cerebro-spinal axis. When occurring during the act of micturition, it may come on independently of any pathological seminal loss, and may have as an occasional cause a blennorrhagic urethritis. Occurring during defecation, as it frequently does, an occasional cause may be and probably frequently is the simultaneous contraction of the seminal vesicles and the rectum, aided by pressure of the abdominal muscles. Since impotence often accompanies this form as well as that which is prodromic of tabes, the latter condition must be looked for. It is rare for neurasthenic spermatorrhœa to reach an advanced degree. Usually the symptoms improve under proper treatment.—GOLDSPIEGEL, *Thèse de Paris*, 1896, No. 526.
